FROM the accounts of meetings at which pressure vessels with full heads have been discussed, the emphasis put upon the empirical and the older experimental methods would seem to suggest that the existence of a theory which will predict these findings is not sufficiently known. This is possibly due to the form in which the theory has appeared, and it is hoped here to make some contribution which will better the situation in that respect. Inasmuch as improvements in experimental methods permit a triple check, one set of measurements with another and both with the theory, the question has a new appeal. A brief survey of the most significant experiments will bring out the facts with which it is expected to work.

Vessels which carry inner pressure have, as is well known, a zone of high stress concentration at the inner surface of the knuckle, both in the flat crimped head and the dished head whos meridian is built up of two circular arcs. This fact was established by measurements of displacements at the outer surface, in the direction of the axis and perpendicular thereto.[2] From the picture thus obtained of the deformed shape of the head, conclusions are possible concerning the state of stress in it.

Later experiments showed[3] the following:

The full dished head, when subjected to increasing inner pressure, approaches a shape which has elliptical meridians.

A series of heads which have the same radius of curvature at the crown and the same diameter of base, is arranged to have meridians built up of two circular arcs, with the knuckle radius of curvature larger for each successive head. Then the pressure at which the first significant permanent deformation occurs will also be larger for each successive head.[4]

If the head be ellipsoidal, such that for its elliptical meridian

$$\frac{\text{semi-major axis}}{\text{semi-minor axis}} = \frac{\text{diameter of cylinder}}{\text{depth of head}} = \frac{2}{1}$$

then it will resist a pressure sufficient to cause the first slight permanent deformation to be in the cylinder.

Experiments made by the Swiss Association of Boiler Owners[5] verified the above findings on full-size vessels and noted especially the greater ability of the ellipsoidal head (axis ratio 2) to resist permanent deformation even at high pressures. In this group of experiments not only was the deformed shape of the head found, but also extensometers were introduced to procure the strain distribution along meridians of the outer surface of the vessel. This was found to be highly irregular in all cases,[6] but markedly more favorable for the ellipsoidal head above, and for heads whose meridians had two radii of curvature with a sufficiently large knuckle radius.

A series of experiments at the Testing Materials Laboratory in Stuttgart[7] showed again the superiority of the ellipsoidal shape (axis ratio about 2) over those with smaller knuckle radii. Here the elastic and permanent deformations of the heads were found, and the pressures at which the yield point was reached.

All of the previous investigations were confined to phenomena at the outer surface of the vessel. With no possibility of applying instruments at the inner surface of the knuckle where the maximum stresses were to be expected, recourse was had to obtaining the angular displacement of normals to the surface. These measurements, combined with those of elongations at the outer surface, permitted establishing the strain due to bending, and this permitted the computation of strains, hence also stresses, at both outer and inner surfaces.[8,9]

The study of yield lines on the surface was also extended

to include yield phenomena within the material, by means of etched sections.[10]

Thus we find a development of three experimental methods:

1 The investigation of the state of stress in a pressure vessel before the elastic limit of the material is passed, by means of fine extensometers and instruments for procuring angular deflections. (The use of dials for measuring axial or normal displacements is also possible here, but is of more interest in the next group, due to the small magnitudes of these displacements.)

2 The investigation of elastic and plastic deformation of the vessel, principally of the head, along its normals and in the direction of or perpendicular to the axis.

3 The investigation of yield phenomena, on the surface or within the material. This may be combined with tests of specimens from the destroyed vessel.

The first of these methods especially recommends itself for industrial purposes, since it may be carried out without injuring the vessel, and, with slight provision, may be made part of the routine test of a new vessel. Also it is the only one of the three which gives the quantities of fundamental interest, namely, the stresses which are set up.

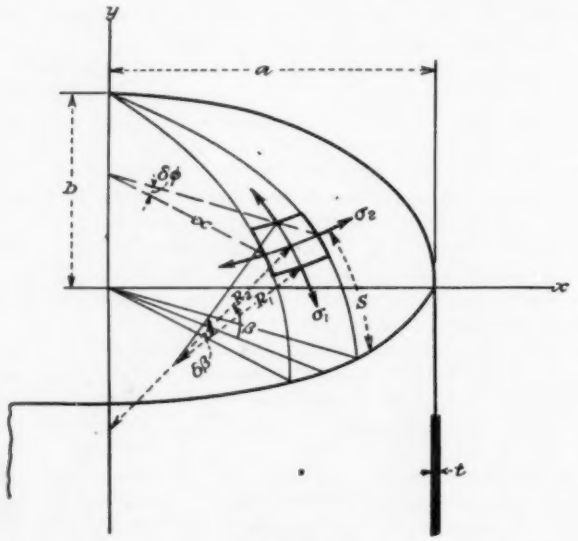

FIG. 1

The logical outcome of these experiments in the form of empirical methods has not been missing. These will not be discussed here since the interest is in how far the findings can be predicted without such considerations. Along with experiment, in part independently of it, went an improvement in the theoretical attack; and this was used to good advantage in at least one set of experiments.[11] The following is an attempt to give a simplified presentation and method of application of this theory. As long as the head may be considered thin and its shape is near that shown to be desirable by experiment, it is possible to compute all the quantities which can be measured.

STATEMENT OF THE PROBLEM

The pressure vessel is assumed to be as follows: Its side walls are in the form of a right circular cylinder whose length exceeds its diameter. Each head is a half-ellipsoid of revolution of base radius a and depth b; or it may also be a surface of revolution whose meridian is an approximation to an ellipse by two or more circular arcs, with that at the knuckle tangent to the element of the cylinder where they join. This last shape has several technical designations. It will be called here "quasi-ellipsoidal." The thickness t is taken to be constant throughout the vessel. The load is a uniformly distributed inner pressure, of intensity p. This will therefore give a normal stress perpendicular to the surface, of amount 0 at the outer surface and p at the inner. Since p is small in comparison with the meridional and hoop stresses developed, it will be assumed that a two-dimensional state of stress exists in which the material is not stressed beyond the elastic limit. Then it is desired to find expressions for the stresses and the displacements at any point of the vessel.

THE MEMBRANE EQUATIONS

The simplest assumption is that the shell[12] offers no resistance to bending. It is then called a "membrane." For a surface of revolution under uniform inner pressure, the membrane stresses take the well-known form

$$\left.\begin{aligned} \sigma_1 &= \frac{pR_2}{2t} \\ \sigma_2 &= \sigma_1\left[2 - \frac{R_2}{R_1}\right] \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

in which σ_1 = meridional stress, uniformly distributed over the thickness of the shell

σ_2 = hoop stress

R_1 = radius of curvature of the meridional section

R_2 = radius of curvature of the section perpendicular to the meridian at the point in question (see Fig. 1).

Use will be had for the following special cases:

(*a*) The Hemisphere: $R_1 = R_2 = a$

$$\left.\begin{aligned} \sigma_1 &= \frac{pa}{2t} \\ \sigma_2 &= \sigma_1 \end{aligned}\right\} \quad \ldots\ldots [1a]$$

(*b*) The Cylinder: $R_1 \longrightarrow \infty$, $R_2 = a$

$$\left.\begin{aligned} \sigma_1 &= \frac{pa}{2t} \\ \sigma_2 &= 2\sigma_1 \end{aligned}\right\} \quad \ldots\ldots [1b]$$

(*c*) The Ellipsoid: $R_1 = kav^3$, $R_2 = kav$

$$\left.\begin{aligned} \sigma_1 &= \frac{pka}{2t}\, v \\ \sigma_2 &= \sigma_1\left[2 - \frac{1}{v^2}\right] \end{aligned}\right\} \quad \ldots\ldots [1c]$$

$$\text{where } k = \frac{a}{b} \text{ and } v = \frac{1}{\sqrt{1 + (k^2 - 1)\cos^2\beta}}$$

The displacement of any point P of the shell, due to the applied load, is resolved into a component u along the tangent to the meridian, and a component w along the normal to the surface. The zero value of the *meridional displacement* u is taken at the plane in which head and cylinder join, and for each surface u is positive away from this plane. This will cause no confusion since the two surfaces are discussed separately. The zero value of the *normal displacement* w is taken at the unstrained middle

[10] Mitt. a.d. K.W.I. für Eisenforschung zu Düsseldorf, Abhandlung 62. Siebel und Pomp: "Das Zusammenhang zwischen der Spannungsverteilung und der Fliesslinienbildung an Kesselböden u.s.w.," 1926.

[11] See especially Part II of the pamphlet mentioned in footnote 9.

[12] The term "shell" is used to define a curved plate of thickness small in comparison with its other dimensions. Here it may be either the head or the cylinder. A certain technical usage would limit it to the cylinder.

surface, and w is positive outward. These components for a membrane under uniform inner pressure become:

(*a*) For the hemisphere:

$$\left.\begin{aligned} u &= 0 \\ w &= \frac{pa^2}{2Et}(1-\mu) \end{aligned}\right\} \quad \ldots\ldots\ldots [2a]$$

(*b*) For the cylinder:

$$\left.\begin{aligned} u &= \frac{pas}{2Et}(1-2\mu) \\ w &= \frac{pa^2}{2Et}(2-\mu) \end{aligned}\right\} \quad \ldots\ldots\ldots [2b]$$

(*c*) For the ellipsoid:

$$\left.\begin{aligned} u &= \frac{pa^2}{2Et}\frac{\sqrt{k^2-1}}{2k}\mathbf{L}\cos\beta \\ w &= \frac{pa^2}{2Et}\left\{\frac{\sqrt{k^2-1}}{2k}\mathbf{L}\sin\beta + k^2[(2-\mu)v^2-1]\right\} \end{aligned}\right\} \quad \ldots\ldots [2c]$$

in which μ = ratio of unit lateral strain to unit longitudinal strain and is here taken as 0.3

s = distance measured along the meridian from the junction plane to the point in question and is positive away from the junction; and

$$\mathbf{L} = \left\{[2k^2-(1-2\mu)]\log(k+\sqrt{k^2-1}\sin\beta)v - [(1-2\mu)k\sqrt{k^2-1}\,]v^2\sin\beta\right\}$$

in which the square-bracketed expressions are constant for any given case.

By use of these expressions for the displacements, we may now examine the pressure vessel with regard to its behavior as a membrane.

For a vessel with hemispherical heads, and p, a, E, t, and μ constant, the normal expansion w of the cylinder (Equation [2*b*]) exceeds that of the head (Equation [2*a*]) in the ratio $(2-\mu)/(1-\mu) = 2.4$. The assumption that these shells behave as membranes leads to the state shown by heavy lines in Fig. 2. The light lines represent the unstrained position. In the actual vessel, the occurrence of such a discontinuity is prevented by the ability of each shell to resist forces normal to its middle surface or bending couples acting in meridional planes. The head and cylinder experience reactions from each other as shown in Fig. 4, and consequently, at least in the neighborhood of the junction, they may not be considered purely as membranes.

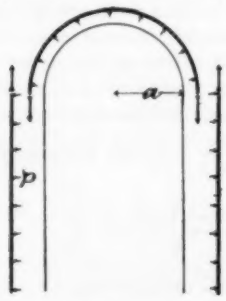

Fig. 2

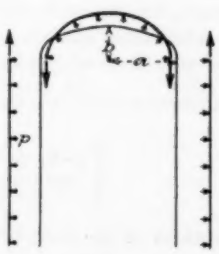

Fig. 3

In case the vessel has an ellipsoidal head, a still greater discontinuity results from the assumption that the shells behave as membranes. From Equation [2*c*], at the edge, $\beta = 0$, and $v = 1/k = b/a$. Then

$$\mathbf{L} = (\log 1) - 0 = 0 \quad \text{and} \quad \left\{\begin{aligned} u &= 0 \\ w &= \frac{pa^2}{2Et}[(2-\mu)-k^2] \end{aligned}\right.$$

For the hemisphere, $k = 1$ and $w = \frac{pa^2}{2Et}(1-\mu) = \frac{pa^2}{2Et}(0.7)$ in agreement with Equation [2*a*]. With a constant base radius a, as the depth b decreases, k increases. When $2-\mu = k^2$, that is, when $k = 1.3$, the normal displacement w at the edge is zero. For $k > 1.3$, w is negative, hence the edge of the ellipsoid contracts instead of expands. In the usual design $k > 2$, consequently the condition of contraction shown in Fig. 3 is expected in such vessels on the basis of their behavior as membranes. It is recalled that the cylindrical side wall always expands (Equation [2*b*]), therefore the edge reactions of the sort shown in Fig. 4 increase in importance as the depth of the head is reduced from that for a hemisphere.

Similar results may be obtained in the case of a quasi-ellipsoidal head. A discontinuity in the normal membrane displacement w arises there not only at the junction of head and cylinder, but also at each junction of zones of different ring surfaces.

Analysis of the General Problem

It has been shown that a discontinuity exists in the values of the normal displacement w at the junction of head and cylinder. The equations upon which the discussion was based, [2*a*, *b*, *c*], were obtained on the assumption that the shells behave as membranes. For thin shells under uniform inner pressure with no restraints at the edges, the bending stresses which are set up during these displacements are negligible in comparison with the normal stresses. Then the predicted discontinuity would exist in the actual vessel if it were not prevented by another set of forces, namely, the reactions shown in Fig. 4. From their nature, they cannot be carried by a membrane. They will set up in the shell normal, shearing, and bending stresses, which are of local character for shells of a certain design. The consideration of these effects forms a second part of the analysis of the state of stress in the vessel.

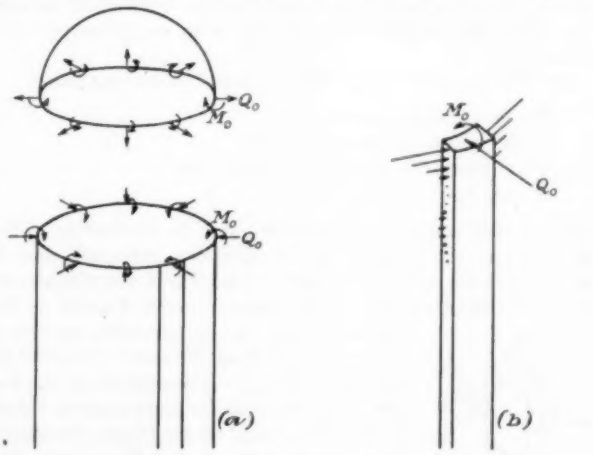

Fig. 4

It is therefore found convenient to make the following division:

1 *Membrane Analysis* of the shells, under uniform inner pressure. (See Fig. 2 or 3.)

2 *Analysis of Local Effects.* The shells are considered as surfaces capable of carrying bending stresses, and the loads are taken to be the uniformly distributed edge shearing forces and bending couples shown in Fig. 4. Then the resultant effect at any point is obtained by superposition. The equations necessary for the first part of the analysis have been given, and it remains to develop those for the second part. In discussing the shell as a membrane, it was found possible to deter-

mine the stresses directly, since the problem is a statically determinate one. From the stresses, the strains, and thence the displacements, were found. In the case of a shell which supports bending stresses, this method cannot be used since the statical conditions of equilibrium give only three equations in five unknowns, viz., the quantities T_1, T_2, Q, M_1, and M_2, shown in Fig. 6. Consequently, as is usually done, the elastic properties of the material are introduced. These involve the displacements, which will be most conveniently determined first. The solution for the stresses will then follow.

The Cylindrical Shell With Edge Loads Only

The shell is as shown in the lower part of Fig. 4. The intensities of the loads, which are uniformly distributed along the edge circle, are Q_0 and M_0, respectively, each per area $t \times$ unit arc. The cylindrical shell of a vessel is usually sufficiently long that the effects of these loads at the end do not extend into the neighborhood of the other end; therefore it may as well be assumed that the length is infinite. The strip shown in Fig. 4 is isolated as a free body in Fig. 4(*b*). The forces acting on this body are the loads Q_0 and M_0 at the end, and the forces and bending couples which are set up on the longitudinal sections. The latter are omitted from the figure to avoid complications there.

An element of the strip (Fig. 5) is in equilibrium under:

T_2, the normal hoop force;
Q, the meridional shearing force;
M_1, the meridional bending couple; and
M_2, the hoop bending couple.

Other forces and couples drop out, due to symmetry. Those given above are positive in the direction indicated, and the magnitudes are for an area unity $\times$ t. The force which resists the radial displacement of the element varies directly as that displacement; that is, the strip receives an elastic support from the rest of the shell (see Appendix No. 1). The analysis of the local effects in the cylinder consequently reduces to that of a beam on an elastic foundation, loaded by a force and a bending couple at one end.[13]

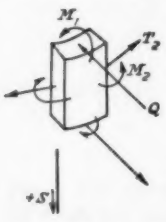

Fig. 5

The normal displacement of any element at distance s from the edge is then given by the equation:

$$\frac{d^4w}{ds^4} + 4\lambda_0^4 w = 0 \quad \ldots\ldots [3]$$

in which

$$\lambda_0 = \sqrt[4]{\frac{3(1-\mu^2)}{a^2t^2}} \quad \ldots\ldots [4]$$

For the assumed values of the edge loads, this equation has the solution:

$$w = -\frac{1}{2\lambda_0^3 D} e^{-\lambda_0 s}[Q_0 \cos \lambda_0 s + \lambda_0 M_0(\cos \lambda_0 s - \sin \lambda_0 s)] \quad \ldots [5]$$

in which

$$D = \frac{E}{1-\mu^2} I = \frac{E}{1-\mu^2} \frac{1 \times t^3}{12} = \frac{Et^3}{12(1-\mu^2)} \quad \ldots\ldots [6]$$

is the flexural rigidity of the shell and has the role here of EI in the case of a simple beam.

From the above value of w are obtained the expressions for the normal and shearing forces and the bending couples on any element of the shell.

[13] See Timoshenko and Lessells, "Applied Elasticity," p. 143.

$$\left.\begin{aligned}
T_2 &= \frac{Et}{a} w = -2a\lambda_0^2 e^{-\lambda_0 s}[Q_0 \cos \lambda_0 s \\
&\qquad + \lambda_0 M_0(\cos \lambda_0 s - \sin \lambda_0 s)] \\
Q &= D\frac{d^3w}{ds^3} = -e^{-\lambda_0 s}[Q_0(\cos \lambda_0 s - \sin \lambda_0 s) \\
&\qquad - 2\lambda_0 M_0 \sin \lambda_0 s] \\
M_1 &= -D\frac{d^2w}{ds^2} = \frac{1}{\lambda_0} e^{-\lambda_0 s}[Q_0 \sin \lambda_0 s \\
&\qquad + \lambda_0 M_0(\cos \lambda_0 s + \sin \lambda_0 s)] \\
M_2 &= \mu M_1
\end{aligned}\right\} \quad \ldots\ldots [7]$$

This solution has the advantage that the variables enter only in the forms:

$$e^{-\lambda_0 s} \cos \lambda_0 s, \quad e^{-\lambda_0 s} \sin \lambda_0 s, \quad e^{-\lambda_0 s}(\cos \lambda_0 s \pm \sin \lambda_0 s)$$

These functions have all been tabulated,[14] and are displayed in Fig. 11. Each is oscillatory, and its amplitude is very rapidly damped out by the factor $e^{-\lambda_0 s}$. The zero values

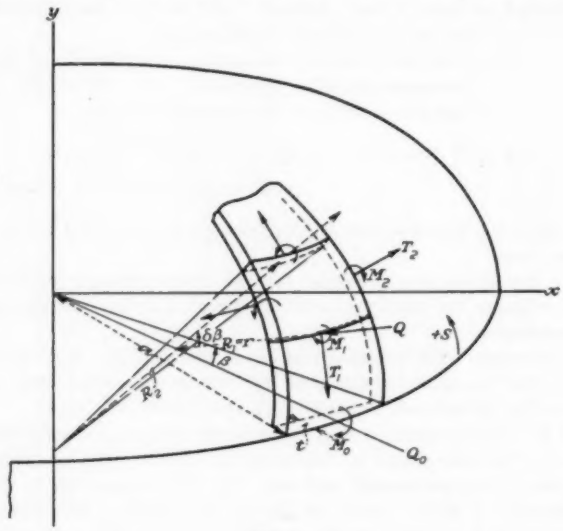

Fig. 6

of each occur at an interval of π in the values of $\lambda_0 s$. The same interval separates the zero values of the derivative of each function, hence the critical ordinates occur at such intervals. Also, it may be noted that zeros and critical ordinates for any of these functions occur with a phase difference of $\pi/4$. For example, the function $e^{-\lambda_0 s} \cos \lambda_0 s$ has a zero value at $\lambda_0 s = \pi/2$, a minimum at $\pi/2 + \pi/4$, another zero at $\pi/2 + \pi$, a maximum at $\pi/2 + \pi + \pi/4$, etc. Successive critical ordinates of each function are in the ratio $e^{-\pi} = \frac{1}{23.1} = 0.043$. For example,

$$\left[\frac{e^{-(\lambda_0 s + \pi)} \cos(\lambda_0 s + \pi)}{e^{-\lambda_0 s} \cos \lambda_0 s}\right] = e^{-\pi}$$

The width of the zone between critical ordinates is

$$s = \frac{\pi}{\lambda_0} = \frac{\pi\sqrt{at}}{1.285}$$

or $2.44\sqrt{at}$. This is also the distance between successive zeros. As the thickness t is diminished for the same radius

[14] Such functions are characteristic of the problem of a beam on an elastic foundation, and their importance in this connection, e.g., for computing the stresses in a rail, led to tabulation. See Zimmermann, "Die Berechnung des Eisenbahn-Oberbaus," Berlin, 1888. Also Timoshenko and Lessells, "Applied Elasticity," p. 138.

a, this distance is also diminished; consequently the thinner the shell, the narrower the zone of influence of the forces and moments set up by the loads Q_0 and M_0. Equations [7] give the final results for these if Q_0 and M_0 are known; however, when the cylinder is joined to a head to form a pressure vessel, these edge loads have to be determined (see Appendix No. 1). This determination must be preceded by the analysis of the head.

The magnitudes of the stresses may be calculated from Equations [7]. To avoid a partial repetition of tabulation, the final statement of the stresses will be postponed until Q_0 and M_0 have been found.

The Head With Edge Loads Only

The head is to have the following character: Its middle surface is generated by revolving about the y-axis (Fig. 6) a meridian curve which approximates an ellipse, of longer semi-axis a and knuckle radius $R_1 = r$ constant for a certain zone, and not too small a part of a. The thickness t is small in comparison with a. The edge is in the equatorial plane, which contains also the centers of curvature of the knuckle surface. If the head has openings such as manholes, etc., they are to be sufficiently remote that the region of their local effects shall not extend into that in which we are interested near the junction of head and cylinder.[10]

The strip shown in Fig. 6 is isolated as a free body. It is in equilibrium under the action of the applied loads Q_0 and M_0 at the edge, and the restraining forces and couples which they will set up in the strip. These are shown acting on an element of the strip in Fig. 6.

The following notation, in part already presented, will be used:

T_1 = normal meridional force
T_2 = normal hoop force
Q = shearing force in the cross-section perpendicular to meridian, and in the direction perpendicular to the middle surface
M_1 = meridional bending moment
M_2 = hoop bending moment.

These are positive in the directions indicated in Fig. 6, and the magnitudes are for an area, in each case, unity $\times$ t.

The stresses due to the normal and shearing forces are assumed to be uniformly distributed over the thickness of the shell.

The stresses due to the bending couples are assumed to vary linearly over the thickness of the shell, with zero value at the middle surface and numerical maxima at the outer and inner surfaces.

$$\left.\begin{aligned} \sigma_1 &= \frac{T_1}{t} = \text{meridional normal stress} \\ \sigma_2 &= \frac{T_2}{t} = \text{hoop normal stress} \\ \tau &= \frac{Q}{t} = \text{meridional shearing stress} \end{aligned}\right\} \quad \ldots\ldots\ldots [8]$$

$$\left.\begin{aligned} \sigma_{1e} &= \frac{M_1\left(\frac{t}{2}\right)}{\frac{1 \times t^3}{12}} = \frac{6M_1}{t^2} = \text{maximum meridional stress due to bending; } e \text{ subscript for external surface, } i \text{ for internal} \\ \sigma_{2e} &= \frac{6M_2}{t^2} = \text{maximum hoop stress due to bending.} \end{aligned}\right\} \quad \ldots [9]$$

s = length of arc measured along meridian, positive away from edge
s_2 = length of arc on hoop circle (rarely used)
r = meridional radius of curvature at the edge.

The solution obtained for the cylinder is exact for thin shells. In the case of the head, the inclusion of the expressions for certain forces which are known to be slight has undesirable mathematical consequences. By omitting these terms we come to an approximate solution, which should be, however, physically adequate.

The following assumption is made as a basis:

For a value of "s" small as compared with "a," and for a sufficiently large value of "r/a," the displacement of each point of the strip is essentially normal to the middle surface; its component in the direction of the meridian is negligible.

In the zone in which this assumption holds, the meridional component of Q_0 is negligible, hence, even assuming it is all transmitted along the meridian, T_1 would be negligible. The stress σ_1 is therefore taken to be zero.

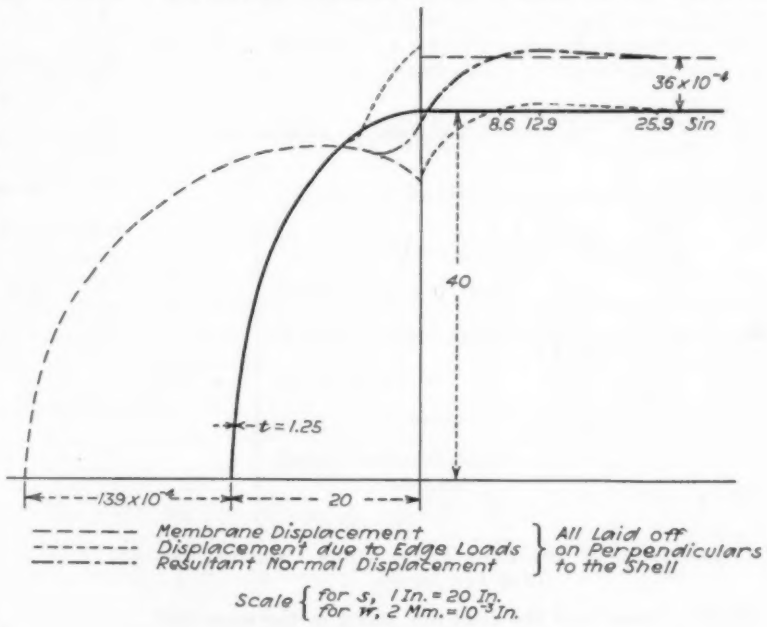

FIG. 7 THE NORMAL DISPLACEMENT w

In this case the force which resists the radial displacement of the element varies directly as that displacement and inversely as the square of the second radius of curvature of the shell.

Since R_2 increases with β, the factor $1/R_2^2$ decreases. Continuing the analogy used in the case of the cylinder, it may be said here that the strip behaves as a beam on an elastic foundation with a decreasing "modulus of foundation" (see Appendix No. 1) the loads being a shearing force and a bending couple at the end.

The normal displacement of an element at distance s from the edge is given by:

$$\frac{d^4w}{ds^4} + 4\lambda^4 w = 0 \quad \ldots\ldots\ldots [10]$$

in which

$$\lambda = \sqrt[4]{\frac{3(1-\mu^2)}{R_2^2 t^2}} \quad \ldots\ldots\ldots [11]$$

It is to be noted that λ here involves R_2, which is variable for most surfaces. Equation [3] is a special case of Equation

[10] for the cylinder, in which $R_2 = a$ = constant. Another case in which R_2 is constant is that of a hemispherical head. Then the integration of Equation [10] takes the same form as that of Equation [3], except for the determination of the constants of integration.

In case R_2 is variable, as for all types of ellipsoidal or quasi-ellipsoidal heads, the equation may be integrated numerically. Starting with $s = 0$ a meridional arc is taken, so short that by regarding R_2 as constant for this arc, we make no appreciable error in the computation (see cols. 4 and 7, Table 2). Then we have the same case for the first zone as for a hemisphere, and also as for the cylinder, with the following differences:

The sign of Q_0 is changed since the edge of the head is pulled outward radially.

λ varies as $1/\sqrt{R_2}$ and is equal to λ_0 only at the edge. Its value is approximately the edge constant for the first zone, but will be different for the next zones. To keep this clear, we distinguish the edge constant from the variable by the subscript. The derivatives of λ are taken to be negligible.

The solution to Equation [10] for a hemisphere, or for the first zone of an ellipsoid or quasi-ellipsoid, is

$$w = \frac{1}{2\lambda_0^3 D} e^{-\lambda s} [Q_0 \cos \lambda s - \lambda_0 M_0 (\cos \lambda s - \sin \lambda s)] \quad \ldots\ldots [12]$$

The forces and the bending couples are then

$$\left.\begin{aligned} T_2 &= \frac{Et}{R_2} w = 2\lambda_0 a \frac{a}{R_2} e^{-\lambda s} [Q_0 \cos \lambda s \\ &\qquad - \lambda_0 M_0 (\cos \lambda s - \sin \lambda s)] \\ Q &= D \frac{d^3 w}{ds^3} = \frac{a}{R_2} \sqrt{\frac{a}{R_2}} e^{-\lambda s} [Q_0 (\cos \lambda s - \sin \lambda s) \\ &\qquad + 2\lambda_0 M_0 \sin \lambda s] \\ M_1 &= D \frac{d^2 w}{ds^2} = \frac{a}{R_2} \frac{1}{\lambda_0} e^{-\lambda s} [-Q_0 \sin \lambda s \\ &\qquad + \lambda_0 M_0 (\cos \lambda s + \sin \lambda s)] \\ M_2 &= \mu M_1 - D (1 - \mu^2) \frac{\tan \beta}{R_2} \frac{dw}{ds} \end{aligned}\right\} \quad \ldots\ldots [13]$$

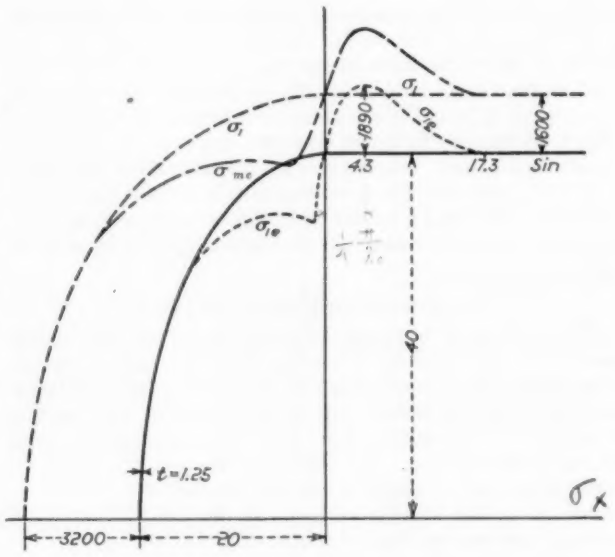
Determination of the Edge Loads When Cylinder and Head Are Joined

If the cylinder and the head are joined in the equatorial hoop of the latter to form a vessel which is then submitted to a uniformly distributed inner pressure, the following conditions must be fulfilled:

1 The total radial displacement, which is the sum of the radial displacement of the membrane and that due to the edge reactions, must be numerically the same for the two edges.

2 The tangent to the total-radial-displacement curve for the head and the tangent to the similar curve for the cylinder are common at the junction.

In the case at hand the shells have the same thickness t, and the first condition gives (Appendix No. 1) the value of the edge shearing force

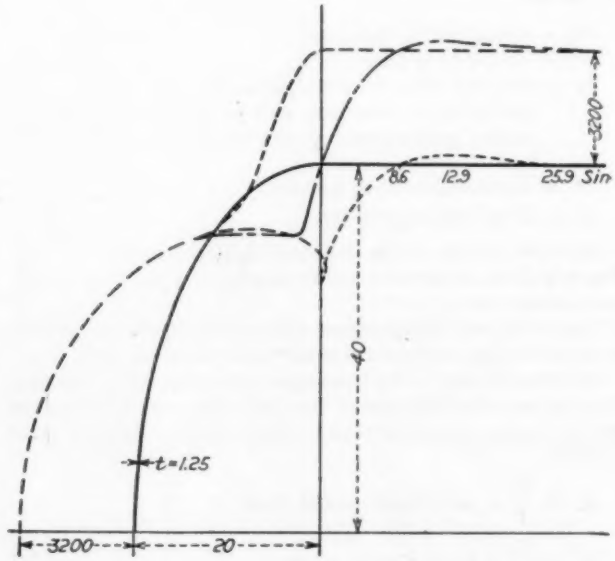


$$Q_0 = \frac{pk^2}{8\lambda_0} \quad \ldots\ldots [14]$$

The second condition gives the value of the edge bending moment

$$M_0 = 0 \quad \ldots\ldots [15]$$

Equations for the Local Effects Near the Junction of Head and Cylinder



The values of the forces and couples set up by the mutual reactions at the junction of head and cylinder are found by substituting the values of Q_0 and M_0, given by Equations [14] and [15], in Equations [5] and [7], and [12] and [13]. The corresponding stresses are then obtained by use of Equations [8].

Fig. 9 The Hoop Stresses σ_2

$$
\left.\begin{aligned}
w &= -\frac{pk^2a^2}{4E\,t}\,e^{-\lambda_0 s}\cos\lambda_0 s;\quad \sigma_{1e} = \frac{3pk^2}{4\lambda_0^2t^2}\,e^{-\lambda_0 s}\sin\lambda_0 s\\
\sigma_2 &= -\frac{pk^2a}{4t}\,e^{-\lambda_0 s}\cos\lambda_0 s;\quad \sigma_{2e} = \mu\sigma_{1e}\ *\\
\tau &= -\frac{pk^2}{8\lambda_0 t}\,e^{-\lambda_0 s}(\cos\lambda_0 s - \sin\lambda_0 s);\\
&\qquad\qquad \sigma_{1i} = -\sigma_{1e}\\
&\qquad\qquad \sigma_{2i} = -\sigma_{2e}
\end{aligned}\right\}\quad ..[16]
$$

For the cylinder, these expressions hold for any point at distance s from the junction.

For the ellipsoid, or the quasi-ellipsoid, all signs are reversed and the expressions hold only for an edge zone whose radius of curvature R_2 may be regarded as constant within the accuracy desired.

The variation of these stresses is that of the functions $e^{-\lambda_0 s}\times\cos\lambda_0 s$, etc. discussed above and displayed in Fig. 11. The ordinates there have only to be multiplied by the constant factors which enter Equations [16]. The most important of these stresses are σ_2 and σ_{1e} (see illustrative example, local effects in cylinder), and their magnitudes are such as to make the use of the membrane formulas alone quite meaningless for the computation of stresses near the junction. The stresses σ_{2e} and τ are comparatively small. All of these local stresses are so rapidly damped out that their values outside an edge zone of width $s = 2.44\sqrt{at}$ are of no concern.

In superposing the membrane stresses and the local stresses it is to be noted that the bending stresses have opposite signs for the outer and inner surfaces, whereas each direct stress has the same sign throughout the thickness. Consequently, if we are concerned with numerically maximum values of the resultant stress, we shall consider both surfaces.

For the cylinder, the numerically greatest value of σ_2 is $\frac{pk^2a}{4t}$ and it occurs at the edge; the first maximum of σ_{1e} is $\frac{3pk^2}{4\lambda_0^2t^2}$ (0.32) and it occurs at $\lambda_0 s = \pi/4$, that is, $s = 0.61\sqrt{at}$. Since the values of $e^{-\lambda_0 s}\cos\lambda_0 s$ and $e^{-\lambda_0 s}\sin\lambda_0 s$ are equal for $\lambda_0 s = \pi/4$, the value of σ_2 when σ_{1e} is maximum is numerically $\frac{pk^2a}{4t}$ (0.32).

In dealing with the head it may happen that the edge zone within which R_2 may be regarded as constant is too small a part of the edge zone within which the local stresses are damped out. In that case, starting from the edge we take a sufficient number of zones, within each of which R_2 may be regarded as constant, to cover the region in which the local stresses are significant. After the edge zone, Equations [16] no longer hold for the head. They are replaced by (see footnote 20, p. 127):

$$
\left.\begin{aligned}
w &= \frac{pk^2a^2}{4Et}\left(e^{-\int_0^s\lambda ds}\right)\cos\left(\int_0^s\lambda ds\right)\\
\sigma_2 &= \frac{pk^2a^2}{4tR_2}\left(e^{-\int_0^s\lambda ds}\right)\cos\left(\int_0^s\lambda ds\right)\\
\tau &= \frac{pk^2a^2\sqrt{2}}{8\lambda tR_2^2}\left(e^{-\int_0^s\lambda ds}\right)\cos\left(\frac{\pi}{4}+\int_0^s\lambda ds\right)\\
\sigma_{1e} &= \frac{-3pk^2a^2}{4\sqrt{3\,(1-\mu^2)}\,tR_2}\left(e^{-\int_0^s\lambda ds}\right)\sin\left(\int_0^s\lambda ds\right)\\
\sigma_{2e} &= \mu\sigma_{1e}
\end{aligned}\right\}\quad ..[17]
$$

The values of the expressions $\int_0^s\lambda ds$ may be conveniently obtained by numerical integration, as illustrated in the following paragraphs.

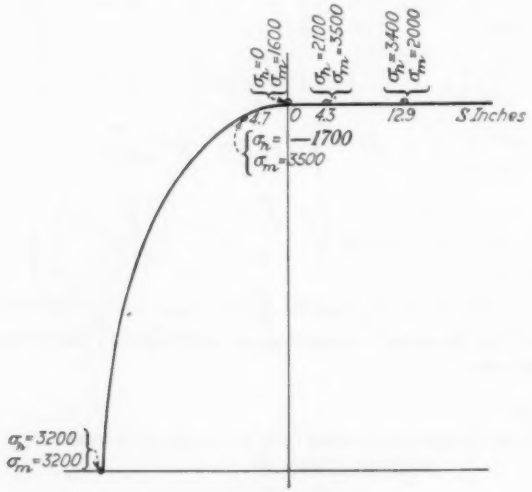

FIG. 10 KEY STRESSES

σ_h = resultant hoop stress — Tensile if written outside contour
σ_m = resultant meridional stress — Compressive if written inside contour

a = radius of cylinder or semi-major axis of ellipse = 40 in.
b = depth of head or semi-minor axis of ellipse = 20 in.
k = a/b = 2
t = thickness of shell for both head and cylinder = 1.25 in.
μ = ratio of lateral to longitudinal strain (in simple tension) = 0.3
E = Young's modulus = 3×10^7 lb. per sq. in.
p = 100 lb. per sq. in.

The length of the cylinder is, say, greater than the diameter.[15]

The investigation of the state of stress in the vessel involves, as has been seen, the membrane analysis and the analysis of local effects. (See page 123.) We are now in position to make each of these. The entire computation is shown in two charts, Tables 1 and 2, and was made with a log-log slide rule. In Table 1 it is not necessary to take so many points, nor need the interval $\delta\beta$ be always the same. The 5-deg. interval was taken for convenience in the v-column of Table 2. The order of filling the columns in Table 1 was 1, 12, 2, 3, ...In the local stress analysis of the cylinder, the values of the functions $e^{-\lambda_0 s}\cos\lambda_0 s$, etc., were found by assigning values to $\lambda_0 s = X$ in Fig. 11 and picking off the corresponding ordinates.

ILLUSTRATIVE EXAMPLE

A vessel with ellipsoidal heads is taken and the following values are assigned to the constants connected with its design:

[15] From the preceding discussion it is seen that it might be taken still shorter, as long as the local effects at the ends do not interfere mutually.

Explanation of Table 2. The value of $\int_0^s \frac{ds}{\sqrt{R_2}}$ for any value of s may be found in terms of β (see Fig. 1) from the relations

$$\delta s = R_1 \delta\beta; \quad R_2 = kav = \frac{ka}{\sqrt{1 + (k^2 - 1)\cos^2\beta}}$$

Neither δs nor R_2 is constant, but both may be so regarded if the interval $\delta\beta$ be taken so short that the variation of R_1 and R_2 within it is negligible. Then we may compute $\frac{\delta s}{\sqrt{R_2}}$ for each such interval, and at any β, such as β_n, we may write

$$\int_0^s \frac{ds}{\sqrt{R_2}} = \sum_{\beta=0}^{\beta_n} \frac{\delta s}{\sqrt{R_2}}$$

Thus we fill out the table as follows: Column 2 from that of the preceding table; column 3 represents the values of the meridional radius at the hoops $\beta = 0°, 5°, \ldots$; column 4 represents the average radius for the zone between the hoops; in column 5 it is recalled that $\delta\beta$ is in radians; columns 6 and 7 are similar to 3 and 4; column 8 is self-explanatory; each entry in column 9 is the sum of the entries in column 8 down to and including its level β_n. From the entries in column 10 as abscissas,

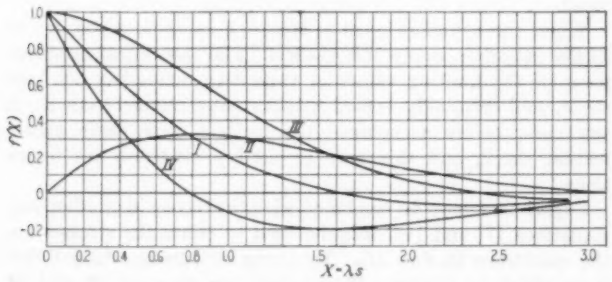

FIG. 11 THE CHARACTERISTIC FUNCTIONS $f_1(X) = e^{-X}\cos X$, $f_2(X) = e^{-X}\sin X$, $f_3(X) = e^{-X}(\cos X + \sin X)$, AND $f_4(X) = e^{-X}(\cos X - \sin X)$

the values of the functions tabulated in columns 11 and 12 are found as ordinates on curves I and II of Fig. 11.

With regard to the choice of intervals $\delta\beta$, each was taken as 5 deg., although nothing about the method requires that it be constant, to bring out the point that it may be taken longer near $\beta = 0$ and shorter as we progress. This is seen from the values of R_1 and R_2 in columns 4 and 7, or from column 8. However, we see from columns 13 and 14 that the stresses decrease numerically as β increases, and we expect to stop the computation as soon as they become negligible, or even as soon as the sum of the numerical values of the meridional membrane and local stresses passes its maximum. Experience with the method, applied to usual designs, will bring out a choice of intervals which will give desired accuracy with the least computation.

If the other quantities τ and σ_{2s} are desired, they may be readily obtained once column 10 is filled. Then the values of the four characteristic functions for any value of X may be picked off from Fig. 11. For example, the computation of τ would mean only the addition of a column which tabulates its values after a single series of slide-rule computations.

The results of the analyses are shown graphically in Figs. 7, 8, and 9. In Fig. 7 the scale for the displacements must be greatly exaggerated, and since the contour of the vessel is drawn to another scale, this leads to an unpleasant distortion. For example, the position of the ellipsoidal membrane after strain is such that the meridional tangent at the junction is horizontal. In Fig. 8 the bending stresses σ_{1s} are those at the outer surface. For the inner surface, the signs are reversed. The curves which display σ_{1i} could thus be obtained by reflecting those shown in the contour of the vessel. The maximum resultant meridional stress is consequently at the inner surface of the knuckle.

Fig. 9 displays the hoop stresses. If it is desired to include the effect of σ_{2s} (or σ_{2i}) it may be done by noting that the values are essentially three-tenths the corresponding values of σ_{1s} (or σ_{1i}). Thus, the ordinates of σ_{1s} in Fig. 8 could be shrunk by this factor and added to those shown.

In general, the significant stresses are those at the crown, the inner surface at the knuckle, and the outer surface of the cylinder near the junction. These are shown in Fig. 10. After one criterion, the favorable head, from the point of view of stress distribution, is one in which these key stresses are about equal. In this case they are all in the neighborhood of 3500, hence this is a favorable design. It should be noted that there is a tensile meridional stress and a compressive hoop stress at the inner surface of the knuckle, consequently a high stress difference there, with the attendant possibility of failure due to shear as the load p is increased. This is especially to be kept in mind in the usual design, for which we may expect a much higher value of the meridional stress at this point.

In his work cited in footnote 9, Huggenberger obtained similar results by use of a method of another form, from the point of view of derivation and application. He had also the opportunity to measure the strains and the angular displacements on a full-scale vessel of about the same dimensions in centimeters as are here given in inches.[16] He found a satisfactory check of computed and experimental results.[17] Using the above method and exactly his data we have the curves given in Fig. 12 as a check of his computations with ours.

GENERAL DISCUSSION OF THE METHOD

The work has been carried through here completely for one ellipsoidal head, but with slight consideration the results will apply to all such heads with $k = 2$, as may be seen from the computation charts. In Table 1, all the variation is taken care of by v in which the only constant is k. The values in columns 9 and 10 for $w/(pa^2/2Et)$ and $u/(pa^2/2Et)$ are for all ellipsoidal heads with $k = 2$. It is seen at once that the values in 11 and 13 could be similarly arranged for $\sigma_1/(pka/2t) = \sigma_1/(pa/t)$ and $\sigma_2/(pa/t)$. In Table 2, the situation is not quite so favorable, but still not unpleasant. A change in the value of a will have the following effect on the variable parts of the local stresses given in columns 11 and 12. If, for example, a becomes $3a$, all the values in column 8 will be multiplied by $\sqrt{3}$, which will therefore be a factor of the sum given in column 9. Consequently X in columns 10, 11, and 12 becomes $\sqrt{3}\,X$, and the values can be found from Fig. 11. Graphically this means that the results could be picked off a new series of curves which are gotten from those in Fig. 11 by shrinking along the axis of abscissas by the amount $\sqrt{3}$.

By considering the general Equations ([16] or [17]) instead of Tables 1 and 2, it is possible to make further conclusions. The factors there may be arranged to involve only the ratios a/t and a/R_2; consequently if a, t, and R_2 be changed in such a way as to keep these ratios constant, the stresses will be the same. From this we have the similarity theorem stated in the previous footnote. The stresses are in general con-

[16] It may be shown that, for one material and the same uniformly distributed inner pressure, geometrically similar vessels develop equal local stresses in similarly located points.

[17] See Fig. 38, p. 169, of the work cited in footnote 9.

trolled by the ratios k, a/t, and a/R_2, and the assignment of actual magnitudes to a, b, t, and R_2 is left free for satisfying other conditions attached to the design.

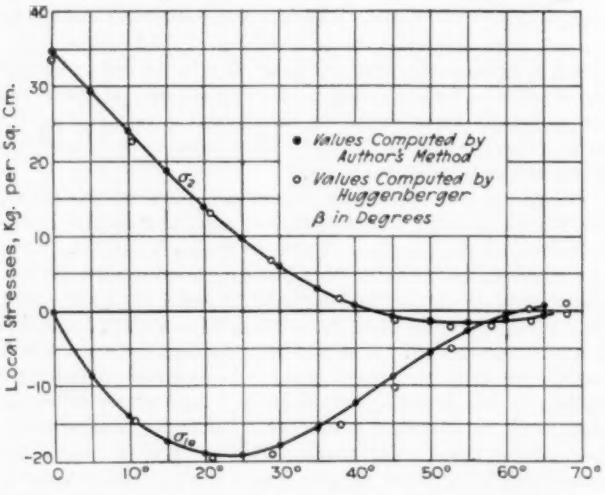

FIG. 12 COMPARISON WITH COMPUTATION OF HUGGENBERGER
(See Table VI, p. 163, "Ueber die Festigkeit der gewölbten Böden und der Zylinderschale.")

The assumption that the head and cylinder are of the same thickness is not a necessary one. A difference in thickness will give other values of Q_0 and M_0 which may be determined by the same method. Thus, for example, it is possible to compute the thickness which should be given to a hemispherical head to have it carry as high a stress as occurs in the cylinder.

In the case of the quasi-ellipsoidal head, the method given takes care of the local effects at the junction of head and cylinder. Then $R_1 = r$ is constant and R_2, of course, is computed from another law than that for the ellipse. This may be written, in one form, as

$$R_2 = r + (a - r) \sec \beta$$

The set of local effects at the shoulder where R_1 is changed will be of less consequence than those at the joint, and deformation of the head tends to reduce them further.

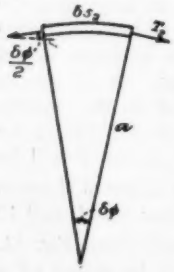

FIG. 13

The display of the displacements and stresses given in Figs. 7, 8, and 9 was designed for pictorial rather than practical purposes. Actually it will be more desirable and easier to develop the meridian of the head as an extension of the element of the cylinder, and lay off all quantities as ordinates with this line as axis of abscissas. The abscissas will then be found from Table 2, column 5, recalling that here we have only the increments in s, and that s at any point will be $\sum_0^{3p} \delta s$. The stress curves will then be roughly symmetrical with respect to the origin (at the joint) and therefore a rough estimate of the numerical maxima of the local stresses in the head will be those of the cylinder:

$$\sigma_2 = \frac{pak^2}{4t} \text{ occurs at edge } s = 0$$

$$\sigma_{1\phi} = \frac{3pk^2}{4\lambda_0^2 t^2} (0.32) \text{ occurs at } s = 0.61\sqrt{at}$$

In the case at hand, which, it will be recalled, is nearly the most favorable from the point of view of stress distribution, these values are

$$\sigma_2 = 3200$$

$$\sigma_{1\phi} = 1890 \text{ at } s = 4.3 \text{ in.}$$

It is seen, therefore, that the computation of these stresses is not an unnecessary refinement. Even here they are of the same order as the membrane stresses, and in less favorable shapes they will of course be higher. From the more exact equations ([17]), we find that the position of these maximum stresses, and the length of the zone in which they damp out, is controlled by the factor $\sqrt{\frac{R_2}{a}\frac{t}{a}}$, which is independent of p. This is of interest in the problem of the location of a welded joint. It is seen also that an increase of t lengthens this zone.

The applicability of the method is limited by the hypotheses contained in the discussion of the form of the head. These involve in spirit the two ratios mentioned, R_2/a and t/a. For the cylinder, $R_2/a = 1$ and the solution of the equations is exact. As the head approaches a flat plate in form, R_2/a becomes rapidly larger, and the assumptions which were made in order to get the solution are not fulfilled. For values of the ratio which characterize the heads shown desirable by experiment, the assumptions should be satisfied, always subject to the restriction that t/a is small.

When the cylinders must be regarded as thick pipes, we no longer expect to apply this theory. The theoretical establishment of the limiting values of these two ratios has not been made, and seemingly logical attacks have not succeeded. In any case, before acceptance the method must have experimental check, and this may be used to establish its limitations.

Experiment may be combined with the theory in another way. Equations [7] and [13] may be used to relate the stresses and the quantities Q_0 and M_0. By using instruments to get data from which to compute the stresses, we may get Q_0 and M_0 from these equations. This will check the theoretically determined values with those actually occurring in the vessel, and we can go on with the computation, using the corrected values.

This is important in the case of a riveted construction, since we do not expect the hypothetical boundary conditions to be exactly realized there. Actually also in welded vessels there is a restraint due to the material of the weld.[18] As has been mentioned, one complete experimental check of this method has been made on a full-size vessel with $t/a \cong 0.03$. Another on a model was made by Geckeler[19] with $t/a \cong 1/240$. Another was made on a vessel with hemispherical heads.[18] These checks may not, however, be regarded as sufficient. In the first place, there are not enough of them to properly test a theory which contains many rather bold assumptions; and in the second place, as far as is known, no tests have been made to compare well-designed quasi-ellipsoidal heads with ellipsoidal heads, axis ratio about 2, by determining the stresses in each while they are still below the elastic limit. Since it is claimed by many good authorities that it is possible to get a favorable distribution without going to the depth of the above ellipsoidal head, it would seem that a settlement of this question would logically precede any discussion of standardization of forms or changing of code.

Appendix No. 1

The Displacements of the Ellipsoidal Membrane

THE derivation of the formulas for the membrane stresses, and those relating displacement and strain in a shell, are found in various books on the subject.[20] The expressions for the displacements of the ellipsoidal membrane given by Equation [2c] are believed to be new. They are derived as follows:

Consider the elliptical meridian in the xy-plane of Fig. 1. Its equation in parametric form is

$$x = a\cos\psi$$
$$y = b\sin\psi$$

Between the parametric angle ψ and the angle β we find the relation

$$b\cot\psi = a\cot\beta \quad \ldots\ldots\ldots\ldots\ldots [18]$$

From the well-known formula

$$R_1 = \frac{\left[1+\left(\frac{dy}{dx}\right)^2\right]^{3/2}}{\frac{d^2y}{dx^2}}$$

for the above values of x and y,

$$R_1 = -\frac{a^2}{b}\csc^3\beta\sin^3\psi$$

Upon the elimination of ψ by use of Equation [18]

$$|R_1| = \frac{a^2}{b}\frac{1}{\left(1+\frac{a^2-b^2}{b^2}\cos^2\beta\right)^{3/2}}$$

From Fig. 1,

$$R_2 = x\sec\beta = a\cos\psi\sec\beta = \frac{a^2}{b}\frac{1}{\left(1+\frac{a^2-b^2}{b^2}\cos^2\beta\right)^{1/2}}$$

Therefore

$$\left.\begin{aligned} R_1 &= kav^3 \\ R_2 &= kav \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [19]$$

in which[21]

$$k = \frac{a}{b} \text{ and } v = \frac{1}{\sqrt{1+(k^2-1)\cos^2\beta}}$$

These formulas are more convenient than those in terms of x and y, especially in the following derivation. From the theory of thin shells we have the equations

$$\left.\begin{aligned} u &= \cos\beta\int_0^\beta \frac{\epsilon_1 R_1 - \epsilon_2 R_2}{\cos\beta}\,d\beta \\ w &= u\tan\beta + \epsilon_2 R_2 \end{aligned}\right\} \quad \ldots\ldots\ldots [20]$$

in which

ϵ_1 = meridional strain
ϵ_2 = hoop strain,

and the relations between these and the stresses are

$$\left.\begin{aligned} \epsilon_1 &= \frac{1}{E}(\sigma_1 - \mu\sigma_2) \\ \epsilon_2 &= \frac{1}{E}(\sigma_2 - \mu\sigma_1) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [21]$$

For σ_1 and σ_2, the values given by Equations [1] are used with the values of R_1 and R_2 given by Equation [19]. The introduction of all these quantities into the integrand of Equation [20] gives

$$u = \frac{p\cos\beta}{2Et}\int_0^\beta \frac{1}{\cos\beta}\left\{(v-v^3)\left[v-v^3(1-2\mu)\right]\right\}\frac{d\beta}{v^2}$$
$$= \frac{pk^2a^2(k^2-1)}{2Et}\cos\beta\left[\int_0^\beta v^3\cos\beta d\beta - (1-2\mu)\int_0^\beta v^4\cos\beta d\beta\right]$$

The integrals may be evaluated exactly; then u takes the form given by Equation [2c]. From this the value of w is found in the form given in Equation [2c], by use of the values of ϵ_2 and R_2 determined from Equations [21], [1], and [19].

The Cylindrical Shell With Edge Loads

The differential equation for the normal displacement w is derived from the equilibrium of the element shown in Fig. 5 under the forces and couples:

T_2, the normal hoop force
Q, the meridional shearing force
M_1, the meridional bending couple
M_2, the hoop bending couple.

We have assumed the normal stresses to be uniformly distributed over the thickness of the shell; therefore $\sigma_2 = T_2/t$. The meridional stress σ_1 is here zero. From Equation [21] the hoop strain is

$$\epsilon_2 = \frac{W}{a} = \frac{1}{E}\frac{T_2}{t}$$

Then

$$T_2 = \frac{Etw}{a} \quad \ldots\ldots\ldots\ldots\ldots [22]$$

From Fig. 13, the radial component of $T_2\,\delta s$ is

$$T_2\,\delta s\sin\frac{\delta\varphi}{2} = T_2\,\delta s\frac{\delta\varphi}{2} = T_2\,\delta s\frac{\delta s_2}{2a}$$

Then, from [22], the radial component of both hoop forces on the element is

$$T_2\,\delta s\frac{\delta s_2}{a} = \frac{Etw}{a^2}\,\delta s\,\delta s_2$$

For unit arcs in each direction s and s_2 this is Etw/a^2; in other words, this component, which represents the resistance to radial displacement of the element, varies directly as the amount of that displacement. This is the condition that the strip behave as a beam on an elastic foundation. The elastic constant of this foundation, the so-called *modulus of foundation*, is here Et/a^2.

Since we have a two-dimensional state of stress with lateral deformation in bending prevented, E is replaced by $E/(1-\mu^2)$, and the usual beam formula becomes

$$\frac{d^2w}{ds^2} = -\frac{M_1}{D} \quad \ldots\ldots\ldots\ldots\ldots [23]$$

[20] For example, A. and L. Föppl, "Drang und Zwang," vol. II, Oldenbourg, Munich, 1928. For convenience, they are given, along with a fuller treatment of this whole question, in "The State of Stress in Thin-Walled Pressure Vessels," by W. M. Coates, Engineering Research Bulletin, University of Michigan.

[21] See "Handbuch der Physik," vol. VI, "Mechanik der elastischen Körper," in article by Geckeler.

in which $D = \dfrac{Et^3}{12(1-\mu^2)}$

From Equation [23],

$$\frac{d^2w}{ds^2} = -\frac{1}{D}\frac{dM_1}{ds} = -\frac{1}{D}Q \quad \ldots\ldots\ldots\ldots [24]$$

From the equilibrium of the element of Fig. 5 with respect to forces normal to the middle surface,

$$\frac{Etw}{a^2}\,\delta s\,\delta s_2 + Q\,\delta s_2 - \left(Q + \frac{dQ}{ds}\,\delta s\right)\delta s_2 = 0$$

$$\therefore \frac{dQ}{ds} = \frac{Etw}{a^2}$$

Equation [24] is differentiated again:

$$\frac{d^4w}{ds^4} = -\frac{1}{D}\frac{dQ}{ds} = -\frac{Etw}{Da^2} = \frac{-12(1-\mu^2)}{a^2t^2}\,w$$

after D is replaced by its value. Then

$$\frac{d^4w}{ds^4} + 4\lambda_0^4\,w = 0 \quad \ldots\ldots\ldots\ldots\ldots [3]$$

in which

$$\lambda_0 = \sqrt[4]{\frac{3(1-\mu^2)}{a^2t^2}} \quad \ldots\ldots\ldots\ldots\ldots [4]$$

This equation has the complete solution

$$w = e^{-\lambda_0 s}(a_1 \cos \lambda_0 s + a_2 \sin \lambda_0 s) + e^{+\lambda_0 s}(a_3 \cos \lambda_0 s + a_4 \sin \lambda_0 s)$$

in which the constants of integration are a_1, a_2, a_3, a_4. Since the deflections w decrease numerically with an increase in the distance s from the edge, the terms with the factor $e^{+\lambda s}$ are physically impossible for the long cylinder here taken. Then $a_3 = a_4 = 0$.

At $s = 0$, $Q = Q_0$ and $M = M_0$; therefore

$$Q_0 = -2D\lambda_0^3[(a_1 + a_2)]$$

$$M_0 = 2D\lambda_0^2[a_2]$$

and

$$a_1 + a_2 = -\frac{Q_0}{2\lambda_0^3 D},\quad a_2 = \frac{M_0}{2\lambda_0^2 D},\quad a_1 = -\frac{1}{2\lambda_0^3 D}(Q_0 + \lambda_0 M_0)$$

The equation of the radial-displacement curve of the cylinder becomes

$$w = -\frac{1}{2\lambda_0^3 D}\,e^{-\lambda_0 s}[Q_0 \cos \lambda_0 s + \lambda_0 M_0(\cos \lambda_0 s - \sin \lambda_0 s)] \ldots [5]$$

and from this we obtain the expressions for the forces and the bending couples given by Equations [7].

The Head With Edge Loads

The analysis follows the lines laid down in the previous paragraph, except that approximations are introduced.

The bending moments in a thin shell are

$$M_1 = D\left[\frac{1}{R_1}\frac{d\Theta}{d\beta} + \mu\frac{\tan\beta}{R_2}\Theta\right]$$

$$M_2 = D\left[\frac{\tan\beta}{R_2}\Theta + \frac{\mu}{R_1}\frac{d\Theta}{d\beta}\right] = \mu M_1 + D(1-\mu^2)\frac{\tan\beta}{R_2}\Theta$$

in which

$$\Theta = \frac{u}{R_1} - \frac{1}{R_1}\frac{dw}{d\beta}$$

represents the angular deflection of the normal to the middle surface of the shell, and is taken positive in the same sense as the angle β. The terms in the brackets represent the changes in the first and second curvatures of the middle surface. Thus, $\dfrac{1}{R_1}\dfrac{d\Theta}{d\beta}$ is the change in $\dfrac{1}{R_1}$, and $\dfrac{\tan\beta}{R_2}\Theta$ is the change in $\dfrac{1}{R_2}$. For example, the cylinder has a constant zero meridional curvature, and the second term drops out in the bracket of M_1 since $\beta = 0$; correspondingly the first term drops out of M_2; also the u-term drops out of Θ since the curvature $\dfrac{1}{R_1} = 0$. The equations for the cylinder then become $M_1 = -D\dfrac{d^2w}{ds^2}$ and $M_2 = \mu M_1$ as we have them.

Introducing the hypothesis that $u = 0$, we find $\Theta = -dw/ds$, and the expressions for the moments become

$$M_1 = -D\left[\frac{d^2w}{ds^2} + \frac{\mu\tan\beta}{R_2}\frac{dw}{ds}\right]$$

$$M_2 = \mu M_1 - D(1-\mu^2)\frac{\tan\beta}{R_2}\frac{dw}{ds}$$

Guided by the knowledge of the behavior of a cylinder, we assume that for heads of the type hypothesized, the term in dw/ds may be neglected in comparison with that in d^2w/ds^2. After the solution is obtained, we may return with the value found for w and investigate this question.[22] With this assumption

$$M_1 = -D\frac{d^2w}{ds^2}$$

The discussion of the hoop strain is as with the cylinder, with R_2 in place of a. The radial component of both hoop forces together is Etw/R_2 for each element $1 \times 1 \times t$.

The equilibrium of the element of Fig. 6 with respect to radial forces gives

$$\left(Q + \frac{dQ}{ds}\delta s\right)\delta s_2 - Q\delta s_2 - \frac{Etw}{R_2^2}\,\delta s\,\delta s_2 = 0 \quad \therefore \frac{dQ}{ds} = \frac{Etw}{R_2^2}$$

The equilibrium of the element with respect to meridional moments gives

$$\left(M_1 + \frac{dM_1}{ds}\,\delta s\right)\delta s_2 - M_1\delta s_2 - Q\delta s\delta s_2 = 0 \quad \therefore Q = \frac{dM}{ds}$$

Then

$$M_1 = -D\frac{d^2w}{ds^2},\quad Q = \frac{dM}{ds} = -D\frac{d^3w}{ds^3},\quad \frac{Etw}{R_2^2} = \frac{dQ}{ds} = -D\frac{d^4w}{ds^4},$$

$$\frac{d^4w}{ds^4} + \frac{Etw}{DR_2^2} = 0, \quad \text{and} \quad \frac{d^4w}{ds^4} + 4\lambda^4 w = 0$$

in which λ is as defined in Equation [11].

---

[22] From Equation [17], we see that except at $\beta = 0$ the value found for w bears out this assumption for a sufficiently small t/a. At the edge we may expect some effect of the neglected term, and experiments show a slight moment here, as against the predicted value $M_0 = 0$.

Determination of the Edge Loads When Cylinder and Head Are Joined

Let w_m denote the radial displacement of the membrane and w_l that due to the edge loads.
At the edge hoop circle,

$$w_m = \frac{pa^2}{2Et}(2 - \mu) \text{ for cylinder, from Equation [2}b\text{]}$$

$$w_m = \frac{pa^2}{2Et}(2 - \mu - k^2) \text{ for head, from Equation [2}c\text{]}$$

$$w_l = -\frac{1}{2\lambda_0^3 D}(Q_0 + \lambda_0 M_0) \text{ for cylinder, from Equation [2}c\text{] for } s = 0$$

$$w_l = +\frac{1}{2\lambda_0^3 D}(Q_0 + \lambda_0 M_0) \text{ for head, from Equation [2}c\text{] for } s = 0$$

The first condition stated under this heading in the paper itself becomes

$$w_{m]\text{cyl.}} + w_{l]\text{cyl.}} = w_{m]\text{head}} + w_{l]\text{head}}$$

$$\therefore Q_0 = \frac{\lambda_0^3 D p a^2 k^2}{2Et} = \frac{pk^2}{8\lambda_0}$$

As for the second condition, the membrane displacement gives no angular deflection at the edge because of symmetry, and the edge load gives that found by substituting the value of w in the expression for Θ.
At the edge of the cylinder, $s = 0$, $\lambda = \lambda_0$,

$$Q_{0]\text{cyl.}} = -Q_{0]\text{head}} \qquad \Theta_{0]\text{cyl.}} = \frac{1}{2\lambda_0^3 D}\left(-Q_0 - 2\lambda_0 M_0\right)$$

At the edge of the head, $s = 0$, $\lambda = \lambda_0$,

$$\Theta_{0]\text{head}} = \frac{1}{2\lambda_0^3 D}\left(Q_0 - 2\lambda_0 M_0\right)$$

Since ds for the head equals $-ds$ for the cylinder

$$\Theta_{0]\text{head}} = -\Theta_{0]\text{cyl.}}$$

$$\therefore M_0 = 0$$

Acknowledgment

In addition to the works referred to in the various footnotes, the author wishes to acknowledge the approximate method due to Meissner (*Schweizerische Bauzeitung*, July 4, 1925), and to mention once more that of Geckeler (footnote 19).

Discussion

D. B. Wesstrom.[23] The writer confesses that he is interested mainly in the practical application of the theory presented in this paper. The general attitude of the pressure-vessel industry on the subject of accurate calculation of strains and stresses in heads is a passive one. The designing engineer today is satisfied with the knowledge, supported by both experiment and theory, that the ellipsoidal and quasi-ellipsoidal heads with an axis ratio of 2 to 1 are the best type of head from the combined standpoint of cost, manufacturing convenience, and maximum utilization of the strength of the material without exceeding the working stress. Regardless of this, the accurate calculation and determination of strains and stresses in heads of pressure vessels will become increasingly important in the next few years and will be of paramount importance in the case of vessels designed to operate at very high temperatures, where the effect of "creep" in the steel is introduced. This is readily seen when it is noted that an excess of the actual working stress over the design working stress of only 10 or 15 per cent may double or triple the amount of "creep" or cumulative plastic deformation, thus shortening the life of the vessel.

It is gratifying to know, then, that theory is ahead of practice on the subject of stresses in heads, and the author is to be congratulated for his admirable investigation of this subject, and also for his thorough treatment of it and the excellent manner in which he presents it.

Attention is called to the fact that the A.S.M.E. Boiler Code Committee has recently considered tolerances for quasi-ellipsoidal heads in which a deviation of the head section from the true ellipse of 1.25 per cent of the head diameter is allowed, which tolerance, it is believed, was determined by manufacturing limitations. It would be interesting if the author were to apply his equations to this problem and determine the ratio of maximum stress in such a head to that in a truly ellipsoidal one for various plate thicknesses.

The mathematical curves derived by the author are remarkably similar to corresponding curves derived from experimental data presented by E. Höhn in footnote 5, and likewise to curves determined independently by T. W. Greene and the writer. The similarity is evident in the shape of the curves and in the general location and magnitude of the maximum and minimum points.

Although the author's curves show the point of normal meridional stress, or point of zero bending, at the edge of the head, where $s = 0$, the experimental data referred to place this point a certain distance beyond, somewhere in the cylinder. This disagreement may be due partly to inaccuracies in locating the edge point in an actual experiment and partly to the neglect of minor effects, as in footnote 22. It seems to the writer that this is the most favorable location of a welded joint, and he would like to ask the author to amplify his remarks on this matter. Would the reinforcing effect of the weld modify the location of this optimum point?

This paper furnishes an excellent example of the application of mathematics to refined mechanical design.

A. B. Kinzel.[24] The author is to be complimented on a very ingenious piece of work. The basic assumptions made are the same as those which have been used by many others in the past, including Huggenberger's work on the same subject, although the mathematical treatment is very much more simple than that used by Huggenberger. The author has given a flexible and reasonably simple method of calculating stresses in full heads, and by means of this calculation has checked the values obtained by the more complicated method of computation, showing the local stress concentration at the junction of ellipsoidal heads with cylindrical shells.

In the past few years considerable progress has been made in the design of heads for pressure vessels, and the elliptical head with the 2 to 1 major-minor axis ratio has been largely adopted. Huggenberger has further calculated the local stresses, with the result that a seven-arc head in which the stresses are further reduced in the general vicinity of the point of tangency of the head and cylindrical shell is recommended. It seems that the author has an opportunity of giving an even better solution of this problem, due to his greatly simplified mathematical attack. It

[23] Research Engineer, M. W. Kellogg Company, Jersey City, N. J. Jun. A.S.M.E.

[24] Union Carbide and Carbon Research Laboratories, Inc., Long Island City, N. Y.

occurs that in a large pressure vessel the sections near the ends of the cylindrical section could be formed so as to be conical or even portions of ellipsoids or paraboloids, and that by so forming these sections the stress concentration at the continuity of the elliptical section with the cylindrical section could be greatly reduced.

The introduction of the elliptical head to replace the short knuckle radius head has reduced the stress concentration from approximately three to five times that of the calculated stress, to approximately 25 per cent local stress increase, and a design of the shape of the head to reduce this 25 per cent to approximately 5 per cent is available in a rather complicated form by Huggenberger's work, and should be available in a more simple form by the extension of the work of the author. This leads to the hope that in the not too distant future the design of pressure vessels with a factor of safety less than $5^1/_2$ will be produced as it has been clearly demonstrated in the past that the factor of safety was really about 2, with the factor of ignorance about 3.

S. Timoshenko.[25] The author must be congratulated for his very interesting paper which is of practical importance to designers of pressure vessels. He has reduced the problem of stress analysis in pressure vessels to that of bending of a beam on an elastic foundation. In this manner the problem is considerably simplified as compared with existing solutions of the same problem given by Huggenberger and by Geckeler. The numerical example illustrates that all calculations can be made with sufficient accuracy by using the slide rule, hence the method can be adapted for practical use.

The only criticism the writer has refers to the derivation of Equation [10]. Although this equation is satisfactory at the joint and gives satisfactory values of local stresses at this place, the use of the same equation at points far away from the joint can be justified only on the basis of a more thorough investigation of this equation. The derivation given on the twelfth page, in which δS_2 is considered as a constant, is satisfactory at the joint, but at the points distant from the joint the variation of the width δS_2 of the strip should be taken into account.

F. L. Everett.[26] Several of those who have discussed the paper have inquired whether physical tests have been made which check the analytical expressions obtained by the author. The writer is aware that tests have been performed on full-size riveted vessels which showed good qualitative agreement with the analysis which has been presented. The design of heads was the usual dished type having a radius of curvature equal to the diameter of the drum and a short knuckle radius of several inches.

The drums were subjected to hydrostatic pressure. Simultaneously sufficient measurements of strain were made to determine the stresses in meridional and hoop directions on and in longitudinal and circumferential directions on the cylindrical shell. Marked local effects, particularly at the knuckle, were observed, and even an area under compression was noted here.

The pressure during a later part of the test was increased until failure of the head at the knuckle resulted. A head of "basket-handle" form, however, on test showed superior characteristics and was adopted as the design for future practice.

Author's Closure

The author wishes to thank those who have discussed this paper for the appreciation which they have expressed. Although the presentation of a method for computing the stresses in shells requires considerable mathematical notation, the mere statement of the results can be made in a very simple form, which permits rapid calculation, for such cases as here discussed. It is hoped that this has been made clear, in spite of errors which have occurred in the preprint, especially in the placing of the parts of the analysis in the illustrative example.

As regards the discussion by Mr. Wesstrom, the author agrees that the interest of the engineer is in the application of the theory, not in its presentation. This means that he need be concerned only with formulas [1], [2] and [16] or [17]. The general passive attitude on the computation of stresses in heads may be explained by the difficulty attached to such computations. As soon as results may be obtained rapidly on paper, it is to be expected that the designs will follow and check them. It is shown here how easily this may be done for a certain class of heads, also that some experimental check has been made. It is hoped that more will follow. It cannot, however, be said that "theory is ahead of practice" in this field since a simple fundamental method for the computation in manheads does not exist, nor even one for full heads beyond a certain thickness. As already mentioned in the paper good authorities, e.g., Höhn on the empirical side and Biezeno on the theoretical, do not agree that the 2 to 1 ellipsoid is the most desirable form. The author knows of no publications, either of theory or of experimental results, which demonstrate that such a ratio of diameter to depth is the best for full quasi-ellipsoidal heads. Höhn, for example, would not agree with this, but maintains that a shallower one is fully as satisfactory from the viewpoint of stress distribution, and more satisfactory from that of manufacture. As for manheads, there has been no demonstration that this ratio is the best. Experiment shows (Abhandlung 70 in the series referred to in footnote 8) that near the manhole flange there should be a zone which is concave outward. A theoretical discussion of the comparative merits of quasi-ellipsoidal and true ellipsoidal heads requires the investigation of the second set of discontinuity effects which are introduced at the junction of the knuckle and the spherical cap in the former, but are absent in the latter. These are of the same character as the local effects at the junction of head and cylinder, although smaller in good designs. A design could possibly be arranged in which these sets of local effects were opposed. Without a demonstration that the mathematical hypotheses are satisfied in the physical problem, such computation could not be conclusive. The question is an interesting one, of fundamental importance in settling the shape of the head, and also one for which theory will at least provide the design for a series of experiments. Concerning the location of the weld, it is again necessary to introduce experiment, as indicated in the paragraph just preceding the Appendix, p. 10, to determine if the value of M_0 is significantly different from the value zero, which this method gives. If such is the case, the position of zero moment is determined from Equation [7], with M_0 and Q_0 at their experimentally determined values (see the corrected curves in footnote 17). The reinforcing effect of the weld would affect this position for any value of M_0 other than zero. The amount of this reinforcing could be determined only by experiment. Some measurements are given in the work cited in footnotes 9 and 18.

With regard to the discussion by Mr. Kinzel it is perhaps in place to call attention again to the two pieces of work mentioned in the acknowledgment at the end of the Appendix. Both preceded the mentioned work of Huggenberger, although neither contains the extended experimental discussion found there. This paper seeks to give the theoretical side another presentation, and makes simplifications in the computation. The application of this method to a seven-arc head is, as suggested, not difficult; in the computation presented the elliptical meridian may be

[25] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[26] Research Assistant, Department of Engineering Research, University of Michigan, Ann Arbor, Mich. Jun. A.S.M.E.

thought of as a 14-arc one. As the number of arcs decreases, however, the question of the discontinuity effects at their junctions enters, as mentioned before for the meridian made up of two arcs.

The comparison of multi-arc heads and ellipsoidal ones is probably only a mathematical question, and one in which the manufacturer is hardly in position to distinguish one form from the other. The practical problem, as suggested by Mr. Westrom, is the comparison of the two-arc head (or maybe three-arc) with the ellipsoidal one. An important reason for not including a "most favorable form" computation in this paper is that the use of the method is not justified as the head becomes flat, and the limitations have not been established to show just how far up it may be used. Until this is done, it is questionable practice to use this method to compare the behavior of heads so alike in character as the ellipsoidal and the head built up on a multi-arc meridian, since the differences may very well be of the same order as the effects neglected in the method. It may be said that the discontinuity effects cannot be entirely removed at the junction of a cylinder with any full-dished head, entirely concave inward; however, they approach zero as the depth of the head becomes infinite. Even when not zero, they may be negligible in good designs. Thus, for the hemispherical head they are so small that the greatest resultant stress in the vessel occurs in the cylinder. As the head is made shallower, to approach the ellipsoidal shape of diameter twice the depth, the greatest resultant stress in cylinder and head approach each other. The rigorous establishing of a mathematically "most favorable form" in which they are equal is still outstanding, and the question is open whether it may be accomplished in a shallower head than that given by the 2 to 1 ellipsoid. Mathematically there is no advantage in thinking of the meridian as made up of parabolic arcs, and practically, for such short lengths as those taken, the distinction between arcs of a circle, ellipse, parabola, or torus is not realizable. As for a conical head, the method permits extension to give the discontinuity effects set up at the junction with the cylinder, provided the cone is not too flat. Another point to consider is that there is a meridional force to account for at the junction of a cone and a cylinder. The hope for a fundamental solution to the problem of the design of the head, after the form desired, will be realized most speedily by the use of existing theory and experimental methods in combination. The cases for which this has been done by Huggenberger, as mentioned by Mr. Kinzel and also in the paragraph preceding the Appendix, are for shells of the type $\frac{\text{thickness}}{\text{diameter}} \leqq 0.03$. Thicker shells, such as occur in high-pressure vessels, are still to be investigated; and there is small reason to expect that the approximate method (as by Geckeler, Huggenberger, or here) will give accuracy to within five per cent.

Professor Timoshenko's criticism of the derivation of Equation [10] is justified, and the presentation in the Appendix at the place mentioned is decidedly inadequate. The entrance of additional variables beyond those which enter in the case of the cylinder has been taken into account, however, although the derivation does not show this. After their order was found to be negligible, they were dropped off. The explanation for the omission of this discussion is that the author was too drastic in cutting out mathematics which he felt would be out of place in this paper. Instead of adding it here now, a more complete presentation will be given later, in which the question of the range of applicability of this method will also be discussed. This will give a more satisfactory presentation and avoid duplication in publishing.

There was some oral discussion as to experimental check of this method. It will be noted that the paragraph before the Appendix lists some such checks. The work mentioned by Mr. Everett represents another, and one which has not been published, as far as the author knows. It is of interest to get more than a qualitative check, since the question is practically settled from that viewpoint. As has been pointed out, quantitative results can be obtained with no injury to the vessels, and the design of heads can be worked into a settled question as soon as a sufficient number of these results are published.

Torsional-Vibration Dampers

By J. P. DEN HARTOG,[1] and J. ORMONDROYD,[2] EAST PITTSBURGH, PA.

In this paper the authors present a theory of the action of friction dampers on systems in torsional resonance, with special application to gas- and Diesel-engine installations. Model tests carried out to check this theory are described. The effect of introducing springs in the Lanchester damper is also discussed.

THE frictional-vibration damper—commonly known as the Lanchester damper—is used extensively on gas and Diesel engines to limit the amplitudes of critical torsional vibrations. The damper (Fig. 1) consists of two flywheels *a*, free to rotate about one end of the cranskhaft on bushings *b*, and driven by the crankshaft through friction rings *c*. The flywheels are pressed against the friction rings by means of loading springs and adjustable nuts *d*.

The purpose of the damper is to dissipate energy when the amplitude of vibration on the damper hub *e* tends to become large, as in the case of torsional resonance of the engine. When violent oscillations occur on the damper hub, the inertia of the flywheel prevents it from following the motion; the resultant relative motion between the hub and the flywheels gives rise to rubbing on the friction surfaces and a consequent loss of energy. When the oscillations on the hub are small, the flywheels stick to the friction rings, follow the motion of the hub, and no energy is dissipated. Thus the friction-driven flywheel possesses the valuable property of dissipating energy only when energy should be dissipated—that is, when the vibrations of the crankshaft threaten to become large.

It is clear that the most advantageous location of the damper on the engine is the place where the torsional-vibration amplitudes are largest. Since a gas or Diesel engine always carries a rather large flywheel of which the torsional-vibration amplitudes are small, the logical place for the damper is the end of the crankshaft away from the main flywheel.

Lanchester's patent considers only *viscous* friction as a means of driving the flywheel and dissipating energy. This limitation was probably suggested by the apparent ease of mathematical treatment, since viscous friction gives rise to forces simply proportional to the rubbing velocity. Although the mathematical analysis of the viscous-friction damper is simple, the practical difficulties inherent in its construction have always been so great that this type of friction is never used. All practical dampers known to the authors employ ordinary dry friction as the means of energy dissipation. So far as they know, no rational theory of the action of a dry-friction damper has yet been published. Dampers are just made—not designed.

The Energy Method of Calculating Effects of Friction Dampers

It is proposed to discuss the action of dry-friction dampers by means of the energy method. This method of calculating the effects of the damper depends on the fact that the energy put into the vibration by the variable gas pressures in the cylinders equals the energy dissipated by all the damping actions of the system. Wydler[3] was the first to discuss torsional resonance in Diesel engines by means of this method. He considered all the damping actions lumped into one single damping force which was proportional to the velocity. The equivalent constants of this assumed law he obtained empirically by measuring the amplitude of torsional vibration at resonance in several Diesel engines. Lewis[4] used the same methods, but assumed that the damping arose chiefly from the internal hysteresis of the crankshaft metal. He used Rowett's[5] experimentally de-

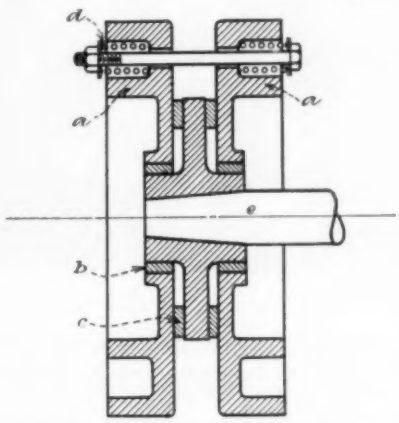

Fig. 1 Torsional Friction Damper

termined law of energy loss in mild steel under torsional stresses. These experiments show that the energy loss per unit volume per cycle is independent of the frequency and proportional to some power of the maximum shear stress existing during the cycle. Below the fatigue limit Lewis showed that the energy loss per unit volume per cycle W followed the simple law:

$$W = H\alpha_0^{2.3} \quad [1]$$

where H is a constant calculated from the test results and α_0 is the amplitude of twist in the test piece. Above the fatigue limit, α_0 must be raised to a higher power to express the results found in the experiment.

Assumptions Made in Applying Energy Method

In applying the energy method to the system of an engine with a friction damper the following assumptions are made:

1 The existence of sinusoidal vibrations in the crankshaft and 90-deg. phase relationship between impressed moments and resultant motions at resonance
2 The dissipation of all vibrational energy in the friction damper and in the metallic hysteresis of the crankshaft
3 The existence of Coulomb friction in the damper.

The first assumption of approximately sinusoidal motion is justified by numerous records of vibration at resonance which always show almost pure sinusoidal motion. The assumption

of a 90-deg. phase relationship between the oscillating moments and the motions they cause is used in calculating the input energy. It can be shown that this leads to accurate values of damping losses in the case of damping forces which are proportional to velocity, even when the maximum amplitudes occur with the phase angle far from 90 deg. For the case of a damping force which leads to the law that the energy loss per unit volume per cycle is proportional to the square of the maxi-

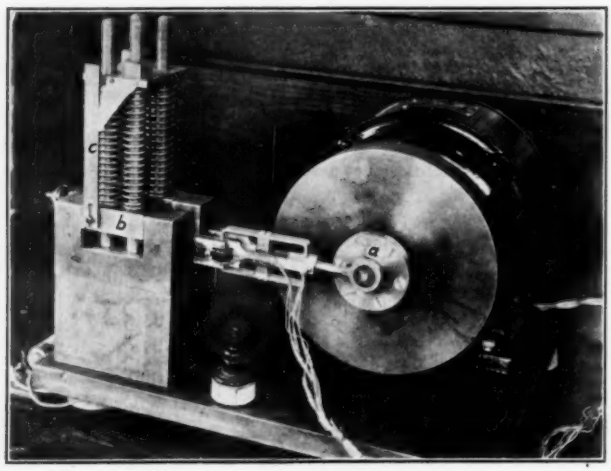

FIG. 2 FRICTION TESTING DEVICE

mum stress, the phase angle *is* always 90 deg. at resonance.[6] For the authors' case the experimental results will have to justify its use.

The second assumption indicates that the presence of all friction, windage, and impact dampings which may be effective in limiting torsional vibration are being neglected. The laws of these dampings are not known, and it appears that experimental facts can be explained without assuming their existence.

The third assumption has been found to be true with a high degree of accuracy by means of a series of tests, which will now be described.

TESTS SHOWING EXISTENCE OF COULOMB DAMPING

A variable-speed motor (Fig. 2) carrying a fairly heavy flywheel was made to drive a small, light table (2 sq. in. in area) back and forth by means of an $^1/_8$-in. eccentric *a*. The table was lined with the kind of brake lining commonly used in dampers, and any desired pressure up to 100 lb. per sq. in. could be exerted on it by means of a pressure plate *b* and four calibrated springs *c*. The table was coupled to the eccentric by means of a connecting rod on which two magnetic extensometers were mounted. These extensometers were fed with 500-cycle current and were connected in a Wheatstone-bridge circuit with an oscillograph. The amplitude of the 500-cycle wave recorded in the oscillograph varies linearly with the widths of the air gaps in the extensometers, so that a record is obtained of the changes in length of the connecting rod. In order to translate this into stress, a calibration was carried out as shown in Fig. 3. The table *a* was taken from between the pressure plates, swung aside, and loaded with a dead weight *b* by means of a pulley *c*. The reading thus obtained in the oscillograph made it possible to read the records directly in terms of the force in the connecting rod.

Fig. 4 shows a typical record thus taken. It is seen to have a practically flat top and bottom, so that Coulomb's law of a friction independent of the velocity actually holds for the conditions in the damper. The curvature of the vertical sides of the diagram can be explained by elasticity in the connecting rod and in the shaft and bearings of the driving motor. In case this flexibility were zero the vertical sides should theoretically be straight lines, while with the elasticity they should be parabolic arcs. The theoretical parabolas have been completed on the record by dotted lines.

Viscous friction would have given a sine curve instead of one with flat tops and bottoms. The presence of oil, even of a bath of oil, with the ordinary pressures of about 30 lb. per sq. in. did not alter the shape of the curve, but merely decreased its height, i.e., decreased the "coefficient of friction." Only with an oil bath and a pressure as low as 5 lb. per sq. in. was it possible

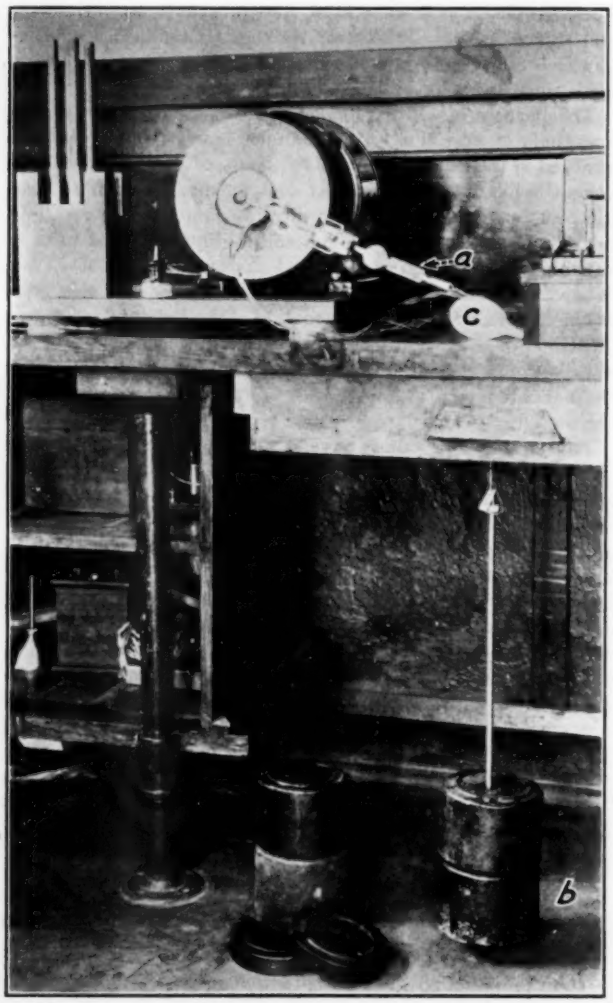

FIG. 3 METHOD OF CALIBRATING

to obtain an approximately sinusoidal diagram. The fact that it was actually possible to get this diagram with such low stresses in the connecting rod shows conclusively that the flat tops of the Coulomb damping diagram are not caused by any mechanical hysteresis or binding in the connecting rod or extensometers. It may also be mentioned that the stresses in the rod were of the order of 100 times the stresses caused by the dynamical effect of the table, which fact was also checked experimentally.

[6] See Kimball and Lovell, *Mechanical Engineering*, May, 1927, p. 440.

The data obtained for the coefficients of friction in the various tests show that for each particular surface condition Coulomb's law holds fairly well, but that there is an enormous variation in the coefficient for various surface conditions. In other words, once the machine was running, changes in pressure hardly affected the coefficient of friction (there was a tendency for a decrease in f for increasing pressure); neither did changes in the running speed of the motor have any appreciable effect (the tendency being to increase f with the speed). The influence of the condition of the surface is best illustrated by the following history of a series of tests:

1 Freshly cleaned and sandpapered surface.... f = 50 per cent
2 The same surface after being exposed to the atmosphere (Pittsburgh) for two months... f = 40 per cent
3 Oil just put on surface..... f = 18 per cent
4 Oil soaked in overnight..... f = 15 per cent
5 Soaked in gasoline for one hour..... f = 21 per cent
6 Sandpapered..... f = 27 per cent

The temperature also has an appreciable effect as shown by the following test. At room temperature f was found for a clean dry surface to be 42 per cent. The pressure plates and table were then heated to about 60 deg. cent. by a gas flame, which decreased f to 30 per cent. Immediately thereupon a fan was turned on the machine, cooling it down to room temperature in about five minutes, when f became 39.5 per cent.

On actual engine dampers the surfaces are always found to be more or less greasy and hot, so that for design purposes a coefficient of friction of not higher than 15 per cent should be taken.

In general, these tests have shown that the assumption of Coulomb friction in the damper is well justified.

The System to Be Analyzed

Since in nearly all practical cases of torsional resonance in gas or Diesel engines it is only the lowest natural frequency of the system which is dangerous, the system can be represented in the simplified form shown in Fig. 5.

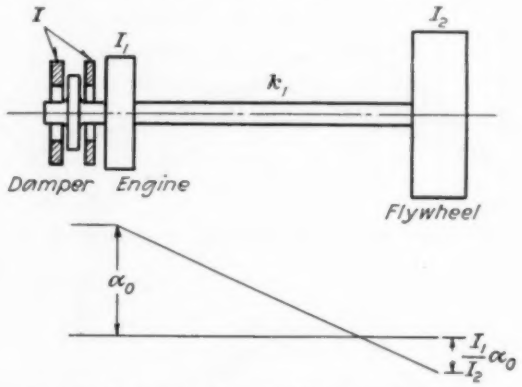

Fig. 5 Simplified System Used for Analysis

the total moment of inertia of all the slipping parts of the friction damper.

One Harmonic Torque Acting on Engine

At resonance the effects of all the harmonic gas-pressure torques except the one in synchronism with the natural frequency are negligible. Therefore, we can consider a single simple harmonic torque as acting on the engine.

Let this torque be

$$M = M_0 \sin \omega t \quad [2]$$

where $\omega = 2\pi$ times the natural frequency of the system. For methods of calculating the value of M_0, see Lewis' paper.[4] This moment gives rise to an oscillation in the system in which I_1 and I_2 have the relative amplitudes at resonance shown in the diagram of Fig. 5. Let the motion of I_1 be

$$\alpha = \alpha_0 \sin (\omega t - \varphi) \quad [3]$$

This is also the motion of the damper hub in the simplified scheme of Fig. 5. When α_0 is known, the motions and stresses in the whole system are known.

M is superimposed on the constant average working torque of the engine, and α is superimposed on the steady rotation of the engine.

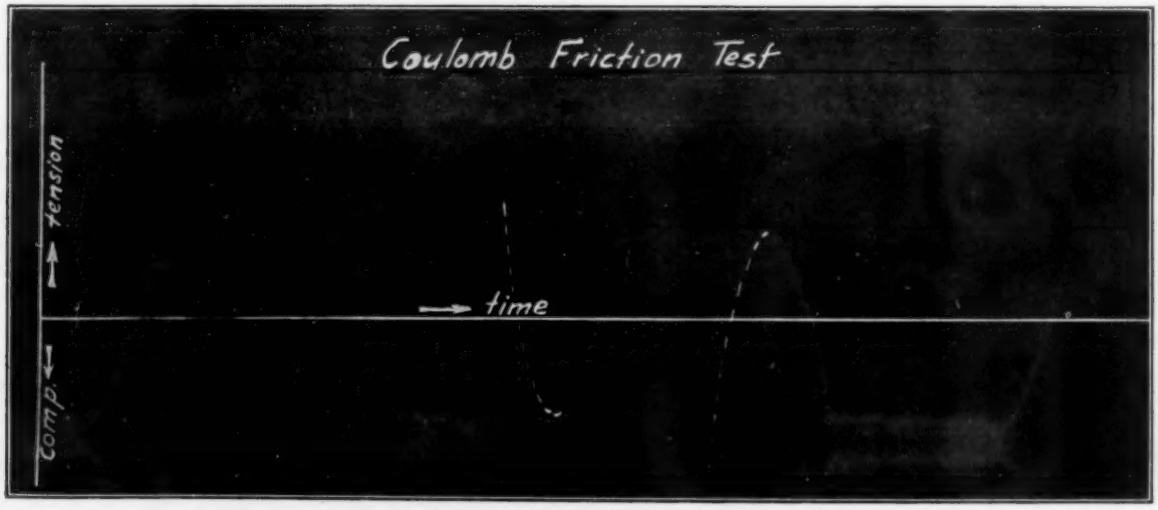

Fig. 4 Oscillogram Showing Coulomb Friction

Here I_1 represents the moment of inertia of the rotating and reciprocating parts of the gas or Diesel engine; I_2 the moment of inertia of a flywheel or electrical generator driven by the engine; k_1 the torsional stiffness of the shaft (torque units per radian twist) connecting the engine and the flywheel; and I

Energy Put Into Vibration per Cycle

Let W = work per cycle put into the vibration by M. Then

$$W = \int_0^{\frac{2\pi}{\omega}} M d\alpha = \pi M_0 \alpha_0 \sin \varphi \quad [4]$$

M and α are given as functions of the time in [2] and [3] and $2\pi/\omega$ is the period of one complete cycle. At resonance φ = 90 deg. according to the first assumption made, and the work per cycle is

$$W = \pi M_0 \alpha_0 \quad [5]$$

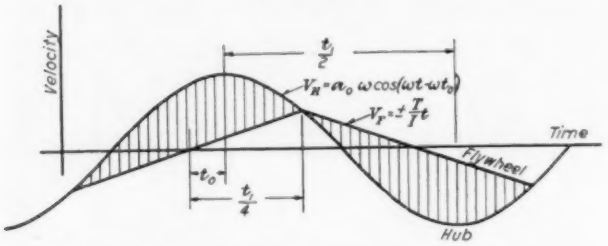

Fig. 6(*a*) Continuous Slipping of Flywheel

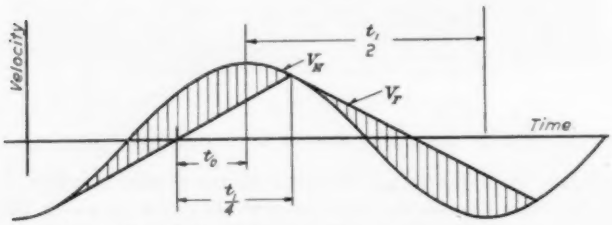

Fig. 6(*b*) Limit of Continuous Slip

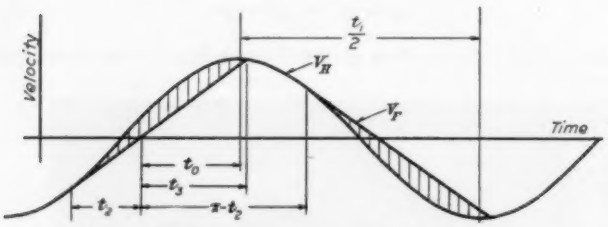

Fig. 6(*c*) Partial Slip

Friction Torque in Damper

In calculating the energy lost in the damper it is necessary to know the torque T required to slip the damper flywheels on the friction rings. This torque is

$$T = 2fF \frac{2}{3} \frac{R_2^3 - R_1^3}{R_2^2 - R_1^2} = 2fFR \quad [6]$$

where f = coefficient of friction on friction rings
$F = nkd$ = total load on friction surfaces
n = number of loading springs
k = stiffness of loading springs (lb. per in. deflection)
d = deflection or set-up of loading springs
R_1 = inner radius of friction ring
R_2 = outer radius of friction ring
R = radius at which the total friction force can be considered as concentrated.

Equation [6] is based on the assumption of a uniform distribution of pressure over the surfaces of the friction rings. Because of variations in the pressure distribution which commonly occur in some practical designs, R may vary considerably from the value as found in Equation [6].

First Approximation to Damper Action

If we assume that the damper flywheels are so heavy that they rotate uniformly at the average angular velocity of the crankshaft, the angular oscillation of the damper hub is the relative oscillation between the hub and the flywheel. The work done against friction for every cycle is

$$W = 4T\alpha_0 \quad [7]$$

If this work is equated to the input work given in Equation [5], it can be verified that the value of α_0 becomes infinite for $T/M_0 < \pi/4$ and zero for $T/M_0 > \pi/4$, which obviously is physically impossible.

To overcome this difficulty, J. Dickson, of the William Beardmore Co., Glasgow, Scotland, proposed to consider the friction damper in conjunction with the shaft-hysteresis damping as used by Lewis[4] and given in Equation [1]. This leads to the energy equation

$$\pi M_0 \alpha_0 = 4T\alpha_0 + H\alpha_0^{2.3} \quad [8]$$

Here H must be considered as a constant obtained by using Rowett's experimental results and integrating over the whole crankshaft.

Solving [8] leads to

$$\alpha_0 = \sqrt[1.3]{\frac{\pi M_0 - 4T}{H}} \quad [9]$$

This approximate solution is not satisfactory in many respects. It gives no method of proportioning the damper in advance. This is natural since it is based on the assumption that the damper flywheel is "heavy." Next it leads to the result that $\alpha_0 = 0$ when $T = \frac{\pi}{4} M_0$, and furthermore no real solution for α_0 exists for $T > \frac{\pi}{4} M_0$. This does not coincide with observations on engines equipped with dampers, which show that α_0 never becomes zero, no matter how large T is made.

These difficulties led to a closer study of the action of the damper.

Actual Motions of Flywheel in Friction Damper

Under steady conditions the damper flywheel will be rotating with an average angular velocity equal to the average angular velocity of the crankshaft. Superimposed on this motion it will have a motion relative to the oscillating hub. This motion will be periodic in nature and its frequency will be the same as the hub oscillation frequency. There are three possible types of motion for the damper flywheel:

1 If the acceleration of the damper hub is always less in value than T/I the flywheel never slips but follows the motion of the hub completely
2 The damper flywheel may slip continuously
3 The flywheel may follow the motion of the hub during part of the cycle and slip during the rest of it.

These three possibilities can best be understood by an inspection of the velocity diagrams of Fig. 6. During the slipping phase of the flywheel motion it is acted upon by a constant friction torque. Therefore, from Newton's law of motion the angular velocity of the flywheel must be a straight-line function of time. Due to the fact that the hub motion follows a symmetrical law, the damper-flywheel motion must also be sym-

metrical. These conditions can be met only in the manner shown in Fig. 6(*a*). The velocity of the flywheel increases when the hub velocity is greater and decreases when the hub velocity is less than the flywheel velocity. The slope of the flywheel velocity curve is equal to T/I. As the damper loading springs are tightened up the flywheel velocity curve becomes steeper. If the damper hub has a fixed amplitude independent of the damper torque the velocity curves of the hub and the flywheel finally cross at points where their slopes are equal as shown in Fig. 6(*b*). This represents the limit of damper torque below which slipping occurs continuously. If the damper torque is increased further the flywheel clings to the hub until the acceleration of the hub is large enough to shake it loose as shown in Fig. 6(*c*).

Work per Cycle Done in Friction Damper

In Appendix No. 1 it is shown that the work per cycle done against friction in the damper is equal to the friction torque T multiplied by the total shaded area of Fig. 6. For a given constant motion of the damper hub, the work per cycle W thus calculated is shown as a function of the friction torque T in the curve of Fig. 7. The ordinates of this curve are not W and T themselves, but values proportional to those quantities; in fact, they are W and T multiplied by combinations of the characteristic constants of the damper flywheel and the hub motion. This has the advantage of making the relationship in Fig. 7 dimensionless and therefore applicable to any system where I, ω, and α_0 are known. The curve in Fig. 7 indicates that the work per

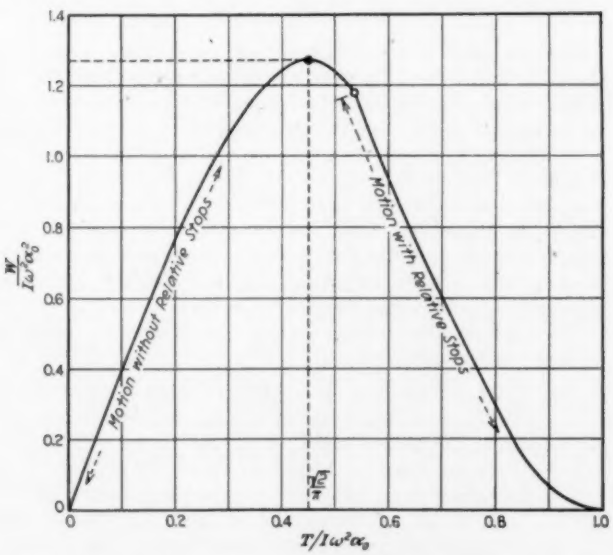

Fig. 7 Work Absorbed in Damper Vs. Friction Torque

cycle absorbed in the damper is zero when the damper torque is zero, and again when the flywheel is following the hub motion completely—that is, when the damper is a solid part of the engine. At some intermediate value of T the work absorbed reaches a maximum. Designers, of course, are interested in obtaining the maximum amount of energy dissipation out of any damper they may build. From Fig. 7 it can be seen that

$$W_{max} = \frac{4}{\pi} I\omega^2\alpha_0^2 \quad [10]$$

when

$$T = \frac{\sqrt{2}}{\pi} I\omega^2\alpha_0 \quad [11]$$

Having an expression for the work absorption in the damper, we can calculate α_0 by equating the energies [7] and [10]:

$$\pi M_0\alpha_0 = \frac{4}{\pi} I\omega^2\alpha_0^2 \quad [12]$$

Solving for α_0,

$$\alpha_{0_{min}} = \left(\frac{\pi}{2}\right)^2 \frac{M_0}{I\omega^2} \quad [13]$$

and

$$T = \sqrt{2}\,\frac{\pi}{4} M_0 \quad [14]$$

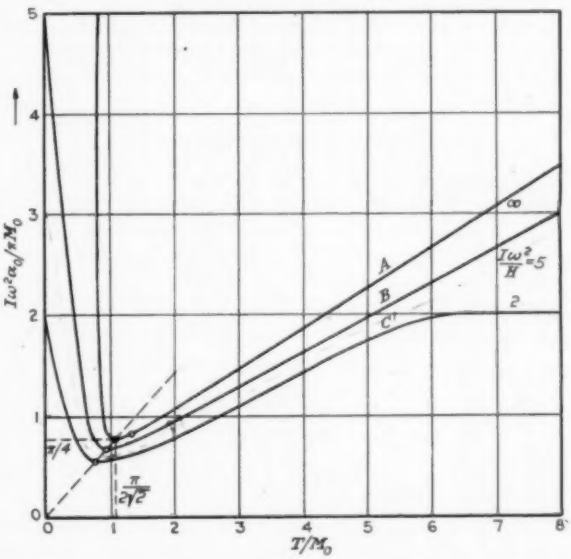

Fig. 8 Resonant Amplitude of Vibration Vs. Friction Torque on Damper

Equations [13] and [14] give the chief design data for any damper when M_0 is known. The amplitude α_0 at resonance will be chosen such that the stresses in the shaft between I_1 and I_2 (Fig. 5) will be below the fatigue limit. The value of α_0 desired determines the magnitude of I when M_0 and ω are the given data. A simple design rule to follow is to limit α_0 to such a value that the maximum oscillating stress is about 10 or 12 per cent of the ultimate tensile strength of the crankshaft steel. This follows from the facts that in most steels the ultimate strength in torsion is about half the ultimate strength in tension; that the fatigue limit in torsion is again about half the ultimate strength in torsion; and that oil holes and abrupt changes of section at the crank cheeks may give rise to stress concentration which may easily double the nominal calculated stress. This chain of facts leads to the simple rule quoted above.

Influence of Shaft Hysteresis Damping

All existing test data on hysteresis losses in steels can be described with fair accuracy for *low* stresses by the law[4]

$$W = H\alpha_0^2 \quad [15]$$

This law is a good approximation where the maximum stresses are below the fatigue limit. Therefore we can consider it to hold when a properly designed and adjusted damper is applied to an engine. The value of H is determined from the experimental curve on the crankshaft steel and an integration over the whole volume of the shaft. Considering hysteresis, Equation [12] becomes

$$\pi M_0 \alpha_0 = \frac{4}{\pi} I\omega^2 \alpha_0^2 + H\alpha_0^2 \quad [16]$$

and

$$\alpha_{0_{\min}} = \left(\frac{\pi}{2}\right)^2 \frac{M_0}{I\omega^2}\left(\frac{1}{1+\frac{\pi H}{4I\omega^2}}\right) \quad [17]$$

$$T = \sqrt{2}\,\frac{\pi}{4} M_0 \left(\frac{1}{1+\frac{\pi H}{4I\omega^2}}\right) \quad [18]$$

In most gas or Diesel engines the hysteresis will give very little assistance to a properly designed damper, set at its optimum torque—it will decrease the amplitude of motion at resonance to about 85 per cent of the value at which the friction damper alone would hold it.

Effect of Variation of Damper Torque

The amplitude of motion at resonance α_0 depends on the damper torque T. This is discussed in Appendix No. 1, sections C and D, while the results of the analysis are shown in Fig. 8. As in Fig. 7, the ordinates of Fig. 8 are dimensionless quantities, making the diagram applicable to any system.

The action of the damper alone, neglecting shaft hysteresis, is shown in curve A, indicating that the damper is completely ineffective until $\frac{T}{M_0} > \frac{\pi}{4}$. At $T = \sqrt{2}\,\frac{\pi}{4} M_0$, the amplitude of motion has its minimum value

$$\alpha_{0_{\min}} = \left(\frac{\pi}{2}\right)^2 \frac{M_0}{I\omega^2}$$

These results are the same as given in Equations [13] and [14] in the earlier part of the paper. As T approaches infinity, the values of $I\omega^2\alpha_0/\pi M_0$ approach infinity also. Physically this means that the amplitude of motion increases until the accelerations are large enough to shake the damper loose, no matter how large T is made.

Curve A, Fig. 8, indicates that if the damper torque is slightly less than the optimum value the damper becomes ineffective; but if the torque is made larger than the optimum value the resonant amplitude increases only slightly over the minimum possible value. In other words, the damper can easily be set too loosely; but it is rather insensitive to overtightening. This is the saving feature which has made it possible to build dampers without designing them. In the hands of a practical man, a damper is more likely to be set too tight than too loose.

Effect of Damper Torque Variation With Combined Damping

In any real system to which a damper may be attached, other types of damping always exist. This is shown by the fact that finite amplitudes of motion always occur in real systems at resonance, even when no damper is used. The largest natural damping existing in a system as shown in Fig. 5 is due to the metallic hysteresis of the shaft material under varying stresses.

For ease of discussion it was assumed in Appendix No. 1 that the hysteresis loss in the shaft followed the simple law $W = H\alpha_0^2$. Under this assumption curves B and C in Fig. 8 were drawn for values of $I\omega^2/H = 2$ and 5. The meaning of this ratio $I\omega^2/H$ is $\pi/4$ times the ratio of the damper work absorption to the shaft-hysteresis work absorption, as can be seen from Equations [10] and [15].

The simple law of hysteresis loss actually only holds for stresses below the fatigue limit. However, the hysteresis loss increases very rapidly for stresses above the fatigue limit, so that there the simple law assumed does not hold. For this reason the curves B and C of Fig. 8 only represent the action of combined damping qualitatively for amplitudes where high stresses exist. The actual curve for any given system can be constructed graphically by using the real hysteresis-loss curve. In real systems where hysteresis damping acts by itself, the amplitude of motion at resonance is usually so large that the maximum stresses in the system are far above the fatigue limit. For this reason a simple law of hysteresis loss as assumed above (or the one used by Lewis) cannot be used in predicting amplitudes at resonance. For instance, Porter,[7] using the law of hysteresis deduced by Lewis from Rowett's tests for *low stresses* in *mild* steel, calculates resonant amplitudes which are much larger than the actual values observed in the engines tested by him. Much more energy was lost than the simple law could predict; and Porter's results would have been off even further if the law he used had been deduced from tests on actual crankshaft steel, since Föppl[8] has shown that the hysteresis loss in crankshaft steels is much less for a given stress than in ordinary mild steel.

From this it can be seen that curves B and C of Fig. 8 are quantitatively accurate only near the minimum values of $I\omega^2\alpha_0/\pi M_0$; for higher values the curves give only a qualitative description of the effect of combined damping. They show that the resonant amplitudes always remain finite and that the amplitude increases much faster for damper torques less than the optimum value than for damper torques larger than this value.

Field Experience

Field experience with dampers indicates that they "run away" or fail to function when the damper torque becomes too small. What is more, it has been found that the damper torque varies up and down even at one setting of the loading springs. If the damper is supposedly set at the optimum torque, a variation below that torque may let the damper "run away," while a variation above it will have little effect. Curve B, Fig. 8, represents about the conditions in most real engines. The ratio of the slopes of the two sides of the curve is about 14:1, showing the relative danger of too little damper torque as against too much damper torque.

There are several practical reasons why damper torques may become smaller than expected:

1 If the optimum torque is set by calculation, the assumed value of the coefficient of friction may be taken larger than the actual value

2 If the coefficient of friction is known for ordinary temperatures it may become small as the damper heats up (see results of friction tests, ante). If the damper torque is set by experiment with the damper at ordinary temperatures, it becomes smaller as the damper heats up

3 If the surfaces of the friction rings are not perfectly true, the rings may "ride" near the inner radius or near the outer radius. In some designs this might make a difference of 50 per cent between the maximum torque and the minimum torque. A variation this large could easily account for the failure of a damper to operate properly, and variations of this magnitude have been found in practice

4 If a damper is designed by means of the approximate formula [8], the damper torque is always made at least

[7] F. P. Porter, Trans. A.S.M.E., vol. 50 (1928), no. 17, paper no. APM-50-8.

[8] O. Föppl, *Z.V.D.I.*, Sept. 15, 1928.

30 per cent less than the optimum value and the system depends on hysteresis or other accidental damping for success

5 Oil frequently gets into the damper friction surfaces

6 Any accidental obstruction which keeps the friction surfaces separated or which hinders the free rotation of the damper flywheels will tend to make the damper fail

7 If the loading springs are very stiff, wear in the friction rings drops the torque rapidly.

A safe operating rule is to set the damper torque cold to somewhat above the optimum value. From Fig. 8, it can be seen that this does not lead to much larger amplitudes than the minimum, and it safeguards the damper against any decrease in torque which may reasonably arise in practice.

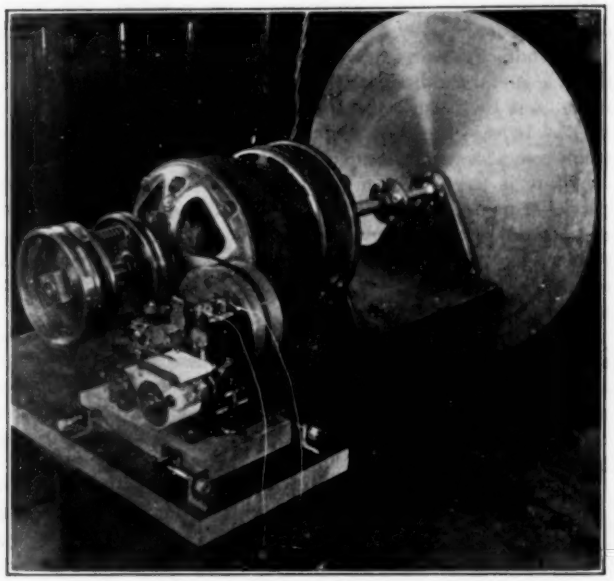

FIG. 9 MODEL USED FOR TESTS

A safe design rule is to assume the coefficients of friction to be 0.15 or less. The actual value of the coefficient of friction does not affect the damper-flywheel design, but it does determine the loading spring design. The smaller the coefficient of friction the larger the spring load required for a given torque.

How will a damper designed for a certain oscillating frequency operate at some other frequency? The question has no practical significance for lower frequencies than the design frequency, since the latter is usually the lowest natural frequency of the system to which the damper is attached.

Higher frequencies (second or third natural frequencies of the system) usually are not dangerous even without a damper, because the relative displacements in the shaft are so large that hysteresis alone is quite sufficient to keep the amplitudes within safe limits. However, if they ever become dangerous it is seen from the expression on the vertical ordinates of Fig. 8, that the damper is even more effective at high frequencies than at low ones.

MODEL TESTS

In order to test the accuracy of the theory given above, a model, Fig. 9, was built. It consisted of a single-phase induction motor, coupled on one side to a flywheel and having a damper mounted on the other side.

The instantaneous power input into a single-phase motor is:

$$[e \sin \omega t][i \sin (\omega t + \varphi)]$$

which expression can be transformed into

$$\frac{ei}{2} \cos \varphi - \frac{ei}{2} \cos (2\omega t + \varphi)$$

The power input consists of a constant part and of a variable part with a frequency equal to twice that of the line voltage. The amplitude of the power input variation is $ei/2$, or EI watts, that is, the product of the readings of a voltmeter and an ammeter. In case all this power is converted to torque, the amplitude of the torque variation can be found to be[9]

$$\frac{7.14EI}{\text{r.p.m.}} \text{ ft-lb.}$$

With the assumption that 10 per cent of this power input goes into losses, we finally find:

$$\pi M = \frac{240\ EI}{\text{r.p.m.}} \text{ in-lb} \qquad [19]$$

The input torque was determined by means of this formula.

The angular oscillations of the shaft near the damper hub were measured by means of a torsiograph.[10] Tests were carried out with three different damper flywheels with moments of inertia of 0.12, 0.27, and 0.42 lb-in-sec.^{2}, respectively.

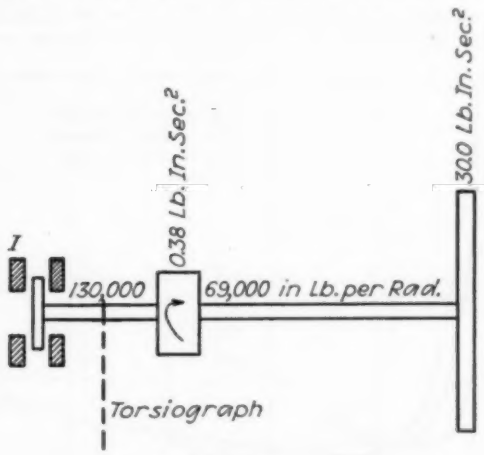

FIG. 10 MODEL CHARACTERISTICS

The test procedure was as follows: The loading springs were set to a certain pressure and the friction torque on the damper was measured by means of a spring scale, while turning the apparatus over very slowly by hand. Then the machine was run, varying the frequency of the input and consequently the speed until the resonance point was found, where a record and the various meter readings were taken. The machine was then stopped in order to reset the loading springs for the next run.

It was found that in case the damper was either entirely loose or fully locked, the critical speed was distinct and could be determined with good accuracy. When the damper was working near its optimum point, however, there was really no "critical speed," the amplitude being almost constant over quite a broad speed range.

It is evident that the critical speed of the machine without

[9] For a more fundamental treatment, see the paper by Kimball and Alger, Trans. A.I.E.E., 1924, p. 730.

[10] Ormondroyd, Trans. A.I.E.E., 1926, p. 443.

damper is higher than the one with the damper locked on. (See Fig. 10.) In fact, in the authors' set-up the variations were rather large; the experiment gave the following values:

From 500 r.p.m. to 435 r.p.m. with the light damper
From 500 r.p.m. to 340 r.p.m. with the medium damper
From 500 r.p.m. to 318 r.p.m. with the heavy damper.

The change from the high critical speed to the lower one as a function of the tightening of the loading springs took place in a highly interesting manner. For any pressure below the optimum the critical speed was equal to the *upper* one, that is, to the one without any damper. In the neighborhood of the optimum point the critical speed became indeterminate as described above, while for pressures distinctly higher than the optimum the critical speed was equal to the *lower* one practically independent of the degree of tightening. The behavior below the optimum pressure may be regarded as an experimental verification of the theoretical result that Coulomb damping in a vibrating system does not affect the critical speed, provided the damping be not so large that partial stops occur in the motion. (See Appendix No. 2.)

On account of the flexibility between the rotor and the damper the angles measured at the torsiograph are not exactly equal to the ones on the damper hub; neither is the work input per cycle equal to α_0 times the expression [19]. To both quantities a suitable correction was applied. The observed data, reduced to a dimensionless form, have been plotted in Fig. 11.

A comparison with Fig. 8 shows that the general shape of the curves obtained corresponds to the requirements of the theory. However, it appears that the experimental curves are considerably lower than the theory predicts. This may be due to any of the following causes.

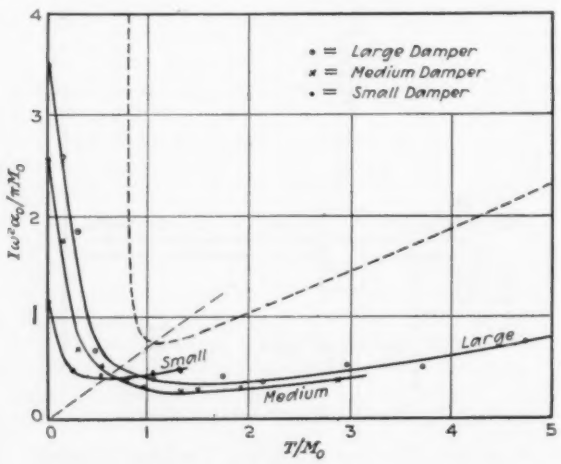

FIG. 11 TEST RESULTS

a Uncertainty in the determination of the electrical input torque
b The existence of additional damping in the system, apart from the friction damper
c Inherent inaccuracy of the three assumptions on which the theory is based.

At the present it cannot be decided yet which of these, or possibly other, factors is the cause of the numerical discrepancy. Additional tests on a yet simpler model are now in course of progress.

It must be remarked, however, that these tests indicate that the damper is approximately twice as effective as the theory predicts, and that a design by means of the formulas [13] and [14] should lead to entirely satisfactory results.

THE DAMPER WITH SPRINGS

It may be possible in certain cases to improve on the design of the damper by coupling its flywheel to the shaft not only by friction but also by some torsional spring. This adds an extra degree of freedom to the system, and consequently adds one more natural frequency to it. In cases where the damper inertia is rather small with respect to the rest of the system, the original critical speeds will not be appreciably altered by the addition of the damper, while the additional critical speed will be nearly equal to that of the damper itself.

With the same three assumptions made before, the work absorbed per cycle by the damper friction has been calculated in Appendix No. 2 and the results are shown in Fig. 12. In this figure ω is still the frequency of the motion of the damper hub, while ω_n is the natural frequency of the damper considered by itself. In case $\omega_n = 0$; that is, for a springless damper, the result coincides with the one of Fig. 7. For the general case that $\omega_n \neq 0$, it has not been possible to obtain a solution where partial gripping occurs [see Fig. 6(*c*)]. However, this limitation is not serious, for we know that all the curves of Fig. 12 have to pass through the point $T/I\alpha_0\omega^2 = 1$, since there the damper is entirely locked. This determines the general trend of the curves also in the region of partial stops.

The graph indicates that by the application of springs a considerably greater amount of energy can be dissipated by a damper of a given size. This increase is obtained on account of the greater relative motion between the damper flywheel and the hub. The limitations of this design, therefore, are the stresses in the springs.

By equating the dissipated and the input energies, an equation is found in Appendix No. 2 from which the angle α_0 can be solved in the same manner as before. This leads to the results shown in Fig. 13, which again coincides with Fig. 8 for the case that $\omega_n = 0$. It is seen that the optimum angle for a given size of damper can be considerably reduced by means of the springs. In fact, theoretically the optimum angle α_0 becomes zero for $\omega = \omega_{n1}$, that is, for a damper in resonance with the forced frequency of the system (dynamic vibration absorber).[11] However, this means a great relative displacement between the damper flywheel and its hub, which would break the damper springs. The stress in the damper springs is determined by the amplitude θ_0 of the relative motion between the damper flywheel and hub. This amplitude is calculated in Appendix No. 2, the results being shown in Fig. 14. It is seen that the stress becomes larger the nearer to its natural frequency the damper is operated. Since the efficacy of the springs increases in the same manner, the design of the damper becomes a matter of compromise. If possible, the natural frequency of the damper should be kept outside the running range. If this is not practicable, a good expedient is the application of motion-limiting stops. For instance, if a gas engine has to be designed for a speed range of from 500 to 1200 r.p.m. and it appears that the main critical speed is around 800 r.p.m., the first thing to attempt is to shift this critical out of the running range by altering the flexibility of the shafts. Quite often this is not possible. Then a damper might be designed with a resonance corresponding to an engine speed of 640 r.p.m. This damper becomes quite light, as can be seen from the relations in the Figs. 12 and 13. If no precautions are taken, however, the damper will be destroyed when the engine is operated near 640 r.p.m. Therefore stops should be provided,

[11] See paper by the authors, Trans. A.S.M.E., 1928, paper no. APM-50-7.

restricting the play of the damper flywheel to an amount insuring the safety of its springs. These stops will be idle in the entire range, except near 640 r.p.m. At that speed, however, the engine is safe by itself and does not need any damper.

It has to be remarked that the theory of the damper with springs as given here has not yet had an experimental verification as far as we know.

Summary and Conclusions

1 A theory has been given of the Lanchester friction damper as applied particularly to gas- or Diesel-engine installations.

2 Tests have been conducted on a model, which as a whole backed up the theory. The damper works somewhat better than the theory states.

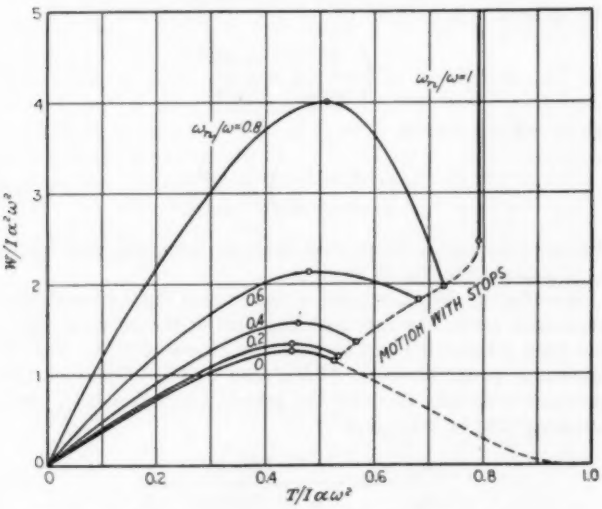

Fig. 12 Work Dissipation in Damper With Springs

3 A possible improvement of the damper, due to the insertion of springs, is discussed, showing that the same effect can be obtained with a damper of much smaller size as when no springs were present.

Appendix No. 1

THEORY OF THE DAMPER WITHOUT SPRINGS

A—Energy Dissipation in Damper

Let W = work done against friction during one cycle of hub motion
v_f = instantaneous "superimposed" angular velocity of damper flywheel
v_h = instantaneous "superimposed" angular velocity of damper hub
$\alpha = \alpha_0 \sin \omega t$ = angular motion of damper hub
ω = 2π times the frequency of damper-hub motion
t = time
$t_1 = 2\pi/\omega$ = period of damper-hub motion
T = torque necessary to slip damper flywheel on friction rings
I = total moment of inertia of the damper flywheels, and
θ = relative angular displacement between damper hub and flywheel.

Then the work done against the friction of the damper during one cycle of the hub motion is:

$$W = \int T d\theta = \int_0^{2\pi/\omega} T \frac{d\theta}{dt} dt = \int_0^{2\pi/\omega} T(v_h - v_f)dt$$

$$= 2T \int_{-\pi/2\omega}^{\pi/2\omega} (v_h - v_f)dt \quad [20]$$

or W is $2T$ times the shaded area in Fig. 6(*a*), 6(*b*), or 6(*c*).

This area will now be calculated. Considering Fig. 6(*a*), 6(*b*), or 6(*c*), the time is taken as zero at the instant the flywheel superimposed velocity is zero and about to become positive, or, more accurately, at the instant the flywheel velocity is equal to its average velocity and about to become greater.

We have

$$v_f = \pm \frac{T}{I} t \quad [21]$$

in which the signs depend on the position in the cycle.

$$v_h = \alpha_0 \omega \cos(\omega t - \omega t_0) \quad [22]$$

These formulas are perfectly general. The further analysis, however, becomes different for the cases of Figs. 6(*a*) and 6(*c*). First calculate the case of continuous slipping [Fig. 6(*a*)]. The time t_0 can be determined from the consideration that $v_f = v_h$ when $t = \pm t_1/4$, or

$$\frac{T}{I}\frac{2\pi}{4\omega} = \alpha_0 \omega \cos\left(\frac{\pi}{2} - \omega t_0\right)$$

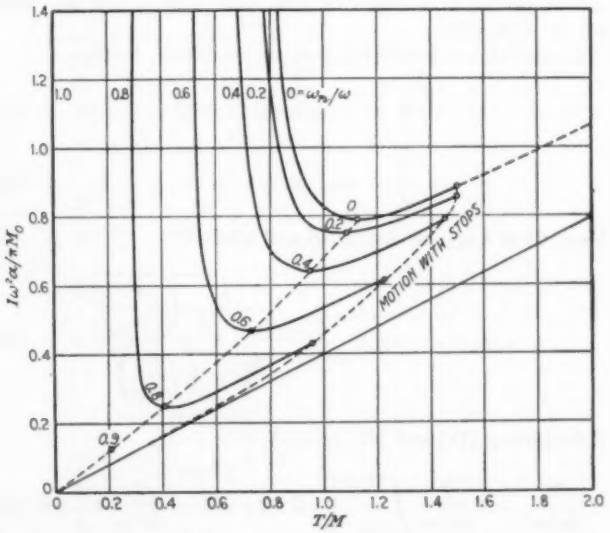

Fig. 13 Amplitudes Vs. Friction Torque for Spring Damper

Solving this for t_0,

$$\sin \omega t_0 = \frac{\pi}{2}\frac{T}{I\omega^2\alpha_0} \quad [23]$$

Substituting [21] and [22] in [20], performing the integration and using the result [23],

$$W = 4T\alpha_0 \sqrt{1 - \left(\frac{\pi}{2}\right)^2 \left(\frac{T}{I\omega^2\alpha_0}\right)^2} \quad [24]$$

which can be written conveniently in the following dimensionless form:

$$\frac{W}{I\omega^2\alpha_0^2} = 4\frac{T}{I\omega^2\alpha_0} \sqrt{1 - \left(\frac{\pi}{2}\right)^2 \left(\frac{T}{I\omega^2\alpha_0}\right)^2} \quad [25]$$

Equations [23], [24], and [25] hold only when

$$\frac{dv_f}{dt} \leqslant \frac{dv_h}{dt} \text{ at } t = t_1/4$$

which is sufficiently clear from the Figs. 6(*a*) and 6(*b*). The limit to which the equations are true [Fig. 6(*b*)] is therefore given by the condition

$$\left(\frac{dv_f}{dt}\right)_{t=\frac{\pi}{2\omega}} = \left(\frac{dv_h}{dt}\right)_{t=\frac{\pi}{2\omega}}$$

Substituting [21] and [22] in this,

$$\frac{T}{I} = \alpha_0\omega^2 \sin\left[\frac{\pi}{2} - \sin^{-1}\frac{\pi}{2}\frac{T}{I\omega^2\alpha_0}\right]$$

or

$$\frac{T}{I\omega^2\alpha_0} = \sqrt{1-\left(\frac{\pi}{2}\right)^2\left(\frac{T}{I\omega^2\alpha_0}\right)^2} = \sqrt{\frac{1}{1+\left(\frac{\pi}{2}\right)^2}} = 0.536 \ldots [26]$$

At this value of $T/I\omega^2\alpha_0$ the damper flywheel begins to move with the damper hub part of the time.

B—Damper Flywheel Locked to Hub Part of the Time

The conditions of motion are shown graphically in Fig. 6(*c*). At the instant $t = -t_2$, it is seen that $v_h = v_f$ and also that $dv_h/dt = dv_f/dt$.

Expressed mathematically, these conditions become

$$\frac{T}{I}t_2 = -\alpha_0\omega\cos\omega(t_0 + t_2) \ldots\ldots [27]$$

$$\frac{T}{I} = \alpha_0\omega^2 \sin\omega(t_0 + t_2) \ldots\ldots [28]$$

From these t_2 can be eliminated and t_0 solved:

$$\omega t_0 = \pi - \sin^{-1}\frac{T}{I\omega^2\alpha_0} - \sqrt{\frac{1-\left(\frac{T}{I\omega^2\alpha_0}\right)^2}{\left(\frac{T}{I\omega^2\alpha_0}\right)^2}} \ldots\ldots [29]$$

Substituting [21] and [22] in [20],

$$\frac{W}{I\omega^2\alpha_0^2} = 2\frac{T}{I\omega^2\alpha_0}\int_{-\omega t_2}^{+\omega t_3}\left[\cos\omega(t-t_0) - \frac{T}{I\omega^2\alpha_0}\omega t\right]\omega dt. [30]$$

The lower limit of integration is determined by [27] and the upper limit by the similar equation

$$\frac{T}{I}t_3 = \alpha_0\omega\cos(t_3 - t_0) \ldots\ldots [31]$$

expressing the fact that at the upper limit the velocities of the hub and the flywheel are equal.

The numerical evaluation of [30] then runs as follows: For a certain value of $T/I\omega^2\alpha_0$, first t_0 is computed from [29]. With this result, t_2 and t_3 are found numerically from [27] and [31], and since the two equations are transcendental, this can only be done by cut and try. With the values t_0, t_2, and t_3 numerically established, the calculation of $W/I\omega^2\alpha_0^2$ from [30] offers no difficulty.

In this manner the right-hand part of the curve Fig. 7 has been determined point by point.

C—Effect of Friction Damper on System

In the main body of the paper it is shown that the work per cycle put into the system, Fig. 5, is:

$$W = \pi M_0\alpha_0 \ldots\ldots [5]$$

The work per cycle absorbed by the damper is given by Fig. 7. Since only for a part of this curve is an explicit mathematical expression available, it will be discussed in the following analysis as:

$$\frac{W}{I\omega^2\alpha_0^2} = F\left(\frac{T}{I\omega^2\alpha_0}\right) \ldots\ldots [32]$$

where F means "function of."

Equating the input and output energies [5] and [32] leads to the general relationship

$$F\left(\frac{T}{I\omega^2\alpha_0}\right) = \frac{\pi M_0}{I\omega^2\alpha_0} \ldots\ldots [33]$$

which can be written

$$F\left(\frac{T/\pi M_0}{I\omega^2\alpha_0/\pi M_0}\right) = \frac{\pi M_0}{I\omega^2\alpha_0} \ldots\ldots [34]$$

This equation gives the relation between $I\omega^2\alpha_0/\pi M_0$ and $T/\pi M_0$ as it is plotted in Fig. 8, curve *A*.

Since for the right-hand part of the curve of Fig. 7 no analytical expression exists, the corresponding part of the curve of Fig. 8 has been calculated point by point by means of [33]. For the left-hand part, however ($T/I\omega^2\alpha_0 < 0.536$), Equation [25] provides a definite form for the general expression [32]. Substituting [25] in [34] gives

$$\frac{I\omega^2\alpha_0}{\pi M_0} = 2\pi \cdot \frac{(T/\pi M_0)^2}{\sqrt{16\,(T/\pi M_0)^2 - 1}} \ldots\ldots [35]$$

representing the equation of the left-hand part of curve *A*, of Fig. 8. It is seen that this curve has a minimum for

$$\frac{T}{\pi M_0} = \frac{\sqrt{2}}{4}; \qquad \frac{I\omega^2\alpha_0}{\pi M_0} = \frac{\pi}{4}$$

The curve shows that the damper is completely ineffective where $T/\pi M_0 < \frac{1}{4}$, that is, for small values of the friction torque.

D—Combined Effect of Friction Damper and Metallic Hysteresis

The friction damper never constitutes the whole damping in any real system to which it may be attached. This is shown by the fact that the amplitude of motion in systems to which no friction damper is attached is always finite even at resonance. If the damper is attached to a system in which the metallic hysteresis in the shaft dissipates an amount of work per cycle according to the law

$$W = H\alpha_0^2 \ldots\ldots [15]$$

Equation [33] must be rewritten as follows:

$$F\left(\frac{T}{I\omega^2\alpha_0}\right) + \frac{H\alpha_0^2}{I\omega^2\alpha_0^2} = \frac{\pi M_0}{I\omega^2\alpha_0} \ldots\ldots [36]$$

Reducing this to the form corresponding to the form [34]

$$F\left(\frac{T/\pi M_0}{I\omega^2\alpha_0/\pi M_0}\right) + \frac{H}{I\omega^2} = \frac{\pi M_0}{I\omega^2\alpha_0} \ldots\ldots [37]$$

The quantity $H/I\omega^2$ appearing in this result indicates the ratio of effectiveness of the shaft hysteresis and of the damper itself. In Fig. 8, the curves B and C have been plotted from the relation [37].

Appendix No. 2

THEORY OF THE DAMPER WITH SPRINGS

IF THE damper flywheel of Fig. 1 is coupled to the shaft not only by plain friction but also by some torsional spring, a theory similar to the one developed in Appendix No. 1 can be given. The first step is to derive an expression for the work absorbed per cycle when the damper hub is executing a harmonic vibration with the amplitude α_0.

If the maximum relative angular displacement θ_0 between the damper flywheel and hub were known, the energy dissipation per cycle $4T\theta_0$ would be known also.

The problem therefore presents itself as the general case of forced vibration in a single-degree-of-freedom system affected by Coulomb damping.[12] Fig. 15 shows a scheme of the system under consideration, presented in linear rather than torsional form merely on account of greater simplicity of the drawing. Let the hub perform the angular motion $\alpha = \alpha_0 \cos(\omega t + \varphi)$, and furthermore let the damper flywheel I be coupled to the hub by the torsional flexibility k (lb-in. per radian) and by the friction torque $\pm T$. Let the angular motion of the flywheel I be β. Then the differential equation of the motion of I becomes

$$I\ddot{\beta} + k[\beta - \alpha_0 \cos(\omega t + \varphi)] \pm T = 0$$

or, using the relative angular motion,

$$\theta = \beta - \alpha_0 \cos(\omega t + \varphi) \quad \ldots\ldots [38]$$

as a new variable:

$$I\ddot{\theta} + k\theta \pm T = I\omega^2\alpha_0 \cos(\omega t + \varphi) \quad \ldots\ldots [39]$$

The + sign of T holds during the half-cycle that $\dot{\theta}$ is positive, while the equation with negative T has to be applied during the time that $\dot{\theta}$ is negative.

At the time $t = 0$, let θ have its maximum positive value θ_0; and let $\dot{\theta} = 0$. Then, assuming that motion starts immediately, $\dot{\theta}$ will be negative, and Equation [39] with the lower sign holds. Its general solution is:

$$\theta = C_1 \sin \omega_n t + C_2 \cos \omega_n t + \frac{I\omega^2\alpha_0}{k} \cdot \frac{\omega_n^2}{\omega_n^2 - \omega^2} \cos(\omega t + \varphi) + \frac{T}{k} \quad \ldots\ldots [40]$$

where $\omega_n = \sqrt{k/I}$ is the natural frequency of the damper.

Substituting the two initial conditions into this expression, C_1 and C_2 can be calculated so that

$$\theta = \theta_0 \cos \omega_n t + \frac{T}{k}(1 - \cos \omega_n t) + \frac{I\omega^2\alpha_0}{k} \cdot \frac{\omega_n^2}{\omega_n^2 - \omega^2} \left[\cos\varphi(\cos \omega t - \cos \omega_n t) + \sin\varphi\left(\frac{\omega}{\omega_n} \sin \omega_n t - \sin \omega t\right)\right] \quad \ldots\ldots [41]$$

Now a "forced vibration" is a periodic motion with the forced frequency ω. Since there is no inherent difference between forward and backward motion in this case, the vibration also has to be symmetrical. In other words, after half a cycle the flywheel I must have reached its other extreme position, or

$$\omega t = \pi \quad \theta = -\theta_0 \quad \dot{\theta} = 0$$

For satisfying these two conditions, Equation [41] contains the parameters θ_0 and φ. Their calculation leads to

$$\sin\varphi = \frac{k\theta_0}{I\omega^2\alpha_0} \cdot \frac{\omega_n^2 - \omega^2}{\omega_n^2} \quad \ldots\ldots [42]$$

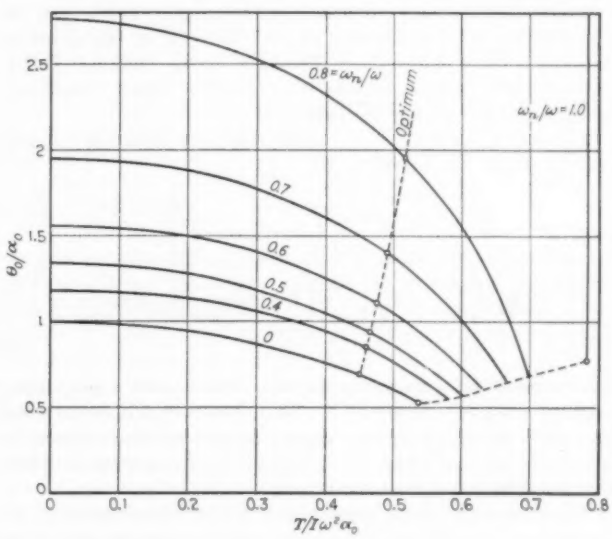

FIG. 14 RELATIVE AMPLITUDE BETWEEN FLYWHEEL AND HUB

$$\theta_0 = \sqrt{\left(\frac{I\omega^2\alpha_0}{k} \cdot \frac{\omega_n^2}{\omega_n^2 - \omega^2}\right)^2 - \left(\frac{T}{k}\right)^2 \left(\frac{\omega_n \sin \frac{\pi\omega_n}{\omega}}{\omega + \omega \cos \frac{\pi\omega_n}{\omega}}\right)^2} \quad \ldots\ldots [43]$$

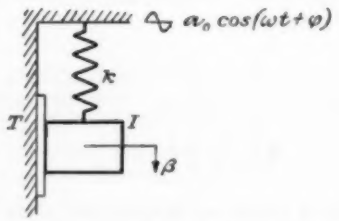

FIG. 15 FORCED VIBRATION WITH COULOMB DAMPING

The latter expression can be rewritten in the dimensionless form

$$\frac{\theta_0}{\alpha_0} = \sqrt{\left[\frac{1}{\left(\frac{\omega_n}{\omega}\right)^2 - 1}\right]^2 - \left(\frac{T}{I\omega^2\alpha_0}\right)^2 \left(\frac{\omega}{\omega_n} \cdot \frac{\sin \frac{\pi\omega_n}{\omega}}{1 + \cos \pi \frac{\omega_n}{\omega}}\right)^2} \quad [44]$$

giving the ratio between the relative amplitude θ_0 in the damper and the absolute amplitude α_0 of the hub. Since this ratio is of importance for the calculation of the stresses in the damper springs, the numerical results of [44] have been plotted in Fig. 14.

As was remarked before, the work absorption per cycle in the damper is $W = 4T\theta_0$, so that by means of [44] it is found that

[12] This problem has been treated in detail in a doctor's thesis presented in June, 1929, at the University of Pittsburgh under the title, "Forced Vibrations With Coulomb Damping."

$$\frac{W}{I\alpha^2\omega^2} = 4\left(\frac{T}{I\alpha_0\omega^2}\right)\sqrt{\left[\frac{1}{\left(\frac{\omega_n}{\omega}\right)^2-1}\right]^2-\left(\frac{T}{I\alpha_0\omega^2}\right)^2\left(\frac{\omega}{\omega_n}\cdot\frac{\sin\pi\omega_n/\omega}{1+\cos\pi\omega_n/\omega}\right)^2} \quad \ldots[45]$$

giving $W/I\alpha_0^2\omega^2$ as a function of $T/I\alpha_0\omega^2$ and of the parameter ω_n/ω. For the case of the damper without springs, $\omega_n = 0$, and it is immediately seen that [45] reduces to [25].

Fig. 12 shows the results of a numerical calculation of [45]. It is seen in this figure, as well as in Fig. 13, that the expressions [44] and [45] are only valid in a certain region, which calls for an explanation. Substitution of [42] and [43] in [40] gives an expression for θ determining the shape of the motion. Differentiating this expression gives the velocity $\dot{\theta}$, which should not become positive during the half-cycle $0 < \omega t < \pi$.

For values $\omega_n/\omega < 1$, i.e., below resonance with the damper, this condition is equivalent to

$$\frac{T}{I\omega^2\alpha_0} \leq \sqrt{\frac{\frac{\omega_n^2}{\omega^2}\left(1+\cos\pi\frac{\omega_n}{\omega}\right)^2}{\left(\frac{\omega_n^2}{\omega^2}-1\right)^2\left[\frac{\omega_n^2}{\omega^2}\left(1+\cos\pi\frac{\omega_n}{\omega}\right)^2+\sin^2\pi\frac{\omega_n}{\omega}\right]}} \quad \ldots\ldots[46]$$

This result is by no means evident, and it takes a good many pages of analysis to arrive at it. Since, however, it does not affect the main argument of the damper theory, reference should be made to the University of Pittsburgh thesis mentioned, which contains the derivations in detail.

For a damping torque greater than the one determined by [46] the damper will be gripped solid by the hub during part of its motion. No solution of the problem has been obtained for his case, except when there are no springs (see Appendix No. 1). However, such a solution would not be of great importance, since the maxima of the work curves (Fig. 12) occur in the region for which [45] is valid.

Applying these results to a complete Diesel-engine installation, we have to equate again the output energy [45] to the input energy [5]. Solving for α_0 and writing the result in a dimensionless form, we obtain finally:

$$\frac{I\omega^2\alpha_0}{\pi M_0} = \frac{\left(\frac{T}{\pi M_0}\right)^2\frac{\omega}{\omega_n}\cdot\frac{\sin\pi\omega_n/\omega}{1+\cos\pi\omega_n/\omega}}{\sqrt{\left(\frac{T}{\pi M_0}\right)^2\left[\frac{1}{(\omega_n/\omega)^2-1}\right]^2-\frac{1}{16}}} \quad \ldots\ldots[47]$$

giving the angle α_0 at the hub as a function of the friction torque T. It can be easily verified again that for the case of the unsprung damper ($\omega_n = 0$) this result reduces to [35].

Numerical calculations of [47] lead to the graph shown in Fig. 13.

Discussion

F. M. Lewis.[13] Methods of avoiding torsional criticals in reciprocating engines may be divided into three general classes:

(1) Those methods which depend upon adjusting the mass and elasticity of the system in such a way that the criticals will be outside the desired operating range.

(2) The vector cancellation methods; for instance, if equal flywheels are placed at each end of an engine, the major criticals will cancel out, since the impulses imparted to the system by the various cylinders considered as vectors will cancel. Then by the choice of a suitable firing order certain minors also may be cancelled. There are also other methods of accomplishing the same result.

(3) There are the damping methods, and these may be subdivided into those which utilize the inherent damping of the system and those which depend upon special devices, such as the Lanchester damper discussed in the paper.

The friction damper has found considerable favor among European engineers, but in this country it has been seldom used except in certain automobile engines. It has been the policy of the writer to avoid using the damper wherever it was possible to apply one of the other methods just mentioned. The objections to the device are based purely on practical considerations. The damper adds another complication to an already complicated machine. As yet no satisfactory method of design has been proposed. As the authors of this paper very aptly state the case, "dampers are not designed, but just built." Further, the damper is somewhat unreliable in action. If of the proper size and properly adjusted, it will suppress criticals, although it apparently does this by removing the sharp peak of the critical and spreading the vibration over a longer range. This spreading is in itself an undesirable feature. With time the adjustment of the damper will alter due to wear of the friction surfaces and the changing of the coefficient of friction of these. It is extremely difficult to determine whether a damper is functioning properly without tests which are beyond the skill of the ordinary mechanic or operator, and this makes its maintenance a difficult problem.

It is significant that although the engines of the *Graf Zeppelin* were fitted with friction dampers of this type, crankshaft failures occurred from torsional vibration. Although the operators of these engines were undoubtedly as skilled as could be reasonably expected, the existence of a dangerous condition was unsuspected until failures occurred. The writer does not wish to infer that the dampers were entirely at fault in this case, however, as other causes also operated.

There will remain cases, however, where it is impossible to suppress criticals in any other way than by a damper, and it would be extremely useful to have a correct theory of damper design which could be applied to these cases. The theory of the damper where viscous rather than Coulomb friction is the damping medium has been very ably presented by Gümbel in Z.V.D.I. and by Carter in the reports of the British Aeronautical Research Committee. A theory dependent on viscous friction, however, cannot be entirely satisfactory, as the action of Coulomb friction must be considerably different. The authors have attempted to supply this need. The paper they present is extremely interesting and thought-provoking.

With regard to the experiments made to demonstrate the action of Coulomb friction, the writer would inquire on one point—that is, whether there was any indication of static friction being greater than sliding friction, or, in other words, was there any indication of initial sticking with the surfaces tested?

The problem which the authors have attacked is one of great difficulty. Where non-linear relations are involved, the theory of vibration, like most physical theories, becomes considerably involved. In the present case one must deal with a damping force which is a discontinuous function of the velocity.

The writer must confess frankly that he does not find the theory as presented by the authors entirely satisfactory. Much of the theory is correct, but the results obtained are rather misleading, and it is difficult to see how these results can be applied to design without much more information than is here presented.

One of the points which gave much difficulty was to determine what the authors meant by the expression "resonant frequency" and its symbol ω. After some correspondence with them on

[13] Professor of Engineering, Webb Institute of Naval Architecture New York, N. Y. Mem. A.S.M.E.

this point, the writer was advised that they mean "frequency of maximum amplitude," but it is thought that a more correct statement might be "frequency at which the exciting moment is 90 deg. in phase to the engine vibration." It should be pointed out that neither one of these definitions is the usual one. This is a point of considerable importance, for when one comes to the authors' results he finds that they are expressed in terms of the dimensionless variable $I\omega^2\alpha/\pi M_o$. Using the authors' definition of ω, this variable contains two unknowns, α and ω, and it is impossible to solve for α without knowing ω. Further, ω will vary over a very wide range with different sizes and adjustments of dampers.

In correspondence the authors state that in design work ω is known from experimental results, but the paper gives no hint of this. It should be pointed out that, in any complete solution of the problem, ω must be expressed as a function of four dimensionless variables. These variables would be:

The ratio of the forcing frequency to the original natural frequency of the system;

The ratio of the damper mass to the engine mass;

A function of the engine friction; and

The ratio of the damper friction to the exciting forces, or T/M.

It is in this manner that the results of Carter for the viscous-friction damper are expressed. One great difficulty of the problem is that of representing α as a function of four variables.

In discussing the infinite damper the authors show that the solution is indeterminate provided that nothing but Coulomb damping is present. It may be shown likewise for the finite damper that this is true where the frequency is equal to the original natural frequency of the system. At some frequency lower than this the relation stated by the authors will be approximately correct, but the authors do not tell us what that frequency is.

The same difficulties are present in the theory of the damper with springs to an even greater extent, and one cannot consider the theory as presented as being at all satisfactory. The problem is one of great difficulty. For a complete solution, five instead of four variables would be needed, an additional one being added for the effect of the damper springs. The effect of adding the spring-connected flywheel is to profoundly alter the original elastic system. Instead of a single original critical speed, there now would be two critical speeds—one above and one below the original critical speed. It is at these new critical points where one is interested in the amplitude of vibration. Provided only Coulomb damping is present, an indeterminate solution is obtained; for the energy absorbed, being a linear function of the amplitude, and the energy put into the system being likewise a linear function, the two cannot, in general, be made equal.

One assumption made in the theory of the spring damper seems highly questionable. The relative motion of the damper and engine masses is determined, assuming a forced periodic motion of the engine masses. In doing this the damper friction T is taken into account. It would seem essential that if the effect of T upon the damper mass is to be taken into account, its effect upon the engine masses should be likewise considered. If this friction T is considered, the harmonic moment M will not produce a harmonic motion in the engine masses, and the energy absorption will therefore not be $\pi M_o\alpha_o$. This may help to explain the fact that the authors obtain a determinate solution for a problem which is essentially indeterminate.

The same difficulty as regards ω applies here as to the damper without springs; that is, results are expressed in the form $I\omega^2\alpha/\pi M_o$, and α cannot be solved for until ω is known, and no hint is given as to how ω may be obtained. This value of ω will vary even more widely than it did with the simple friction damper.

The same objection might be applied to the theory of the simple friction damper; that is, the effect of T upon the damper mass is considered, but its effect upon the engine mass is neglected. The error in this is involved in the assumption of sinusoidal engine vibration and is contained in Assumption 1 on the first page.

J. J. WYDLER.[14] This paper is a fine contribution to the art, and will be welcomed by engineers as a valuable help to a rational solution of the problems to which it relates.

As to the usefulness of dampers in general, the writer would say that attempts have been made in many instances to develop damping apparatus which would make a power plant workable over the whole operating range. Only in particular cases have heavy low-speed engine sets been fitted with special dampers. In general, such dampers have been most widely applied in the form of hydraulic or oil couplings, particularly in marine plants in which oil engines have been used to drive propeller shafts through the medium of reduction gears. More recently such couplings were installed in the power plants of the newest giant Junkers land airplane for passengers.

The greatest use to which such dampers have been put is in the case of high-speed multi-cylinder internal-combustion engines, especially where these are made a part of some of the higher-priced automobile assemblies. One of the most interesting attempts to make use of the damping principle is in connection with the propelling plants of dirigibles.

There is, in fact, a special need for dampers where engines are used to supply power for locomotion, because, primarily, such engines, if they cover the best range of usefulness, need to operate at all speeds unhampered by any critical speed range. However, at best, but small use has been made of damping equipment.

Probably the principal reason why dampers have not been more generally utilized is that they introduce an additional mechanism and a complication to the plant, and one requiring more or less careful attention. A damper absorbs energy by transforming it into the heat of friction which has to be dissipated. In smaller engine sets air cooling may suffice, but in the case of heavier installations water cooling may become necessary. It would be interesting to have the authors tell how long they have found the materials making up the friction surfaces to last in dampers they have used under normal operating conditions.

Another reason why dampers have not been more generally used may be (as indicated in the paper) that a damper cannot be entirely relied upon to protect the power plant if its engine has more than one critical speed range or if the critical speed range for some reason shifts from that of the original installation. A most serious failure of the latter sort resulted in the breakdown of four propeller shafts of the *Graf Zeppelin*. In this case, before starting the trip, a little too much tension was put upon the springs of the couplings between the engines and the propellers. As a result of this, the critical speed ranges were shifted enough to render the dampers ineffective.[15]

In the opinion of the writer the specialists who have to deal with vibration troubles in multi-cylinder plants should not lose sight of opportunities to balance the inciting impulses through choosing proper crank angles. Of course, in the case of six-cylinder sets, little can be accomplished along this line. However, a ten-cylinder set could be built up by a combination of a six- and a four-cylinder set, each one in itself satisfactorily balanced as to the reciprocating mass forces, with the combination properly balanced as to tangential harmonic impulses.

When once torsional vibrations have been suppressed or eliminated in this way, it may be said that this problem has been solved as satisfactorily as the balancing of reciprocating inertia forces.

[14] Combustion Utilities Corporation, New York, N. Y.

[15] Thoma, *V.D.I.*, September 28, 1929, p. 1387.

Until we have learned to render critical speeds harmless by balancing the inciting impulses, we should welcome every means, such as dampers, which aid in the suppression of heavy vibrations.

J. Dickson.[16] The authors are due considerable praise. This paper is probably the first of its kind, judging from the lack of printed matter on this subject. This lack in publications, however, is no argument that "dampers are just made, not designed."

On the fourth page the writer is credited with attempting to overcome a difficulty which later on has increased to difficulties. Equation [8] provides no means of proportioning the damper flywheels in advance. True, but the same in a sense could be said of Equation [13]. The designer must allow for inconsistencies in the coefficient of friction in a practical damper, under service conditions. Suppose the springs are designed on a 15 per cent base as recommended and 30 per cent is obtained, the value of T/I is doubled, and the diagram, Fig. 6 (a), of the continuously slipping flywheel cannot be constructed. Then, again, it is doubtful whether the conditions as represented in Fig. 6(a), on which the theory is based, do exist. Energy is taken from the vibrating shaft by dissipation, as agreed on in the second assumption, also by giving kinetic energy to the damper flywheel (this energy the designer in using Equation [8] corrects for and thus eliminates all the other difficulties mentioned). The greater the ratio T/I, the greater is this latter proportion of the total energy.

At time $t_1/4$ [see Fig. 6(a)] the kinetic energy of the flywheel reaches a maximum and commences to dissipate its energy by exerting on the shaft a torque T, causing a change in velocity either by superimposing on the periodic vibration an increase in speed to the shafting system as a whole, or, as is more probable, by setting up in the shaft another vibration due to its position on the elastic curve, its magnitude, and periodic nature.

Summing up, the writer does not consider that the shaded portion of Fig. 6(a) on which the formulas are based is a true representation of the energy dissipated, and designers should be wary, provided they accept Fig. 6(a), of proportioning the damper flywheels on the optimum values given.

R. G. Gage.[17] Although the chief value of the paper undoubtedly will be for those particularly concerned in the design of dampers, there is definite information which is available for application by the operating engineer, and it is on this alone that this comment is made.

The authors' early statement that "dampers are just made, not designed," is at first frightening, and one wonders just what that may mean. Knowing that dampers of the type under discussion have been in successful operation on Beardmore six-cylinder engines for over two years, one wonders if this has been merely a matter of luck.

It is stated that the damper efficiency is modified by

(*a*) The condition of the surfaces of the friction plates (the coefficient of friction varying from 50 per cent to 15 per cent)
(*b*) The damper-spring tension
(*c*) The temperature of the damper.

In service, the feroda friction plates are found to be covered with oil, and it is best that this is so. The surface wear is thus reduced, and the coefficient of friction, although at its lowest value, is more constant. The spring tension does not vary appreciably between settings. The damper temperature is usually within moderate limits, but when under extreme conditions of cold, the engine is known to be rough at its critical speed.

The secret of the success of the present dampers is probably due to the fact, as stated in the paper, that spring tension greater than that necessary to give the optimum flywheel torque has little effect on the efficacy of the damper. Positive stops between the flywheel halves, if amply designed, guarantee sufficient spring loading. Recognizing the possibility of oil on the surfaces of the friction plates, the designer probably worked on the lowest value of the coefficient of friction, given as 15 per cent.

In what way would a damper which was "designed" rather than "made" be an improvement in operation?

George J. Dashefsky.[18] The New York Navy Yard some years ago had occasion to experiment with vibration dampers of the solid-friction type as applied to the Diesel-engine propulsion plants of submarines. The efficacy in damping a particular mode of vibration was soon observed to depend upon the adjustment of the pressure between the friction surfaces. The main difficulty experienced lay in the glazing of the friction surfaces, with consequent loss in effective damping.

In a recent problem with camshaft vibration of a 3000-hp. submarine Diesel engine, a vibration damper developed at the Navy Yard, utilizing viscous friction, was successfully applied as a solution. This type of damper made its appeal because of its mechanical simplicity.

An investigation made in connection with the development of this viscous-friction damper, in some respects, covered common ground with matter presented in the paper. A description of the experiments and findings may be of interest.

The viscous-friction damper comprises essentially a fluid-tight drum, built upon a hub, and a flywheel or inertia member residing within the casing and free to oscillate upon the hub. A gap of determined size is left between the casing and the sides and the periphery of the inertia member. The casing is filled with a viscous medium. The damper is secured to the vibrating member by means of the hub. Vibration imposed upon the casing of the damper results in relative motion between the casing and inertia member; distortion of the viscous medium takes place, with consequent absorption of vibration energy.

The characteristics of the viscous-friction damper were analyzed mathematically and its predicted damping characteristics checked with fair accuracy by an experimental determination. The "life-size" damper was mounted upon a steel rod and suspended by clamping the free end of the rod in an appropriate bracket so that the axis of the vibration system was in a vertical plane. The stimulating torque was obtained by mounting an adjustable unbalanced mass upon the upper side of the damper. The mass was rotated by an electric motor, the speed of which determined the frequency of the stimulating torque. Simultaneous records of the motion of both the casing (oscillating member) and the flywheel (inertia member) were recorded by an especially adapted torsiograph.

Theory indicates that if the motion of the casing be a simple harmonic, the motion impressed on the inertia member should also be a simple harmonic of the same frequency. This was substantiated by the experiments mentioned. A similar verification of the motion of the flywheel member of the solid-friction damper would be of interest and would possibly show experimentally if, and where, in the cycle of vibration, slipping between the flywheel hub ceases.

The authors have indicated that the solid-friction damper shows a critical point of maximum damping ability. This point depends upon a relation of the "slipping" torque of the damper to the harmonic disturbing torque. In the case of the viscous-friction damper, the friction torque is a function of the coefficient of

[16] William Beardmore Company, Ltd., Glasgow, Scotland.

[18] Vibration Expert, Navy Yard, New York, N. Y.

viscosity of the working fluid, which coefficient is dependent upon temperature. The curves of damping energy absorption with respect to temperature, as indicated by theory and experiment, are similar to those indicated for the solid-friction damper.

In order to spread the range of effectiveness of the viscous friction damper, it has been proposed to divide the damper in two, utilizing two flywheels of different moments of inertia. By properly proportioning the flywheels, two different critical temperatures result, and a broader range of effective damping for the damper as a whole.

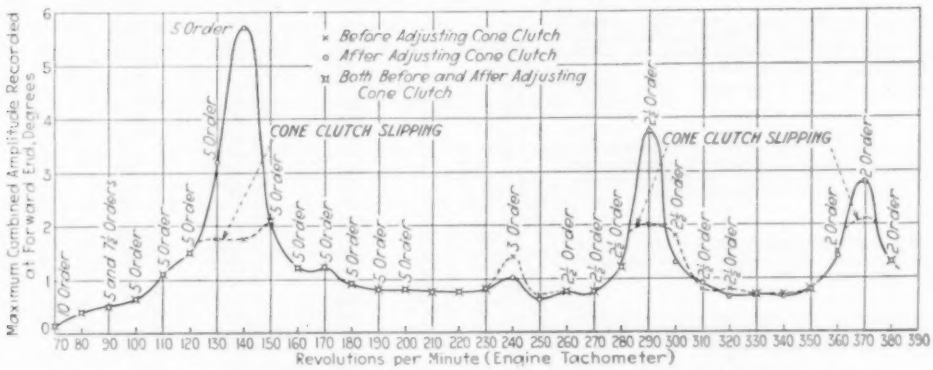

FIG. 15 RECORDED VIBRATIONS FROM RESULTS OF TORSIOGRAPHIC TESTS ON ENGINES OF U. S. SUBMARINES *V-5* AND *V-6*
(See Installation No. 6 in Table 1.)

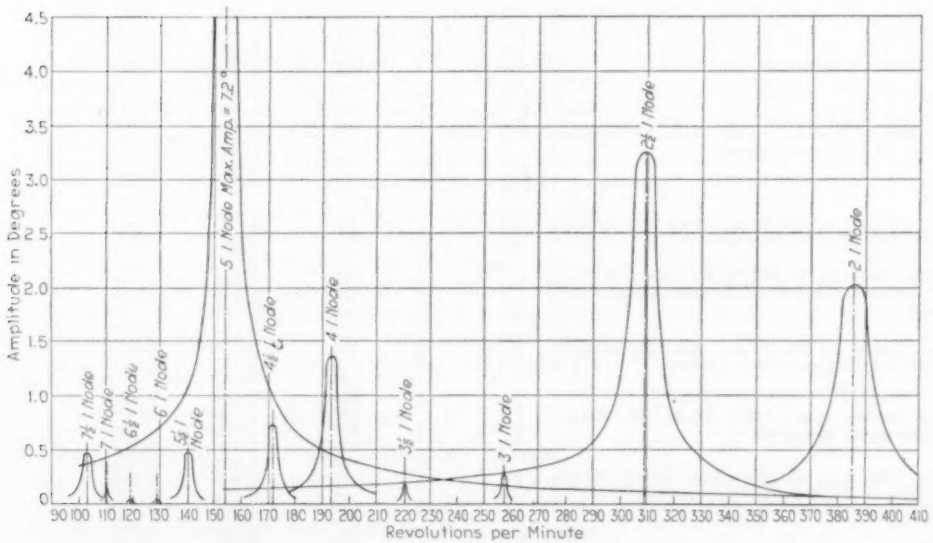

FIG. 16 CALCULATED RESONANCE CURVES, TESTS ON ENGINES OF U. S. SUBMARINES *V-5* AND *V-6*, FOR COMPONENT AMPLITUDES OF VIBRATION AT AIR COMPRESSOR AND FOR CHARGING CONDITION
(All orders given are due to the stimulation at the main cylinders except the fourth order, which is due to the stimulation at the air compressor, and the second order, which is due to the combined effect of main cylinders and alternating cylinders. See Installation No. 6 in Table 1.)

In the case of the solid-friction damper the effectiveness of the damper depends upon a relation between the "slipping" torque of the damper and the torque which stimulates the vibration. (See Equation [14] of the paper.) Where more than one synchronous speed occurs within the operating range of an installation, the adjustment of the solid-friction damper may be such as to be relatively ineffective for some of the critical speeds. In such a case the device suggested for broadening the effective range of the viscous friction damper by employing two flywheels may be utilized. The flywheels and "slipping" torques should be so proportioned as to give a compromise of combined damping, effective on all of the synchronous vibrations encountered.

FREDERIC P. PORTER.[19] The authors have referred in several instances to the law of hysteresis damping. They appear to recognize this law only in a qualitative sense. On the sixth page the authors state that "the largest natural damping existing in a system, as shown in Fig. 5, is due to the metallic hysteresis of the shaft material under varying stresses." Yet shortly after this they say that "in real systems where hysteresis damping acts by itself, the amplitude of motion at resonance is usually so large that the maximum stresses in the system are far above the fatigue limit."

Now, the resonant condition referred to here occurs each time the ratio of a natural frequency of the system to the frequency of a stimulating impulse is equal to unity. In four-cycle engines this will occur whenever the ratio of the natural frequency in v.p.m. to the shaft speed in r.p.m. is one of the series of numbers ½, 1, 1½, 2, 2½, 3, etc., and in two-cycle engines when this ratio is one of the series 1, 2, 3, 4, 5, etc. If a four-cycle installation designed to operate at 300 r.p.m. had a natural frequency of 2000 v.p.m., resonance would occur near 300 r.p.m., as follows:

Order	R.p.m.
6	333
6½	308
7	286
7½	267
8	250

Apparently the authors believe that at each of these speeds a vibration will occur that will exceed the fatigue limit of the shaft material.

Lewis, in a paper mentioned by the authors, proposed using a law for the hysteresis damping in engine installation that he determined from experimental results of Rowett. Following this proposal by Lewis, the writer modified this law by an empirical factor which he determined from the result of measuring the vibrations of actual installations with a torsiograph. This line of investigation led the writer to the formula for hysteresis loss or, which would be more correct, for the overall damping loss in engine installations whose synchronous vibrations are not limited by some attached source of damping such as a marine propeller or friction damper, etc., as follows:

$$K = 4.5 \times 10^{-10} S^{2.3}$$

[19] Fairbanks Morse Company, Beloit, Wis.

where K is the energy (lb-in.) lost per stress cycle per cubic unit (in.^{3}) of steel.

The authors object to this procedure by saying that it cannot be done, even though they admit that the largest natural damping existing in certain installations is due to metallic hysteresis. The writer has used his overall "hysteresis" damping formula for several years and has applied it to many installations that have been tested by him. In all cases he has found a fair agreement between the calculated and recorded amplitudes on actual installations where such conditions as slipping clutches, clearance between connected members of the shaft line-up, etc., have not partially or totally destroyed the resonant characteristics. The procedure of such calculations was described in his previous paper mentioned by the authors, and follows the general scheme outlined by Lewis.

TABLE 1 COMPARISON OF CALCULATED AND RECORDED VIBRATIONS

		Order of vibration	Frequency	R.p.m.	Recorded amplitudes, deg.	Calculated amplitudes, deg.
(1)	Four-cycle, six-cylinder, 1200-i.hp. at 150 r.p.m.; bore, 22; stroke, 32; firing order, 1–4–2–6–3–5; U. S. Army dredges, Dan C. King class, original installation. (Described in A.S.M.E., 1928, Paper No. APM-50-8.)	9	1	102	0.53	0.68
		6	1	156	1.80	1.86
(2)	Four-cycle, 8-cylinder, 600-b.hp. at 380 r.p.m.; bore, 13.5; stroke, 15; firing order, 1–5–7–3–8–4–2–6; Nelseco Diesel engine installation; U. S. submarines *S-18* to *S-41*, surface condition. (Described in A.S.M.E., 1928, Paper No. APM-50-8.)	8	2	241	0.99	1.000
		6½	2	295	0.366	0.580
		5½	2	350	1.002	0.885
(3)	Installation nearly similar to (2); U. S. submarine *S-44*; surface condition	8	2	238	1.0	1.000
		5½	2	342	0.9	0.885
	Charging condition	5½	1	338	1.00	0.885
(4)	Four-cycle, ten-cylinder, 2350-b.hp. at 345 r.p.m.; bore and stroke, 20⅞; port firing order, 1–7–3–9–5–10–4–8–2–6; bureau type engine; U. S. submarine *T-3*; port engine; surface condition. (Described in A.S.M.E., 1928, Paper No. APM-50-8.)	4	2	307	0.264	0.458
		4½	2	273	0.298	0.428
		5	2	246	1.372	2.060
		5½	3	334	0.274	0.563
		7½	3	246	0.175	0.591
(5)	Installation similar to (4); starboard firing order, 1–6–2–8–4–10–5–9–3–7; U. S. Submarine *T-3*; starboard engine; surface condition. (Described in A.S.M.E., 1928, Paper No. APM-50-8.)	4	2	311	0.311	0.440
		4½	2	268	0.218	0.428
		5	2	250	0.935[a]	2.060
		5½	2	230	0.167	0.271
		5½	3	340	0.274	0.563
		7½	3	250	0.248	0.591
(6)	Installation using engine similar to (4); shaft line-up entirely different; U. S. submarines *V-5* and *V-6*; charging condition; preliminary installation tested at New York Navy Yard.	5	1	140	5.70	7.200
		2½	1	290	3.50	3.250
		2	1	270	2.40	2.040
(7)	Four-cycle, six-cylinder, 1000-b.hp. at 390 r.p.m.; bore, 17¾; stroke, 16⅝; firing order, 1–5–3–6–2–4; bureau type engines; U. S. submarines *V-1* to *V-3*; forward auxiliary engines.	6	1	388	1.30	1.512
		7½	1	310	0.31	0.323
		9	1	258	0.67	0.549
(8)	Two-cycle, six-cylinder, 2250-b.hp. at 310 r.p.m.; bore, 21⅝; stroke, 21⅝; firing order, 1–5–3–4–2–6; Busch-Sulzer engines; U. S. submarines *V-1* to *V-3*; main engines; charging condition (propeller disconnected).	6	1	140	1.62	1.660
		9	2	233	0.43	0.570
(9)	Same installation as (8), with 7080 lb-ft.^{2} inertia removed from flywheel, charging condition.	6	1	145	1.97	1.950
		9	2	241	0.52	0.570
(10)	Installation of (9) in surface condition.	6	2	150	2.10	1.950
		9	3	242	0.33	0.570
(11)	Two-cycle, six-cylinder, 4000-b.hp. at 125 r.p.m.; bore, 29; stroke, 44; firing order 1–5–3–4–2–6; Nordberg engine.	6	1	137.5	2.50	2.560
		7	1	118.0	0.14	0.160

(19)	Four-cycle, six-cylinder 1200-hp. at 450 r.p.m.; bore, 17.75; stroke, 16.56; installation described by Wydler.	6	1	358	1.190	1.530

[a] Clutch found to slip at 0.9 deg. amp.

The authors have referred to Föppl's laboratory experiments in this regard. It would be interesting if they would make an actual numerical comparison.

Table 1 gives the results obtained on some of the installations investigated. Installations No. 4 and 5 had been in operation for several years before the torsiographic test was made upon them. It is reasonable to expect, therefore, that certain parts, such as the hub of the motor armature upon the shaft, the couplings, the hub under the clutch, etc., had loosened slightly during the years of service, thus destroying to some extent the synchronous vibrations which would otherwise result.

Figs. 15 and 16 show the recorded and calculated results obtained for installation No. 6. In Fig. 15 the maximum recorded vibrations are plotted upon the speeds recorded by the engine tachometer. This was done to speed up the work of the investigation. When this tachometer was later calibrated, it was found to be reading a little low, particularly at low speeds. In the first series of tests no amplitudes were found greater than about 2 deg. Upon investigation it was found that the cone friction clutch between the engine and motors was slipping. This clutch was adjusted tighter, and the test was repeated. This time the amplitudes increased to the values shown in Fig. 15. Even with this adjustment the clutch was found to slip in way of the large five-order vibration. Since this vibration was recorded to an amplitude of 5.7 deg., however, it can be concluded that the clutch did not slip for those vibrations whose amplitudes are less than this amount.

Installations (18) and (19) were described by Wydler in "Drehschwingungen in Kolbenmaschinenanlagen," Berlin, 1922. The horsepower values for these installations are those given by Wydler and are in the metric units. Wydler also gives results for a third installation which has a friction clutch between the engine and generator. On account of the uncertainty introduced by the possibility of this clutch slipping, a comparison of the calculated and recorded amplitudes for this installation is considered questionable.

The foregoing data, the writer believes, justify the use of his partly empirical formula for the determination of the maximum amplitudes of Diesel-engine installations, at least until some better method is proposed.

On the third page the authors state that "in nearly all practical cases of torsional resonance in gas or Diesel engines it is only the lowest natural frequency of the system which is dangerous." While it is true that in many installations the lowest natural frequency is the only one to cause trouble, the application of Diesel engines to the generation of power is so diversified that many cases also arise in practice where the second or third natural frequency is also objectionable. Table 1 will illustrate this fact.

The authors make a statement on the fifth page to the effect that a safe design factor for vibratory stresses is 10 or 12 per cent of the ultimate tensile strength, since "in most steels the ultimate strength in torsion is about half the ultimate strength in tension, and that the fatigue strength in torsion is again about half the ultimate strength in torsion." They apparently are a little mixed on the ideas of ultimate strength and endurance limit.[20]

Author's Closure

Professor Lewis agrees with the authors that "it would be extremely useful to have a correct theory of damper design," but finds that the theory as presented is not entirely satisfactory. The main points in his objections are the facts that (1) the distortion of the harmonic motion of the engine mass due to the damper torque is neglected, (2) the value of the resonant frequency ω is not known, and (3) the ratio of the damper mass to the engine mass is not considered in the solution.

The authors are well aware that the solution presented is an approximate one. They were and are of the opinion that the approximation is very close, but in the absence of an exact solution the degree of approximation naturally cannot be calculated. In order to reply satisfactorily to Professor Lewis' criticism, the authors have developed an exact solution of the problem since the presentation of the paper in December, which meets the three objections mentioned. The system considered is that of Fig. 5 with the exception that the inertia of the main flywheel I_2 has been made infinite (Fig. 17). In practical cases I_2 is often ten or more times larger than I_1 so that this is justified, especially since the exact solution to be given now only serves the purpose of giving a comparison with the approximate solution of the paper.

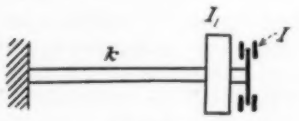

Fig. 17 Scheme For Exact Calculation

Let the angular deflections of I_1 and I be α and γ, respectively, and let the engine torque acting on I_1 be $M_0 \cos(\omega t + \varphi)$. We restrict ourselves to the case of continuous slippage [cf. Fig. 6(*a*)]. During the half-cycle that $0 < \omega t < \pi$, the following differential equations describe the motion:

$$\left.\begin{aligned} I_1\ddot{\alpha} + k\alpha - T &= M_0 \cos(\omega t + \varphi) \\ I\ddot{\gamma} + T &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots [48]$$

in which φ is a phase angle to be determined later. The general solutions of [48] are:

$$\left.\begin{aligned} \alpha &= C_1 \sin \omega_n t + C_2 \cos \omega_n t \\ &\quad + \frac{T}{k} + \frac{M_0}{k} \cdot \frac{\omega_n^2}{\omega_n^2 - \omega^2} \cdot \cos(\omega t + \varphi) \\ \gamma &= -\frac{T}{2I} t^2 + C_3 t + C_4 \end{aligned}\right\} \quad \ldots\ldots [49]$$

where

$$\omega_n = \sqrt{k/I_1}$$

In formulating the boundary conditions, the time $t = 0$ is taken at the instant that $\gamma - \alpha$ is a minimum. At $t = 0$ the relative motion just reverses, and between $t = 0$ and $t = \pi/\omega$ the relative motion has always the same direction, so that $\dot{\gamma} - \dot{\alpha} > 0$ and [48] holds. The eight boundary conditions are:

$$\left.\begin{aligned} t = 0 \quad \alpha &= \alpha_0 \quad \dot{\alpha} = \dot{\alpha}_0 \quad \gamma - \alpha = -\theta_0 \quad \dot{\gamma} - \dot{\alpha} = 0 \\ t = \pi/\omega \quad \alpha &= -\alpha_0 \quad \dot{\alpha} = -\dot{\alpha}_0 \quad \gamma - \alpha = +\theta_0 \quad \dot{\gamma} - \dot{\alpha} = 0 \end{aligned}\right\} [50]$$

expressing the fact that after half a cycle the deflections and velocities must be opposite to those at $t = 0$, which follows from the symmetry of the system under consideration.

It is noted that Θ_0 is the maximum value which $\gamma - \alpha$ reaches during a cycle, but that α_0 is not the maximum of α during the cycle. The eight conditions [50] will be used to determine the four integration constants and the four parameters:

$$C_1,\ C_2,\ C_3,\ C_4,\ \Theta_0,\ \alpha_0,\ \dot{\alpha}_0, \text{ and } \varphi$$

Substitution of [50] into [49] after some lengthy calculations leads to the solution:

$$\left.\begin{aligned} \cos\varphi &= \frac{k\theta_0}{M_0 V} \qquad \sin\varphi = -\frac{T}{M_0 V} \cdot \left\{ U + \frac{\pi}{2} \cdot \frac{I_1}{I} \cdot \frac{\omega_n^2}{\omega^2} \right\} \\ \theta_0 &= \frac{M_0}{k} \cdot \sqrt{V^2 - \left(\frac{T}{M_0}\right)^2 \cdot \left\{ U + \frac{\pi}{2} \cdot \frac{I_1}{I} \cdot \frac{\omega_n^2}{\omega^2} \right\}^2} \end{aligned}\right\} . [51]$$

where the abbreviations U and V have the following meaning:[21]

$$U = \frac{\dfrac{\omega_n}{\omega} \cdot \sin \pi \dfrac{\omega_n}{\omega}}{1 + \cos \pi \dfrac{\omega_n}{\omega}} \; ; \qquad V = \frac{\omega_n^2}{\omega_n^2 - \omega^2}$$

The motion of the engine also is calculated from [49] and [50]:

[20] H. E. Moore and J. B. Kommers, "Fatigue of Metals."

[21] *Phil. Mag.*, 1930, p. 801.

$$\alpha = -\frac{TU\omega}{k\omega_n}\cdot\sin\omega_n t + \frac{T}{M_0}(1-\cos\omega_n t) + \frac{M_0 V}{k}\cdot\cos(\omega t+\varphi)\ldots[52]$$

The maximum value of α during one cycle in which we are primarily interested happens at some time t_0 between $t = 0$ and $t = \pi/\omega$. A direct analytical calculation of this t_0 by differentiation of [52] is not possible, since [52] is transcendental because ω and ω_n are incommensurable. However, for the cases in hand ω is close to ω_n, so that a first approximation for t_0 can be obtained by putting $\omega = \omega_n$. Then α is calculated for this t_0 and for a neighboring value on each side of t_0; the maximum being determined by graphical interpolation.

The maximum thus obtained is yet a function of ω. As such it will reach a maximum or "come to resonance" for some ω smaller than ω_n. This ω cannot be calculated directly, but a first approximation is found by assuming that α becomes maximum at the same frequency that the *relative* motion θ_0 becomes a maximum. This latter frequency can be calculated from [51] by successive approximations.

The numerical calculations are extremely laborious, though several short cuts can be applied.

The solution thus obtained is valid only when no stops occur during the motion. It can be shown that this condition can be expressed as:

$$\frac{T}{M_0}\left(1+\frac{I_1}{I}\right) \leq \frac{V\omega^2}{\omega_n^2}\cdot\cos\varphi\ldots\ldots\ldots\ldots[53]$$

It can also be shown that the solution [51] reduces to the solution given in the paper when $I/I_1 = 0$. Therefore *the solution given in the paper is exact for an infinitely small damper mass.* The results of the numerical calculations are given in Table 2 below and also in Figs. 18 and 19.

TABLE 2

$I/I_1 = 0$			$I/I_1 = 0.1$

1.3	1.050	2.66	...	.....	....
1.327	1.051	2.68	...	.....	....

These two figures give sufficient information to answer Professor Lewis' objections. It is noted that in Fig. 18, the minimum point for $I/I_1 = 0.2$ is $3\frac{1}{2}$ per cent in error with respect to the solution given in the paper. A damper with such a ratio is a rather heavy one, so that it can be stated that *for all practical dampers the solution given in the paper is less than 3.5 per cent in error.* The value of the friction torque at which the minimum occurs also agrees with the approximate value.

Fig. 19 shows the "resonant frequency" ω as a function of the friction torque. The ordinates are presented in a dimensionless form, ω_l being the natural frequency of the system with the damper flywheel completely loose, while ω_t is the natural frequency with the damper completely tight.

It is seen that the minimum amplitude occurs about at:

$$\frac{\omega-\omega_l}{\omega_t-\omega_l} = 0.6\ldots\ldots\ldots\ldots\ldots\ldots[54]$$

for all practical damper sizes. In a heavy damper, $I/I_1 = 0.2$, for instance, [54] gives:

$$\frac{\omega}{\omega_l} = 0.965$$

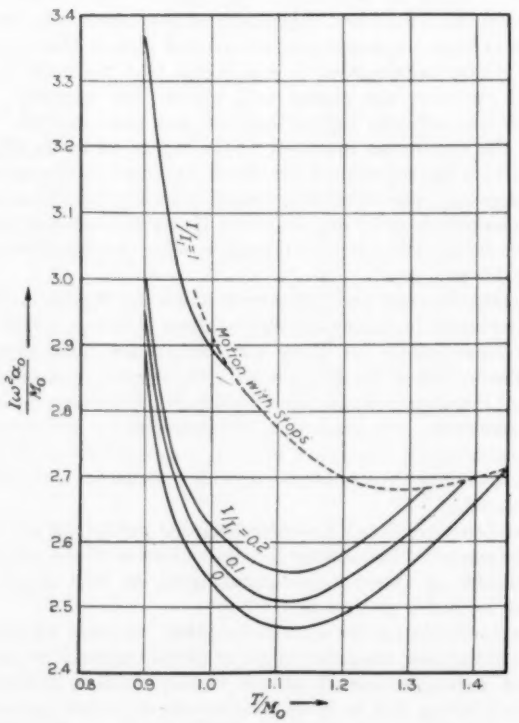

FIG. 18 AMPLITUDES BY EXACT CALCULATION

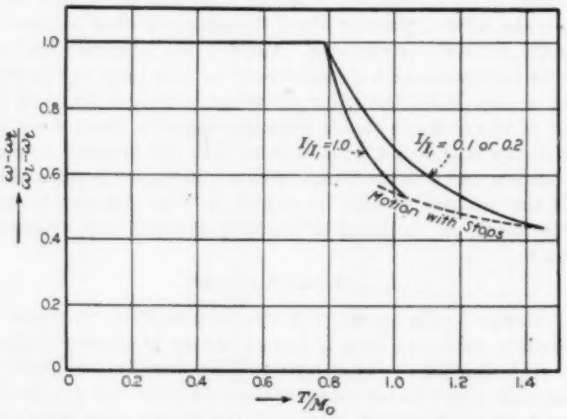

FIG. 19 RESONANT FREQUENCIES BY EXACT CALCULATION

If in formula [13] the original natural frequency ω_l were taken instead of the resonant frequency ω, the result $\alpha_{\min}$ comes out 7 per cent large. But the error due to the finite damper mass is 3.5 per cent in the other direction. The total error committed therefore is 3.5 per cent, which is very satisfactory for an amplitude calculation.

In addition to this exact theory a series of careful tests was carried out on a new model, which had no flexibility between I_1 and I. The torque input was accomplished mechanically by means of a coil spring (Fig. 20). The flywheels were *not* revolving; the driving motor merely twisting one end of the coil spring back and forth through an angle of 30 deg. by means of an eccentric on its shaft.

The recording was done by means of a mirror $^1/_2$ in. in diameter suspended in a universal suspension. A point source of light was reflected by this mirror and thrown on a photographic plate, while the entire room was in the dark. The mirror was moved back and forth about its vertical axis by means of a wire connected to that end of the driving spring which was

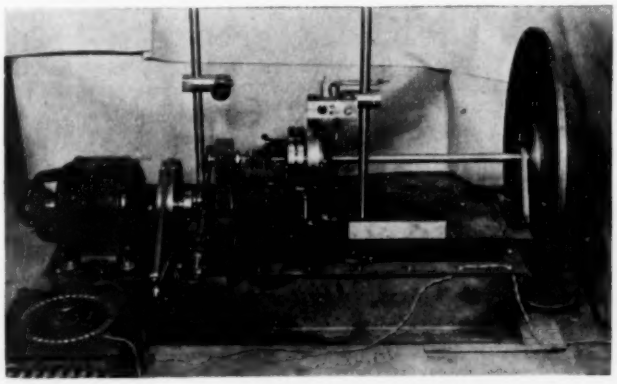

FIG. 20 MODEL WITH MECHANICAL TORQUE INPUT

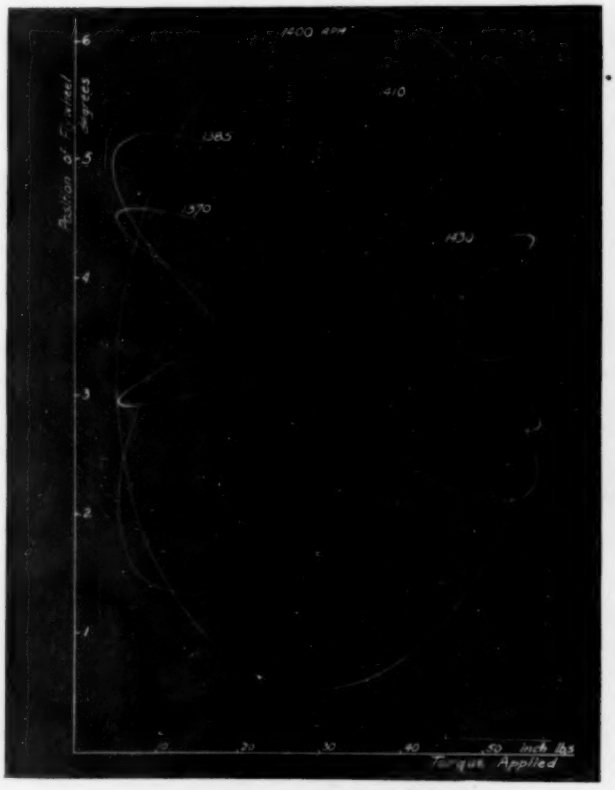

FIG. 21 RECORDS WITH DAMPER LOOSE

moving 30 deg. This gave a horizontal track of light on the plate. The vibration of the flywheel I_1 rocked the mirror about its horizontal axis giving a vertical track of light. The result was a figure resembling an ellipse. Fig. 21 shows a plate which was exposed at five speeds near resonance when the damper was loose, while Fig. 22 gives the same with the damper set in its optimum position.

With this apparatus tests were carried out on three damper sizes with ratios $I/I_1 = 0.104$, 0.241, and 0.963, respectively. The test results are given in Fig. 23, showing a complete agreement with the theory.

The objection raised against the theory of the damper with springs as presented in the paper are of the same order as those against the damper without springs. In general, the objections are quite valid when the damper mass is so large as to *materially* change the critical speeds and to have such a large non-harmonic reaction on the machine that its motion ceases to be harmonic. This is never the case with practical dampers. Though the original critical speed will be changed into two critical speeds by the application of a spring damper, these two criticals will be close to the original and the curves presented will hold for any of these speeds for practical damper sizes. A proof of this by an exact theory seems impossible on account of the difficulties involved.

Professor Lewis' views of the damper as a complicated piece of apparatus which needs expert maintenance and can easily get out of adjustment are somewhat pessimistic. The Diesel-electric engines built by the Westinghouse Company for loco-

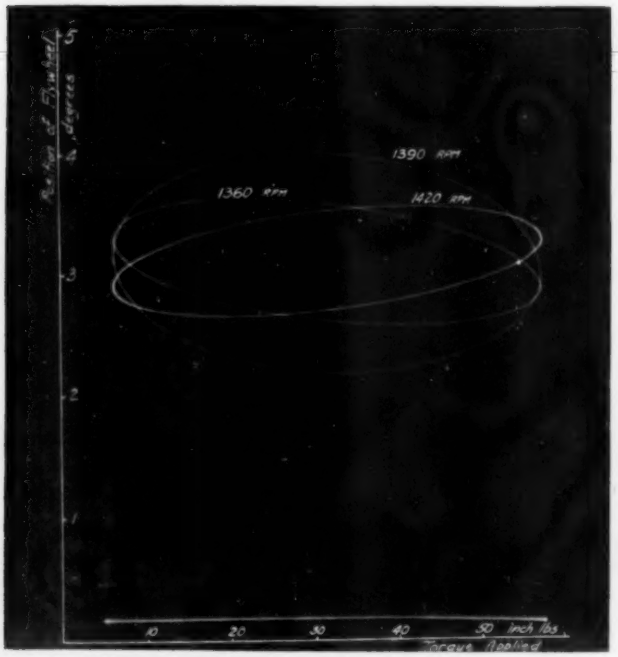

FIG. 22 RECORDS WITH DAMPER TIGHTENED RIGHT

motives and rail cars are in satisfactory operation without adjustments in service.

In reply to Dr. Wydler's questions regarding the cooling and the life of dampers, the following can be said:

No cooling has ever been necessary in the dampers on engines of 1200 hp. and less. In rail-car engines, the damper has lubricating-oil temperature when the engine runs at a speed away from resonance. For continuous running in resonance, the damper runs about 30 deg. fahr. hotter than the lubricating oil. Some dampers under our observation have run almost three years without signs of appreciable wear on the friction rings. It must be remembered that a damper usually operates at the critical speed only a short time. Even when it does operate there it does very little work—less than 1 per cent of the engine rated horsepower is dissipated by the damper in an ordinary case.

Mr. Dickson's design of the dampers on the Beardmore engines was very rational in that it was based on the idea of

energy dissipation. Without having seen Mr. Dickson's design methods, the authors would probably have never written this paper. The only essential difference between our method and Mr. Dickson's is that we consider the motion of the damper flywheels in some detail, while he assumes that it is rotating at the average shaft speed. Our method leads us to a definite damper inertia value for a desired amplitude, while Mr. Dickson was forced to determine his damper size by reasoning not related to energy considerations. Our method leads to a value of the optimum friction torque in the damper which is always larger than the torque which would be used if Equation [8] were followed. In an actual design we both should arrive at about the same damper flywheel inertia; the practical difference coming only in the loading used on the friction surfaces.

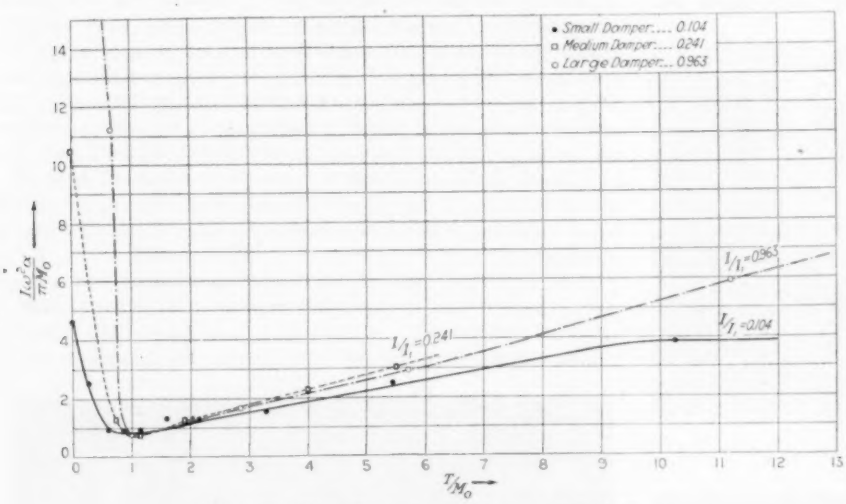

FIG. 23 TEST RESULTS ON MODEL OF FIG. 20

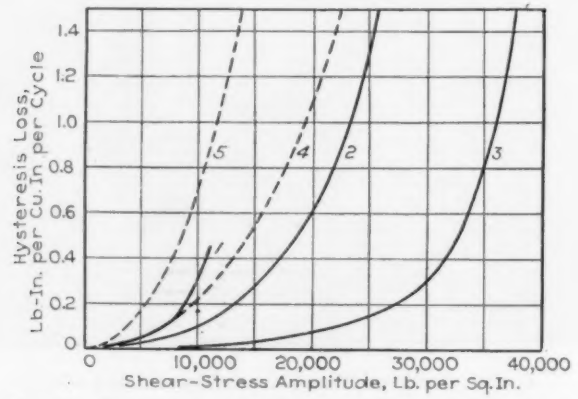

FIG. 24 EXPERIMENTAL HYSTERESIS CURVES COMPARED TO PORTER'S LAW

Mr. Gage's observations from the operating point of view are especially appreciated. There is no difference between a damper "made" right and one "designed" right. The "making" by pure "cut and try" takes much more time than the "designing," and the result in many cases will not be as good.

Mr. Dashefsky's tests on viscous dampers are interesting. The advantage of a purely viscous damper is that the optimum value for α_0 for a given damper flywheel is $\pi/4$ times as small as for the friction damper. This was stated by Carter in a report of the British Aeronautical Research Committee in 1927, and the authors' analysis leads to the same result.

Mr. Porter criticizes the paper on a number of minor points. The first statement made is that "the authors appear to recognize the law of hysteresis damping only in a qualitative sense." In this connection an inspection of Fig. 24 seems instructive. The figure shows several hysteresis damping curves; No. 1 was taken by Rowett on mild steel; No. 2 by Föppl[22] on oil-hardened carbon steel; and No. 3 by Föppl on "crankshaft steel."

Professor Lewis used Rowett's law for stresses below 7000 lb. per sq. in. and expressed it in the mathematical form:

$$K = 1.37 \times 10^{-10} S^{2.3}$$

Curve No. 4 in Fig. 24 shows this law. Mr. Porter found that this law did not give correct results, and replaced the factor 1.37 by 4.5. In looking over Mr. Porter's valuable list of calculated and measured amplitudes, we feel that the coefficient proposed by him is still too small if averages mean anything in discussing the results. While over two-thirds of all the cases given show remarkably good agreement between calculations and tests, three-fourths of them show calculated amplitudes larger than measured amplitudes. This indicates that the actual damping losses are larger than the calculated losses. Taking an average, the coefficient should be 5.85 instead of 4.5 as recommended by Mr. Porter.

The discrepancies shown in Fig. 24, granted that Föppl's results are correct, can be explained by the assumption that hysteresis really plays a small part in damping Diesel-engine vibrations or that stresses much higher than ever imagined exist in parts of the crankshaft.

If this is right, we are back to the position of Holzer and Wydler, who considered the actual law of damping to be unknown and proposed the assumption of an overall damping which followed the law of viscous friction. This, at least, has the advantage of leading to energy losses proportional to the square of the amplitude, which is more convenient for calculation purposes than the exponent 2.3 used by Lewis in his hysteresis law. It may be that the form of Professor Lewis' hysteresis law has been so successful only because its exponent is so near in value to the exponent which would hold in the case of a frankly empirical overall viscous damping law. If, in some manner, a damping force proportional to velocity actually exists, then the frequency of vibration should also be a factor in the energy lost. This may actually be the case. Amplitudes as big as 6 deg. have been reported on installation having low natural frequencies, whereas 3 deg. is a very large amplitude on rail-car Diesels which have one-noded natural frequencies. It is realized that the difference in physical layout of the systems compared might account for the difference in magnitude without calling in any frequency effect.

It would be interesting if all the available torsiograph records of internal-combustion engines along with the pertinent data of the engines from which the records were taken could be tabulated somewhat as Mr. Porter has presented his results. Actual hysteresis tests on crankshaft steels should be carried out. So far as we know, no American investigator has studied the hysteresis loss as a function of stress amplitude.

APM-52-14

Longitudinal Wave Transmission and Impact

By L. H. DONNELL,[1] ANN ARBOR, MICH.

When a force is applied to a body, waves of stress and velocity radiate through the body from the point of application of the force. When these waves strike the boundaries of the body they may be wholly or partially transmitted to surrounding bodies or reflected back into the body, where they may reverberate back and forth within its confines, like sound waves within the body of air in a closed room. By superposition of these radiated and reflected waves the stress and motion of all parts of the body are gradually, and in general discontinuously, brought up to the values ordinarily assumed.

In the case of a small body this whole process takes place so quickly that there is great difficulty in detecting it, and generally it is of little practical importance. But there are cases where it is desirable to study the process in detail, particularly when the dimensions to be dealt with are no longer very small compared to the velocities of such waves, and in consequence the time element is no longer negligible, or where the time of application or variation of applied forces is very small and hence of the same order of magnitude as the aforementioned time element, as in cases of impact or harmonic forces of considerable frequency. In the present paper an attempt is made to consider some of the more important phases of this subject in as simple a manner as possible.

THE wave transmission considered here is "mechanical" wave transmission or the propagation of mechanical states of matter under the action of the simple laws of mechanics. The propagation of sound, of ripples on the surface of liquids, and of earthquake shocks are familiar examples. So-called "standing" waves, such as observed in the strings and pipes of musical instruments, can be considered to be the result of superposition of systems of transmitted waves.

When a force is applied to a given body, even one which we ordinarily think of as rigid, the body does not really behave as a rigid one—that is, it does not at once assume, as a whole, the state of stress or motion which we predict from elementary mechanics. When the force is applied, waves of stress and velocity radiate through the body from the point of application of the force.

When these waves strike the boundaries of the body, they may be wholly or partially transmitted to surrounding bodies (as sound waves to surrounding air, for instance) or reflected back into the body, where they may reverberate back and forth within the confines of the body, like sound waves within the body of air in a closed room. By superposition of these radiated and reflected waves the stress and motion of all parts of the body are gradually, and in general discontinuously, brought up to, or nearly up to, the values ordinarily assumed. It is necessary to say "nearly," because there is almost sure to be some loss of energy in this process, either to the surroundings or through damping action within the body, although this loss is generally negligible.

In a small body this whole process takes place so quickly that we are unaware of it and would have great difficulty in detecting it, and in such cases it is generally of little practical importance.

But there are cases where it is desirable to study the process in detail, particularly when the dimensions to be dealt with are no longer very small compared to the velocities of such waves, and in consequence the time element is no longer negligible, or where the time of application or variation of applied forces is very small and hence of the same order of magnitude as the aforementioned time element, as in cases of impact or harmonic forces of considerable frequency. In the present paper an attempt is made to consider some of the more important phases of this subject in as simple a manner as possible.

Longitudinal Pressure Waves in Thin,[2] Prismatical Bars—General

Consider a long, thin uniform bar of elastic material, Fig. 1. If an impulse is applied to the end of this bar, say, by a uniformly distributed compressive force f acting on the end for a time t, then a "pressure wave" will be started at the end and will move along the rod. This "pressure wave" is merely a zone in which the material of the rod is under longitudinal compression.

In front of the zone and behind the zone the material is entirely uncompressed and at rest. At each instant new material in front of this zone, as the portion ab, is just about to be compressed, while at the same time material at the rear of the zone, cd, is losing its compression. Thus the *zone* can move along the rod with considerable velocity, although individual particles have only the small motion involved in compression and decompression as the zone passes.

Explanation. The explanation of this phenomenon is roughly as follows: When the force f is applied it compresses the material near the end of the rod. The compressed portion is shortened slightly, which means that some of it suffers a displacement, and in being displaced is given a velocity to the right. Due to its inertia it tends to continue moving at this velocity. It strikes the stationary material in front of it and compresses and starts this moving—but in so doing is stopped itself. Thus the zone of compression moves forward.

It should be noted that the material in the compressed zone always has a certain amount of velocity,[3] while the material in front of and behind it is at rest. Hence we could equally well speak of this zone as a "velocity wave" or zone. We shall see that for a given bar there is a definite relation between the magnitude of the compression and this velocity of the particles; also both are respectively equal to the compression f and the velocity which f produced at the end of the bar when the wave was started.

The velocity of propagation of the wave or zone along the bar, on the other hand, is independent of f and is constant for a given material.

---

[1] Assistant Professor of Engineering Mechanics, University of Michigan. Mem. A.S.M.E.

Contributed by the Applied Mechanics Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] The effect of lateral expansion, which would be of more importance in a thick bar, will be neglected.

[3] This velocity of *particles* of material in the zone must not be confused with the velocity of *propagation* of the zone along the bar.

Quantitative Demonstration

Let f = magnitude of compressive force acting on bar
t = time it acts
L = length of pressure zone
v = velocity of individual particles in the zone
V = velocity with which the zone moves along the bar
m = "inertia constant" of the bar, in this case the mass of the bar per unit length
k = "stiffness constant" of the bar, in this case the modulus of elasticity of the material times the cross-sectional area of the bar.

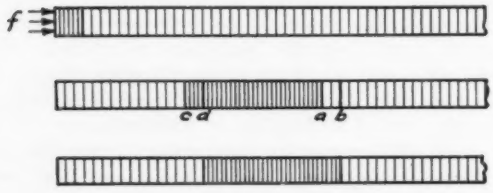

FIG. 1

Assume that, when the constant force f acts on the end of the bar for the time t, the result is a moving pressure zone of length L, all parts of which are under a uniform compression equal to f and have a uniform velocity v. The shortening of the bar due to the compression of this zone will be fL/k. The work done by the external force is therefore:

$$\frac{f^2L}{k} \quad \ldots\ldots [1]$$

This must be equal to the energy stored in the pressure zone, which, no matter where the zone happens to be, consists of the

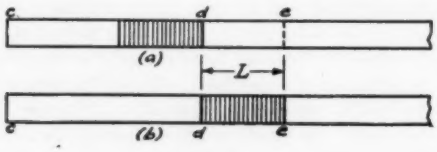

FIG. 2

potential strain energy $f^2L/2k$ (assuming that the material obeys Hooke's law[4]) plus the kinetic energy $mLv^2/2$. Hence:

$$\frac{f^2L}{k} = \frac{f^2L}{2k} + \frac{mLv^2}{2} \quad \ldots\ldots [2]$$

from which

$$v = f\sqrt{\frac{1}{mk}} \quad \ldots\ldots [3]$$

that is, the velocity of particles in a wave equals the compression in the wave times a quantity which depends only on the bar. It is interesting to note that the energy in the zone is, from [2], half potential and half kinetic.

In Fig. 2 consider as a free body a definite portion of the bar de of length L. At a certain instant the pressure zone will be in the position shown in Fig. 2 (a), and, after an interval of time which we shall call for the present t', it will have moved the distance L to the position shown in Fig. 2 (b). During this time t' the element de has had only one external force acting on it, namely, a force f acting on the end d to the right. The total change in momentum of the material in the element during this time is $mL(v - 0) = mLf\sqrt{1/mk}$ (from [3]). The impulse of the external force must equal this change in momentum, or

$$ft' = mLf\sqrt{\frac{1}{mk}}$$

from which

$$\frac{L}{t'} = V = \sqrt{\frac{k}{m}} \quad \ldots\ldots [4]$$

that is, the velocity of propagation[5] of the wave along the bar is $\sqrt{k/m}$, a constant depending only on the material of the bar as both k and m are proportional to the area of the bar. Also the length of the zone is

$$L = Vt' = Vt = \sqrt{\frac{k}{m}}t \quad \ldots\ldots [5]$$

as t' is obviously equal to t, the time the external force f acted on the end of the bar as the wave was started.

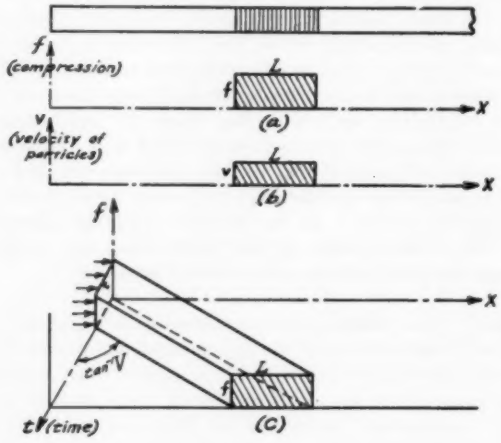

FIG. 3

We have still to prove our assumption that the velocity and compression are constant in all parts of the zone and that the compression equals f. This assumption is certainly true when the wave starts—that is, as it "crosses" the section c at the end of the bar, Fig. 2. Moreover, at the start at least, all longitudinal elements of the bar within the zone[6] have on either side of them elements with the same velocity and pressure. Hence there is no tendency to change conditions within the zone either at this moment or later, and consequently the conformation of the zone remains the same as it started, throughout its motion along the rod (provided the rod is freely supported and no frictional resistances act).

The foregoing equations apply equally well if a *tensile* force acts on the end of the rod, starting a tension wave or zone in which the material is under tension. Tension may be considered to be a negative compression. Equations [3] and [4] show that when the sign of f is changed the sign of v is changed, but V remains the same as before. Thus in a compression wave the

[4] Pressure waves in materials which do not obey Hooke's law are discussed later on.

[5] This is the velocity of the wave relative to the bar. If the bar is moving, then the absolute velocity of the wave will be the vectorial sum of this velocity and the velocity of the bar. Thus sound has a greater absolute velocity *with* the wind than against it.

[6] According to our assumption of a suddenly applied force, elements suffer an infinite acceleration when the *edge* of the pressure zone crosses them. However, the mass involved at any instant is infinitesimal, so it is possible for the unbalanced force f which acts on it at this instant to produce such an acceleration.

velocity of individual particles is in the same direction as the wave moves; but in a tension wave the velocity of the particles is in the opposite direction from that of the wave.

Graphical Representation of Waves

The conditions in a wave such as has been discussed can be shown by diagrams, as in Fig. 3. Fig. 3(*a*) shows the compression f at all points in the rod at a given instant, ordinates above the x-axis representing compression and ordinates below representing tension. Fig. 3(*b*) shows the longitudinal velocity v of particles of the rod at a given instant, ordinates above the x-axis representing velocity to the right and ordinates below representing velocity to the left.

The conditions at all instants can be represented by a three-dimensional diagram such as shown in perspective in Fig. 3(*c*). In this diagram the conditions at any instant are given by a section parallel to the fx plane, as shown shaded.

Methods for Simplifying Complex Problems

If we establish the laws governing simple cases, such as the effect of a constant force under various conditions, it is possible in many cases to study more complex problems by replacing the complex action by an equivalent series of simpler actions and superposing their results.

When conditions are variable it is sometimes convenient to consider the variation to take place in several sudden steps;

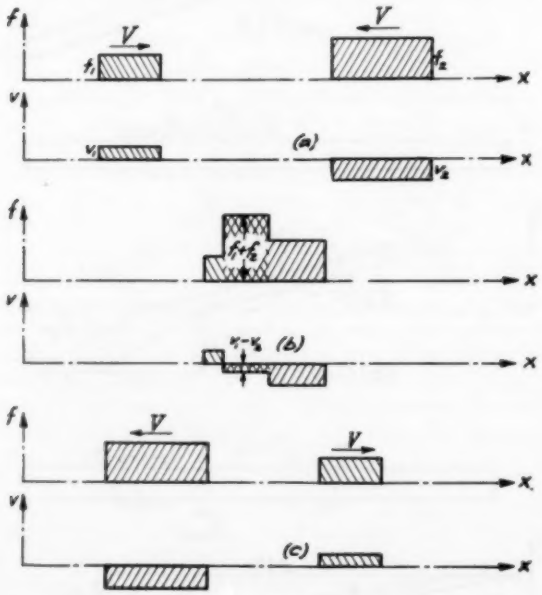

Fig. 4

it is then frequently obvious what the result would be if the number of steps were made infinite.

Superposition of Waves

When two waves such as we have been considering come together, the principle of superposition holds as in other branches of mechanics, if there are no frictional resistances and the material follows Hooke's law. Hence the resulting compression or velocity is the vectorial sum (which in this case is the same as the algebraic sum) of the compressions or velocities in each wave.

When two waves coming from opposite directions meet, as shown in Fig. 4, the compression in the resulting zone is $f = (f_1 + f_2)$, and the velocity is

$$v = (v_1 - v_2) = \frac{(f_1 - f_2)}{\sqrt{mk}} \quad \ldots\ldots\ldots\ldots [6]$$

It is evident that in this zone the relation between f and v given by [3] for a simple wave does not hold, and hence the energy is no longer half kinetic and half potential. However, the total energy in this zone is unchanged; it consists of the potential energy $(f_1 + f_2)^2L/2k$ and the kinetic energy $mL(v_1 - v_2)^2/2 = (f_1 - f_2)^2L/2k$ (from Equations [2] and [3]). The sum of these is $(f_1^2 + f_2^2)L/k$, which equals the energy before meeting. After

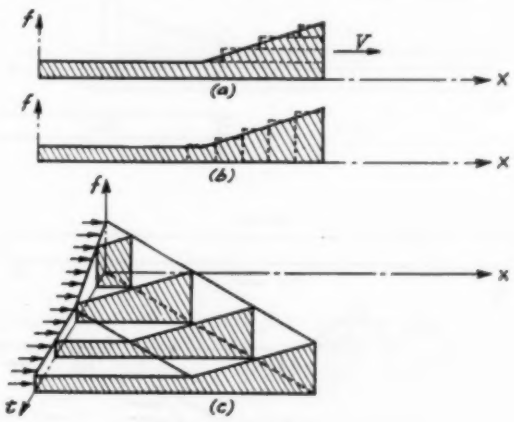

Fig. 5

passing, the waves return to their original conformation the same as if they had never met, as in Fig. 4(*c*).

If two waves going in the same direction superpose (as is possible when waves are started by forces at intermediate points along the rod) the resulting compression, by the principle of superposition, is $(f_1 + f_2)$ and the velocity $(v_1 + v_2)$. The relation between f and v in this case is the same as in a simple wave produced by a single force, Equation [3], and the energy will be half potential and half kinetic. However, the energy will be found to be considerably more than it would be if the superposed waves were separated. (This could also be predicted from the fact that, from [2], the energy of a wave varies as the square of f or v.) The explanation is that additional work is done by one external force due to the particle motion in the wave started by another external force.

Waves Produced by Variable Forces

If the external force producing the wave varies—suppose, for example, it decreases uniformly for a while and then remains constant—we can imagine it to be replaced by a series of constant forces, either as indicated by Fig. 5 (*a*) or Fig. 5 (*b*). In this manner, if we know the laws governing waves produced by constant forces, we can apply them to cases where the forces vary.

It is very useful, for visualizing the action in complex cases, to note that as the wave moves along the rod it keeps the same conformation—just as though the fx curve were constructed on paper and drawn across the end of the rod and out along the rod. Thus in Fig. 6 imagine the shaded figure drawn on a piece of cardboard *abcd* and the cardboard moved to the right past the fixed end of the rod *e*. The ordinate *pq* of the diagram passing the end of the rod represents the magnitude of the external force acting on the end of the rod at the instant. The fx diagram is thus seen to be a moving record of the value of the external force on the end of the rod; the ordinate *rs*, farthest

from the end, represents the initial value of this force, and, as we go back, the ordinates between give a complete history of the value of the external force up to the present. This is also shown by Fig. 5(*c*); the fx diagram at any instant is the same as the ft diagram up to that point (which is the history of the external force) except that the horizontal dimensions are multiplied by V.

Waves Due to a Force Applied at an Intermediate Section

Consider a force f applied at section d, Fig. 7, for a time t. The effect is the same as if the force f acted partly on the end of

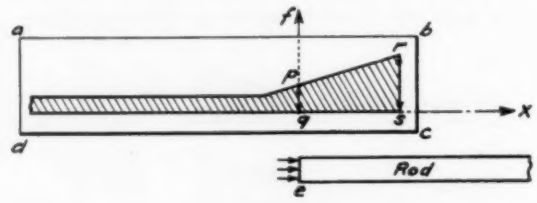

Fig. 6

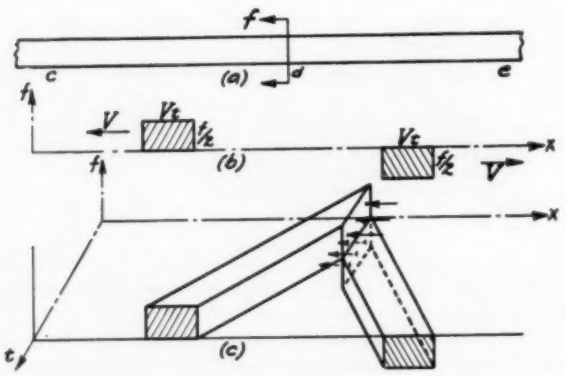

Fig. 7

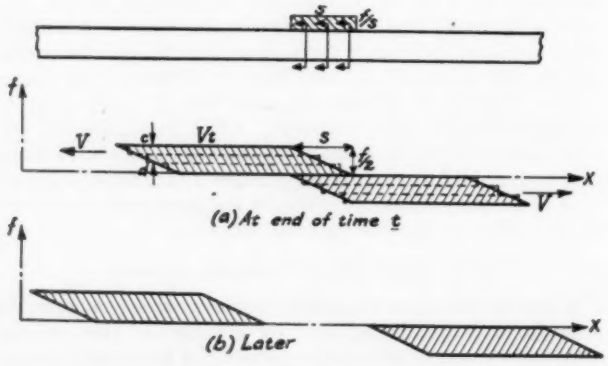

Fig. 8

a rod dc and partly on the end of a rod de, sending a compression wave of length $L = Vt$ along dc to the left, and a tension wave of the same length along de to the right. Since the velocity of particles at the section d is the same for both rods when the waves are started, the force f must, from [3], be equally divided between dc and de.[7] Hence the wave traversing dc will be under a compression of $f/2$ and the one traversing de under a tension of $f/2$, as shown in Fig. 7 [*b*] and [*c*].

If the force f is distributed, say, uniformly over a length s of the rod (that is, a distributed force f/s per unit length, acts for a time t), the result will be the same except that portions of the wave due to different parts of the force will be displaced lengthwise with respect to each other, as shown in Fig. 8. (In these figures the compression at any point is the vertical intercept of the shaded figures, as, for instance, the length cd.) The

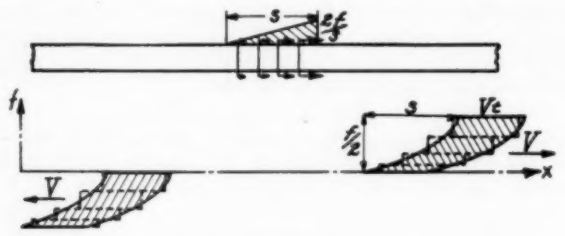

Fig. 9

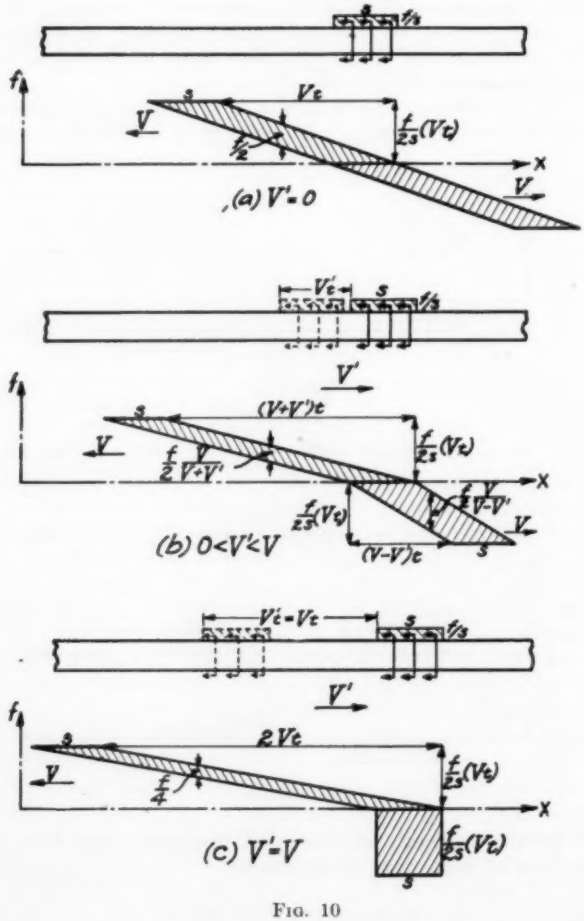

Fig. 10

broken lines show what the result would be if the distributed force were replaced by three concentrated forces; if it were replaced by a larger number of concentrated forces we should obviously approach the condition shown by the full lines.

Similarly a force with triangular distribution would give rise to the waves shown in Fig. 9. These waves, produced by distributed forces, have the same area of fx diagram as if the forces were concentrated. However, their energy is less, because the

[7] If two different rods are joined at d, the condition for equal velocities at d is, from [3]:

$$f_{cd}\sqrt{\frac{1}{m_{cd}k_{cd}}} = f_{de}\sqrt{\frac{1}{m_{de}k_{de}}}$$

and the force f would be divided between the two rods in the ratio given by this equation.

energy depends on the square of f and the first power of L, from Eq. [1]; the explanation is that conditions are here the reverse of those considered before, under superposition of forces—there we were superposing the effects of forces, and here we are separating them.

Waves Produced by Traveling Forces

These are of interest in connection with the study of frictional resistances, longitudinal waves in railway trains, etc. Suppose that a force f is uniformly distributed over a length s and that its place of application moves uniformly along the rod (to the right in Fig. 10) at the rate V'. If the force is applied for a time t, then its place of application will move a distance $V't$ during this time.

When $V' = 0$ we have the case shown in Fig. 8(a); this can evidently be equally well represented in the form shown in Fig. 10 [a]. When V' is not zero we have the result shown in Fig. 10(b); this can be shown by replacing the moving force by a series of fixed forces acting successively at different points along the rod.

If $V' = V$ the conditions become as shown in Fig. 10(c). In this case the effect is cumulative on the wave going in the same direction as the forces. The compression in this wave, $(f/2s) \times (Vt)$, increases with time and is inversely proportional to s. Hence a concentrated force ($s = 0$) whose point of application moves with the velocity V would immediately produce infinite stresses—in practice failure or plasticity—and even a force not perfectly concentrated would soon produce such conditions.

Longitudinal Waves in Railway Trains

When a train passes over an unevenness in the track the effect is the same as that of a force whose point of application travels along the train at the speed at which the train is moving. A long train may be considered roughly as a bar with uniformly distributed mass (at least the part of the train behind the locomotive) and more or less uniformly distributed flexibility (due almost entirely to the coupling springs). It will have a definite rate of propagation of tension or compression waves, depending on the mass of the cars and the characteristics of the couplings.

The longitudinal external forces on a train are: (1) The frictional resistances to the motion of the train, which never change suddenly and so can hardly produce any of the effects we are considering. (2) Braking forces, which may be changed suddenly but which are usually uniformly distributed along the length of the train and hence balanced at each point by the resulting inertia forces, in which case they would not produce waves. (3) The pull of the engine, which may change suddenly and produce waves in the train of the same type as when a force is applied to the end of a bar. (4) The longitudinal component of gravity forces, which may act as a traveling force, as stated at the beginning. It should be noted that what we are interested in here is sudden *changes* in these forces, which are not immediately balanced locally as was assumed to be the case with braking forces. Thus if conditions are steady, with the engine exerting a pull of 5 tons, and its pull is suddenly increased to 8 tons, the effect is to superpose on the previous steady conditions a suddenly applied tensile force of 3 tons; if the pull is decreased the effect is that of a suddenly applied compressive force. If the change is spread over a considerable period of time the result is not so great, because by the time the full change is in effect there are likely to be other counterbalancing forces locally applied and the wave started by the first part of the change may have come back, reflected from the free end of the train as a wave of *opposite* sign, as considered later.

From the previous discussion it would seem that bad effects may be produced by the cumulative effect of gravity components when the train traverses a change in the slope of the track at the same speed as the speed of propagation of longitudinal waves. Such effects might of course be controlled by designing the couplings so that the speed of propagation of waves would be above the speed range of the trains. Let b = length of each car, B = length of the train, W = weight of the train, and K = spring constant of a complete coupling (including the portion

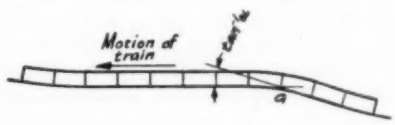

Fig. 11

on both of the cars connected). Then the average inertia and stiffness constants are respectively

$$m \triangleq \frac{W}{gB} \quad \text{and} \quad k = bK$$

The velocity of propagation of waves is

$$V = \sqrt{\frac{k}{m}} = \sqrt{\frac{bKgB}{W}}$$

When the train passes a *change* in slope of the tracks equal to α, as shown at a, Fig. 11, the change in longitudinal gravity component is a distributed force of approximately $W\alpha/B$ per unit length. If the train is moving to the left in Fig. 11, this is equiva-

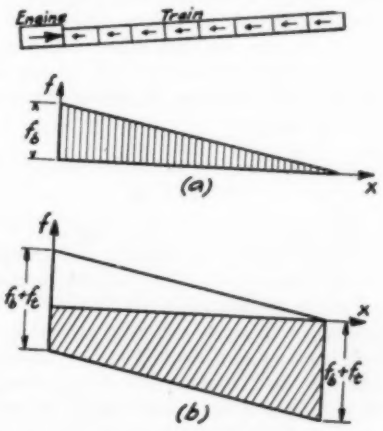

Fig. 12

lent to a traveling force acting to the left and moving along the train to the right a distance equal to the length of the train. Comparing this with Fig. 10(c) it is evident that the greatest effect is a tension in the rear of the train as it passes a, whose magnitude is $W\alpha B/2B = W\alpha/2$. If α is negative, this is a compression.

The greatest load on a coupling under steady conditions is likely to be at the front of a train going up a grade. The maximum tension would be $W'\alpha'$, where W' is the weight of the train minus the engine, and α' the absolute slope of the grade. The dynamic tension $W\alpha/2$ was calculated on the assumption that the train was homogeneous longitudinally. Actually it is a series of distinct units, and it is reasonable to suppose that as the wave front passes along such a series of units the tension will fluctuate above and below the average value $W\alpha/2$, so that the maximum tension may be greater than that calculated. The conditions in practice are more complicated than those assumed.

As another example consider the case of a railway train made up of cars having no individual brakes, so that any braking effort must be applied entirely at the engine. If such a train is descending a grade at a uniform speed, being held back by the braking force f_b applied by the engine (which will be equal to the longitudinal component of the weight of the train minus the frictional resistance), there will be a static state of compression along the train as indicated in Fig. 12(*a*). If now the engineer suddenly releases the brakes and opens the throttle sufficiently to apply a tractive force f_t (as is not unusual, when approaching the bottom of the grade), this is equivalent to superposing upon the foregoing condition a suddenly applied tensile force of $f_b + f_t$. This sends a tension wave along the train which, superposing on the previous condition of compression, produces the condition indicated in Fig. 12(*b*) when it reaches the end of the train. It will be observed that the coupling of the rear car is subjected to a tensile load of approximately $f_b + f_t$ at this instant, which may be sufficient to produce fracture.

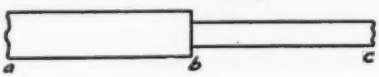

FIG. 13

In the propagation of pressure waves in trains the damping effect of friction is probably not as great as might be thought. If the velocity of the train is in the same direction as the velocity of particles v produced by a wave, or if it is in the opposite direction but is larger than v (as will usually be the case), then the total velocity of any part of the train will always be in the same direction, whether a wave is passing or not. Consequently that part of the frictional resistances which is of the type exhibited by solids rubbing on each other, being independent of the velocity, will exert a constant force unaffected by waves, and can play no part whatever in either the propagation or dissipation of such waves.

EFFECT OF A SUDDEN CHANGE IN CROSS-SECTION OR MATERIAL OF A BAR[8]

Section *b*, Fig. 13, represents the junction of two uniform portions *ab* and *bc* having the inertia and stiffness constants m_a, k_a and m_c, k_c, respectively. Let a pressure wave having the compression f strike the section *b* from the left. We may consider that this wave is wiped out as it crosses *b*, but that the pressure which it exerts at *b* starts two new waves from *b*—one which we shall call the "transmitted" wave moving to the right along *bc* with a compression f_t; and one which we shall call the "reflected" wave moving back along *ab* with a compression f_r. This is shown in Fig. 14.

Equilibrium of an element of the rod at *b* during this process requires that[9]

$$f + f_r = f_t \qquad [7]$$

The resultant velocity of particles to the left of section *b* during this process is, from [6],

$$v = \frac{f - f_r}{\sqrt{m_a k_a}}$$

and this must be equal to the velocity to the right of *b*, or

$$\frac{f - f_r}{\sqrt{m_a k_a}} = \frac{f_t}{\sqrt{m_c k_c}} \qquad [8]$$

Solving [7] and [8] for f_t and f_r, and letting $\sqrt{m_c k_c / m_a k_a} = r$, we find the compression in the transmitted wave is

$$f_t = \frac{2r}{r+1} f \qquad [9]$$

and the compression in the reflected wave is

$$f_r = \frac{r-1}{r+1} f \qquad [10]$$

The velocity of particles in these waves can be found from [3]. The length of the reflected wave is the same as that of the original wave; the length of the transmitted wave is V_c/V_a or $\sqrt{m_a k_c / m_c k_a}$ times the length of the original wave. If the sudden change is one of area only, from A_a to A_c, then the lengths of all three waves are the same and $r = A_c/A_a$.

Equation [10] shows that if $r < 1$ (as when a wave strikes a reduction in area) the reflected wave is of opposite sign to the original—tension if the latter is compression, and compression if the latter is tension. If $r > 1$ (as when a wave strikes an enlargement) the reflected wave is of the same sign as the original. The transmitted wave is, from [9], always of the same sign as the original wave.

If $r = 1$ (that is, *b* is merely a section in a uniform bar) then [9] and [10] reduce to $f_t = f$ and $f_r = 0$, as expected.

FREE AND FIXED ENDS

If m_c and k_c are zero (that is, *b* is a free end of the bar) then r is zero, and we find from [9] and [10] that $f_t = 0$ and $f_r = -f$. This means that a wave is reflected back from a free end unchanged except for sign; a compression wave is reflected as a similar tension wave, and vice versa. Superposition of the incoming and outgoing waves at the free end makes the resultant compression there zero, while the resultant velocity of the particles at this point is

$$\frac{f - (-f)}{\sqrt{m_a k_a}} = \frac{2f}{\sqrt{m_a k_a}}$$

or twice the velocity in the original wave.

If k_c is infinite (that is, *b* is a rigidly fixed end) then r is infinite and we find $f_r = f$; hence the wave is reflected back entirely unchanged. Also $f_t = 2f$; however, the energy in this transmitted wave is, from [1], $f_t^2 L/k_c = 0$. Half of f_t can be considered as produced by the incoming wave, while the other half starts the outgoing wave. The resultant velocity of particles at this point is $(f - f_t)/\sqrt{m_a k_a} = 0$, as would be expected.

LONGITUDINAL IMPACT ON A PRISMATICAL BAR BY AN INFINITE MASS

If a perfectly rigid mass moving with a longitudinal velocity v_0 strikes the end of a bar squarely,[10] a pressure wave will be started having a velocity of particles equal to v_0, and hence a compression, from [3], of

$$f_0 = v_0 \sqrt{mk} \qquad [11]$$

This force will also be acting on the mass, tending to decelerate it. If the mass is of infinite size, however, it will continue to

[8] It will be assumed for the present that stresses are at all times uniformly distributed over the cross-sections, although this is of course not true locally when there is a change in the cross-sections. The effect of non-uniform distribution is discussed under "Gradual Changes."

[9] There are no changes of velocity *within* the waves considered, hence no inertia forces enter this equation of equilibrium.

[10] We must assume that contact takes place at the same instant over the whole surface of the end of the rod, although this condition is difficult to realize in practice.

move at the velocity v_o and the wave sent out will have a uniform compression f_o.

If the other end of the bar is free, this wave, on reaching the other end, will be reflected back with opposite sign. The portion coming back will superpose on the portion going out, producing a resultant compression $f_o - f_o = 0$ and a resultant velocity of particles $v_o + v_o = 2v_o$. When the reflected wave gets back to the starting point (which will be after a total time $2b/V$, where b is the length of the rod), the whole rod will be under zero stress and moving with a velocity twice that of the mass, so that it will separate from the mass at this instant and all waves will cease. This condition will be approximated if a large mass strikes a small free rod.

We also have a condition like this if two equal free rods c and d strike each other longitudinally. If the rods have initial velocities of v_c and v_d, respectively, the plane of contact will have a constant velocity of $(v_c + v_d)/2$ during the impact.[11] Hence the effect on each rod is the same as being struck by an infinite mass moving at this speed, $(v_c + v_d)/2$. Now for rod c,

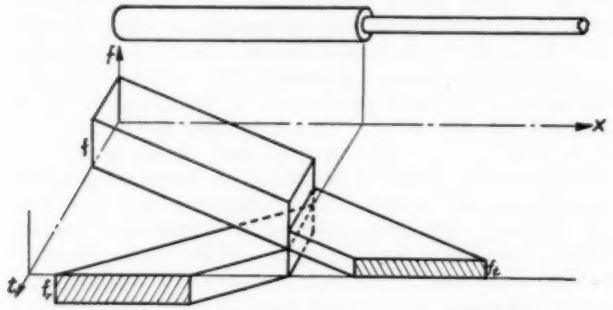

FIG. 14

this would be the same as if it were stationary and the infinite mass had a velocity of

$$\frac{v_c + v_d}{2} - v_c = \frac{v_d - v_c}{2},$$

within an isolated system having a uniform velocity of v_c. From the preceding paragraph the velocity of rebound inside this system will be twice the velocity of the infinite mass, or $2(v_d - v_c)/2 = v_d - v_c$. This, added to the velocity of the system, gives the absolute final velocity of c as $(v_d - v_c) + v_c = v_d$. Similarly, the final velocity of d will be v_c. The length of time the bars are in contact is of course $2b/V$, and the maximum compressive force is $\frac{v_d - v_c}{2}\sqrt{mk}$.

If the bars are of unequal length, b_c and b_d (suppose $b_c < b_d$) but are of the same materials and cross-sections, the conditions will be just the same as above at first, because the lengths can have no effect until the reflected waves get back. The pressure between the bars will become zero when the reflected wave returns in the shorter bar (after a time $2b_c/V$) and the conditions in the shorter bar c will be just the same as above; that is, all waves will have ceased and it will be moving at a velocity v_d. As the end of the longer bar in contact with it is now moving with the same velocity the bars will remain in contact, but without pressure, until the reflected wave returns in the longer bar (after a total time $2b_d/V$), and at this moment the longer bar will have a wave moving in it of total length $2b_c$ and a uniform compression $\frac{v_d - v_c}{2}\sqrt{mk}$. This wave will continue to move along the rod after separation, being reflected from the two free ends with a change in sign at each reflection, until it is damped out by friction. From the law of conservation of momentum, after separation the total momentum of the longer bar divided by the mass of the bar (let us call this the "average" velocity of the bar, v_d') must remain constant and is found from

$$mb_cv_c + mb_dv_d = mb_cv_d + mb_dv_d'$$

which gives $v_d' = v_d + (b_c/b_d)(v_c - v_d)$. This is the velocity which d will have when the waves are all damped out; the kinetic energy in the system will then be $(m/2g)(b_cv_d^2 + b_dv_d'^2)$,

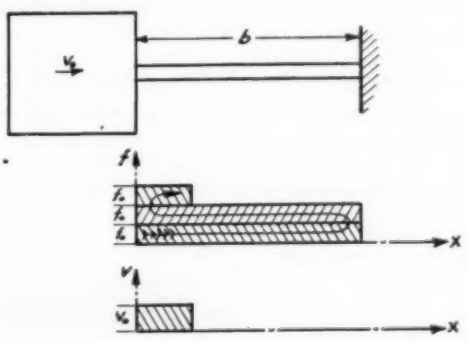

FIG. 15

while the original energy was $(m/2g)(b_cv_c^2 + b_dv_d^2)$. The ratio of lost energy to the original energy is therefore, using the above value of v_d':

$$\frac{(b_cv_c^2 + b_dv_d^2) - (b_cv_d^2 + b_dv_d'^2)}{(b_cv_c^2 + b_dv_d^2)} = \frac{\left(1 - \frac{b_c}{b_d}\right)(v_c - v_d)^2}{\left(v_c^2 + \frac{b_d}{b_c}v_d^2\right)}$$

If the bars are of unequal materials or cross-sections, and have the constants m_c, k_c, and m_d, k_d, then the plane of contact, during the impact, will have a constant velocity v_s of such a magnitude that the compressions of the waves started in the two bars will be the same, or:

$$f_c = (v_s - v_c)\sqrt{m_ck_c} = -f_d = (v_d - v_s)\sqrt{m_dk_d} \quad \ldots [12]$$

from which

$$v_s = \frac{\alpha v_c + v_d}{\alpha + 1}, \text{ where } \alpha = \sqrt{\frac{m_ck_c}{m_dk_d}} \quad \ldots [13]$$

As before, the pressure between the bars will drop to zero when the reflected wave returns in one of the bars, and actual separation will occur as soon as it returns in both of them, that is, after a time $2b_c/\sqrt{k_c/m_c}$ or $2b_d/\sqrt{k_d/m_d}$, whichever is larger. Following the same reasoning as before, if the reflected wave returned first in bar c, then this bar will be unstressed after separation and will have a velocity of $2v_s - v_c$. The bar d will have a wave moving in it, at separation, of length $2b\sqrt{k_d/m_d}/\sqrt{k_c/m_c}$ and with a uniform compression given by [12]. Using the law of conservation of momentum, the "average" velocity of this bar will be constant and equal to $v_d + 2\beta(v_s - v_s)$, where $\beta = m_cb_c/m_db_d$. The maximum compression in each bar is given by [12], and the lost-energy ratio, obtained as before, is

$$\frac{4(\alpha - \beta)(v_c - v_d)^2}{(\alpha + 1)^2(v_c^2 + \frac{1}{\beta}v_d^2)}.$$

[11] If we consider the rods to be parts of an isolated system having a uniform velocity of $(v_c + v_d)/2$, then they will have symmetrical motion within this system, and from symmetry within this system their plane of contact must be stationary with respect to the system—and will thus have an absolute velocity of $(v_c + v_d)/2$.

If a perfectly rigid infinite mass strikes one end of a bar which is fixed at the other end, the resulting wave (with compression given by [11]) will, on reaching the fixed end, be reflected with the same sign. The reflected portion, superposed on the portion going out, produces a resultant compression $f_o + f_o = 2f_o$ and a resultant velocity of particles $v_o - v_o = 0$. When the reflected wave gets back to the end struck, the velocity of this end must remain v_o; hence the wave must be reflected again as from a fixed end, so as to make the resultant velocity due to the three superposed waves $v_o - v_o + v_o = v_o$; the resultant compression is $f_o + f_o + f_o = 3f_o$, as shown in Fig. 15. The wave will continue to emerge from the end struck and to be reflected from both ends without change of sign, so that the compression at the end struck will increase by the amount $2f_o$ at the end of every interval of time $T = 2b/V$.

Longitudinal Impact by a Finite Mass

If the mass is rigid but of a finite magnitude M, then the compression in the rod at the end in contact with it will decelerate it, and its velocity (and hence the velocity of particles in the rod at this point) will gradually decrease, as indicated

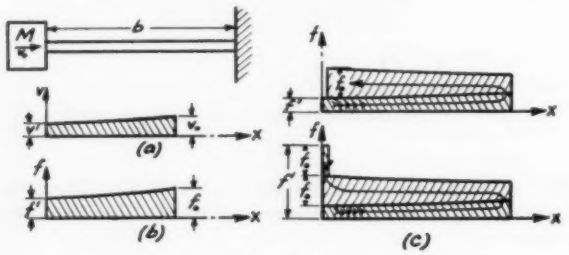

Fig. 16

by Fig. 16(*a*). Also, from [3], the compression in the rod at this point must decrease proportionally, as indicated by Fig. 16(*b*). Calling the compression and velocity of particles at the end struck f' and v', the equation of equilibrium of the mass M is

$$f' + M\frac{dv'}{dt} = 0$$

From [3], $v' = \frac{1}{\sqrt{mk}} f'$, and this equation becomes, letting $\frac{\sqrt{mk}}{M} = B$:

$$\frac{df'}{f'} = -Bdt$$

Integrating,

$$\log_e f' = -Bt + c, \text{ or: } f' = C_e{}^{-Bt}$$

Using the initial condition that $f' = f_o$ when $t = 0$, we find that $C = f_o$, hence

$$f' = f_o e^{-Bt} \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

After an interval of time $T = 2b/V$ (that is, just before the reflected wave returns), f' and v' will be

$$f' = f_o e^{-BT} = f_o e^{-2/\mu},\ v' = \frac{f'}{\sqrt{mk}} = \frac{f_o}{\sqrt{mk}} e^{-2/\mu} = v_o e^{-2/\mu}$$

where $\mu = M/mb$ is the ratio of the mass of the striking body to the mass of the rod, so that

$$BT = \frac{\sqrt{mk}}{M}\frac{2b}{V} = \frac{\sqrt{mk}}{M} 2b\sqrt{\frac{m}{k}} = \frac{2mb}{M} = \frac{2}{\mu}$$

If the other end of the rod is free, the reflected wave will be of opposite sign and, when it returns, v' will be suddenly increased by v_o, the particle velocity of the wave front. As M will still be moving at the above velocity $v_o e^{-2/\mu}$, separation will occur at this instant. The "average velocity" of the rod after separation, found from the law of conservation of momentum, is $\mu v_0 (1 - e^{-2/\mu})$. A wave of length $2b$ and a compression which can be found from [14] will be left moving in the rod. The maximum compression is of course f_0 and the time of contact T. The lost-energy ratio, obtained as before, is:

$$1 - e^{-4/\mu} - \mu(1 - e^{-2/\mu})^2$$

If the other end of the rod is fixed the reflected wave will be of the same sign and f' will be suddenly increased by $2f_0$ at the end of every interval of time T, due to the return of the wave front, as shown in Fig. 16(*c*). We must therefore obtain a separate expression for f' for each one of these intervals. After the first interval there will be waves going out from the end struck and the same waves coming back to this end an interval of time T later, having been reflected from the opposite end. Let us designate by F the total compression, at the end struck, of all waves moving *away* from this end. For the reasons given above we need a separate expression for F for each interval. Let us designate the expressions for F after the intervals of time $0T$, $1T$, $2T$, $3T$, $\ldots\ldots nT$ by: $F_0, F_1, F_2, F_3 \ldots F_n$. F_0 is given by [14]. The resultant wave coming back *toward* the end struck is merely the wave *sent out* during the preceding interval, delayed, however, a time T, due to its travel across the rod and back. The compression which it produces at the end struck is obtained by substituting $(t - T)$ for t in the expression for the wave sent out during the preceding interval. The general expression for the total compression at the end struck during any interval is therefore

$$f' = F_n + F_{n-1}(t - T) \ldots\ldots\ldots\ldots [15]$$

where $F_{n-1}(t - T)$ means the expression F_{n-1} with t replaced by $(t - T)$. The net velocity of particles at the end struck is, from (6),

$$v' = \frac{1}{\sqrt{mk}}\left[F_n - F_{n-1}(t - T)\right] \ldots\ldots\ldots [16]$$

The equation of equilibrium of the mass M during this interval is, as before:

$$f' + M\frac{dv'}{dt} = 0$$

Using [15] and [16] and $B = \sqrt{mk}/M$, this becomes

$$dF_n + BF_n dt = dF_{n-1}(t - T) - BF_{n-1}(t - T)\,dt$$

This can easily be integrated by multiplying through by e^{Bt}:

$$[e^{Bt}dF_n + BF_n e^{Bt}dt] = [e^{Bt}dF_{n-1}(t - T) + BF_{n-1}(t - T)\,e^{Bt}dt] - 2BF_{n-1}(t - T)\,e^{Bt}dt$$

$$d[e^{Bt}F_n] = d[e^{Bt}F_{n-1}(t - T)] - 2BF_{n-1}(t - T)\,e^{Bt}dt$$

Integrating and dividing by e^{Bt},

$$F_n = F_{n-1}(t - T) - 2Be^{-Bt}\int F_{n-1}(t - T)\,e^{Bt}dt + C \ldots [17]$$

Using this we can find the expressions F_0, F_1, F_2, etc., in turn starting with the known value of F_0, the right-hand side of [17] being always given by the preceding expression which we have just determined. The integrals will be of known functions of t, which in our case are easily integrated. The integration constant C is found in each case by using the condition that

f' at the beginning of any interval is equal to $2f_0$ plus the value of f' at the end of the last interval, that is, when $t = nT$,

$$F_n + F_{n-1}(t - T) = 2f_0 + F_{n-1} + F_{n-2}(t - T)$$

In this manner we find that:

$$F_0 = f_0 e^{z_0}(1), \qquad \text{where } z_0 = \frac{2}{\mu}\left(-\frac{t}{T}\right)$$

$$F_1 = F_0 + f_0 e^{z_1}(1 + 2z_1), \qquad \text{where } z_1 = \frac{2}{\mu}\left(1 - \frac{t}{T}\right)$$

$$F_2 = F_1 + f_0 e^{z_2}(1 + 2{\cdot}2z_2 + 2z_2^2), \qquad \text{where } z_2 = \frac{2}{\mu}\left(2 - \frac{t}{T}\right)$$

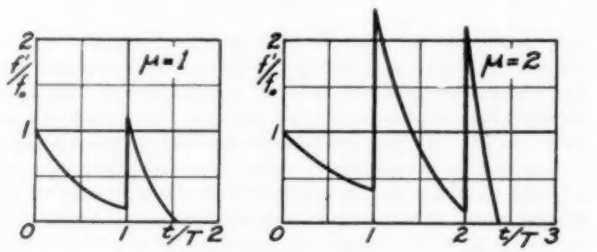

FIG. 17

$$F_3 = F_2 + f_0 e^{z_3}\left(1 + 2{\cdot}3z_3 + 2{\cdot}3z^2 + \frac{2{\cdot}2{\cdot}3}{3{\cdot}3}z^3\right)$$

$$\text{where } z_3 = \frac{2}{\mu}\left(3 - \frac{t}{T}\right)$$

etc. The general expression for any interval is:

$$F_n = f_0 \sum_{m=0}^{m=n} e z_m \sum_{h=0}^{h=m} \frac{m!(2z_m)^h}{(h!)^2(m-h)!} \quad \text{where } z_m = \frac{2}{\mu}\left(m - \frac{t}{T}\right) \qquad \ldots\ldots [18]$$

and where h, m, n are integers, and $0! = 1$ (see footnote 12), $1! = 1$, $2! = 1{\cdot}2$, $3! = 1{\cdot}2{\cdot}3$, etc.

Using these expressions in [15] and [16], the values of f' and v' at all instants are determined for any value of μ. Fig. 17 shows the variation of f' with time, obtained in this way, for $\mu = 1$ and $\mu = 2$.

Separation occurs when f' becomes zero. The time of contact is therefore obtained by setting the various expressions for f' equal to zero and solving for t/T, using only such values of μ as give values of t/T within the interval for which each expression applies. In some cases, for a given value of μ, several values of t/T are obtained (in successive intervals) at which $f' = 0$. In such cases the smallest value of t/T only is used, because separation of course takes place the *first* time f' becomes zero. Subsequent values of t/T at which it becomes zero would have a meaning only if M were attached to the end of the rod. The results of such calculations are plotted in Fig. 18, which also shows an approximate expression for the time of contact, calculated empirically to match the actual curves as closely as possible and, when μ is very large, to approach the value obtained by neglecting the mass of the rod entirely (in which case the end of the rod would undergo a half oscillation of simple harmonic motion):

$$\text{Time of contact} = \frac{b}{V}\left[\pi\sqrt{\mu + \frac{1}{2}} - \frac{1}{2}\right]$$

Method of Obtaining Maximum Compression or Unit Stress in the Rod During Impact

The maximum compression or unit stress in the rod during impact is obtained as follows: The total compression at any point in the rod during impact is always the sum of two values of F, one in the resultant wave going in one direction and one in the resultant wave going in the opposite direction. When the portion of wave with a compression equal to the *maximum* value of F strikes the fixed end and is reflected there, both waves will have this maximum value; the total compression at this point and at this instant is as great as can occur during the impact because at no other point or instant can we have two values

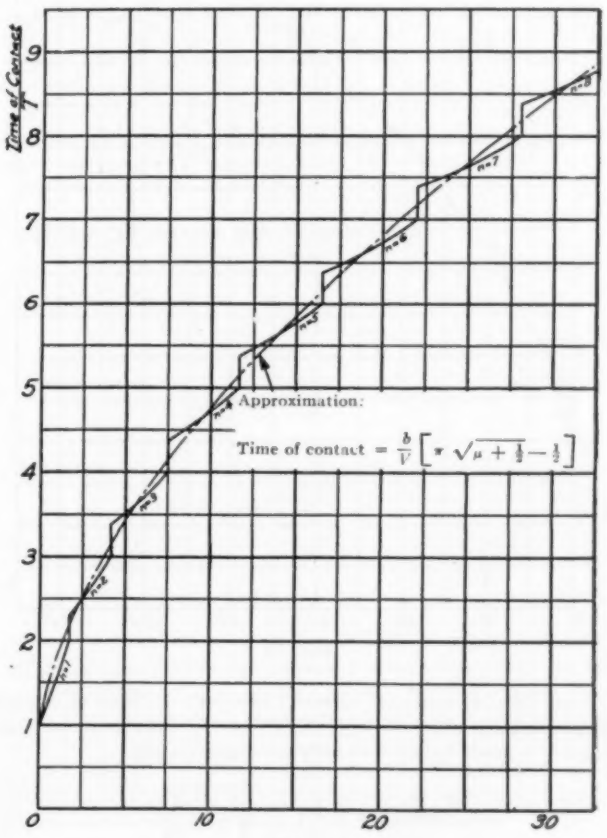

FIG. 18

of F greater than this.[13] Hence the maximum compression during impact occurs in general at the fixed end and is equal to twice the maximum value of F. Now F varies in something the same fashion as f', shown in Fig. 17, rising to a peak at the beginning of each interval and then decreasing. Hence in searching for the maximum value of F we need consider only the values at the beginning of each interval; the general expression for these is obtained by substituting $t/T = n$ in [18], which makes $z_m = 2/\mu(m - n)$. This gives us an expression for F/f_0 as a function of μ and n only. It is then only a question of what

[12] That this is not merely a convention can be shown as follows: $m! = \frac{(m+1)!}{m+1}$, and if $m = 0$, we have $0! = \frac{(0+1)!}{0+1} = 1$.

[13] F may have two equal maximum values an interval of T apart which combine at one instant at the end struck.

value of n to use to get the greatest F for any particular value of μ. This is solved by plotting F/f_0 against μ for *each* value of n (which must be an integer) and selecting only those portions of the resulting curves which rise above their fellow-curves. This has been done in Fig. 19, except that $2F/f_0$ is plotted instead of F/f_0, so that the resulting curves give the maximum compression in the rod for any value of μ.

The empirical curves Max. $f = f_0\,(1 + \sqrt{\mu + 1})$ and Max. $f = f_0(1 + \sqrt{\mu})$, calculated as above, practically form an en-

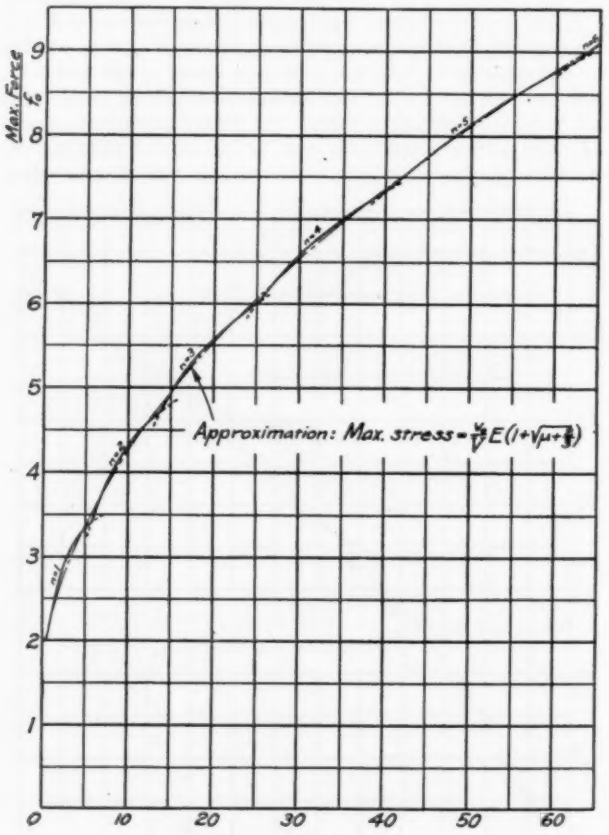

FIG. 19

velope for this series of curves. The first of these is a good approximation which is on the safe side, but the closest approximation is given by a curve between these, namely

$$\text{Max. } f = f_0\left(1 + \sqrt{\mu + \frac{2}{3}}\right)$$

as shown on the chart.

The velocity of the mass M at separation (and from this the lost-energy ratio) can be obtained by taking values of μ, t/T, and n from Fig. 18 and substituting them in [18], and then in [16]. The results of such calculations are plotted on Fig. 20. A rough approximation to this very irregular function, calculated as above and also plotted on the chart, is:

$$\text{Velocity of } M \text{ at separation } = v_0\sqrt{1 - \frac{2}{\mu^{1.3} + 3}}$$

With this approximation the lost-energy ratio, obtained as before, is $\dfrac{2}{\mu^{1.3} + 3}$.

EFFECT OF A GRADUAL CHANGE IN CROSS-SECTION OR MATERIAL OF BAR[14]

A gradual change in section or material may be considered to be brought about in a series of small, sudden steps such as previously considered. As a wave is transmitted through such a series of steps there will be reflection at each step. The reflected waves must travel back through the steps, and in so doing give rise to doubly reflected waves, and these to trebly reflected waves, and so on. The original transmitted wave combines with all waves due to an even number of reflections to form a resultant forward-moving wave, which we shall call the resultant transmitted wave f_t. The waves due to an odd number of reflections combine to form a backward-moving wave which we shall call the resultant reflected wave f_r.

SMALL CHANGE WITH COMPARATIVELY LONG WAVES

If the change is a comparatively small one (say, $4 > r > 1/4$, where r is defined as before), the waves due to successive reflections quickly approach zero. If a long, uniform wave passes through such a change, as, for instance, the change in area shown in Fig. 21, the conditions in the varying portion change at first due to the successive reflections, but quickly approach a stable condition as the successive reflections become smaller. After a length of wave equal to several times the length of the varying portion has passed, we can consider that conditions in this portion of the bar are constant with time. If they are constant with time there are no accelerations or inertia forces, and equilibrium requires that the total compression must be constant along the length of the varying portion. The total velocity of particles must also be constant along the length, as otherwise the compression would change with time. Consequently the compression of the resultant reflected wave f_r at the beginning of the varying portion and of the resultant

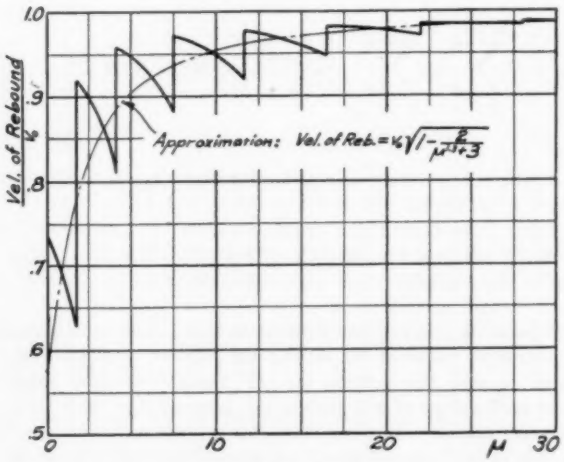

FIG. 20

transmitted wave f_t at the end of the varying portion are found by the same reasoning as for a sudden change, and are given by [9] and [10]. The magnitudes of f_r and f_t at any intermediate section such as b, Fig. 21, are found from the conditions that the resultant compression remains constant, or

$$f_t + f_r = f + \frac{r - 1}{r + 1} f$$

[14] It is assumed that the waves are started on a plane perpendicular to the axis of the rod and remain so. This will not involve great error if the changes in section are gradual.

and that the resultant velocity remains constant, or

$$\frac{f_t - f_r}{\sqrt{m_b k_b}} = \frac{f - \dfrac{r-1}{r+1} f}{\sqrt{m_a k_a}}$$

where m_b and k_b are the constants at section b. Solving for f_t and f_r and letting $\sqrt{\dfrac{m_b k_b}{m_a k_a}} = r_b$,

$$f_t = \frac{r + r_b}{r+1} f \quad \text{and} \quad f_r = \frac{r - r_b}{r+1} f$$

It is well known that when a bar with a *sudden* change in cross-section (such as shown by the broken lines in Fig. 21) is under compression, the material at the corners (shown shaded in the figure) is more or less dead material which takes little part in the action. It may be presumed, therefore, that in the case of a sudden change of cross-section, conditions are actually of the nature of those just described,[15] instead of as previously obtained under the assumption that stresses were uniformly distributed over the cross-section at all points.

Gradual Change With Comparatively Short Waves

Let us consider that portion of the wave which is directly transmitted without any reflection, calling its compression f_t'. We can consider that the change is brought about in n successive steps, as suggested by the broken lines in Fig. 22, where n is to be made infinite. We can take these steps such that, letting $r = \sqrt{m_c k_c / m_a k_a}$ as before:

$$r^{1/n} = \sqrt{\frac{m_1 k_1}{m_a k_a}} = \sqrt{\frac{m_2 k_2}{m_1 k_1}} = \sqrt{\frac{m_3 k_3}{m_2 k_2}}, \text{ etc.}$$

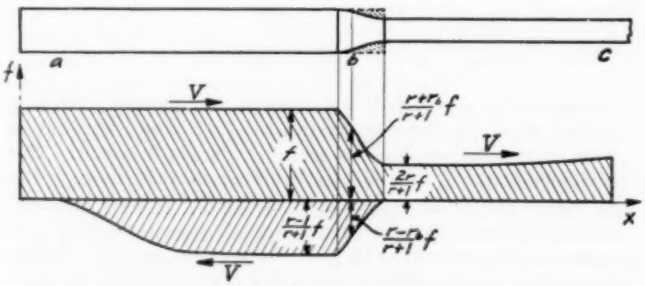

Fig. 21

If a wave with the compression f at section a travels to section c, the compression in the *directly* transmitted wave will, from [9], be multiplied by $2r^{1/n}/(r^{1/n}+1)$ at each step, so that after passing all n steps, the final value of the directly transmitted wave is

$$f_t' = \left[\frac{2r^{1/n}}{r^{1/n}+1}\right]^n f = \left[\frac{2}{2 + (r^{1/n} - 1)}\right]^n rf = \frac{rf}{[1 + \frac{1}{2}(r^{1/n} - 1)]^n}$$

When n becomes infinite, $(r^{1/n} - 1)$ becomes infinitesimal, so we can write $[1 + \frac{1}{2}(r^{1/n} - 1)]^n = [1 + (r^{1/n} - 1)]^{n/2} = [r^{1/n}]^{n/2} = \sqrt{r}$.

Hence:

$$f_t' = \sqrt{r}\, f \qquad [19]$$

If the change is one of cross-section only, and the cross-sections are all geometrically similar, f_t' will therefore vary directly as the linear dimensions of the cross-section, as shown in Fig. 23. The intensity of stress, on the other hand, will vary *inversely* as the linear dimensions of the cross-section. A wave moving toward a pointed end would thus theoretically produce an infinite stress at the end. In a conical bar ft' varies directly as the distance from the apex, and the unit stress inversely as this distance.

The reflected waves, whatever they are, obviously start from zero at the front of the transmitted wave, as suggested by the line gh, Fig. 23. Consequently the *resultant* transmitted wave f_t must have the value given by [19] at the front of the wave (as suggested by the broken lines in Fig. 23), and the resultant reflected wave must have the value zero at the front of the wave.

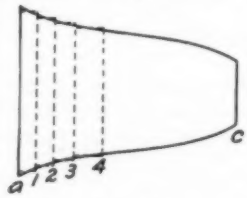

Fig. 22

If the wave is very short, such as the portion bc of the wave shown in Fig. 23, the resultant transmitted wave will be nearly as given by [19] throughout, as well as at the front.[16] Moreover the resultant reflected wave will be of minor importance in this case, as can be shown by considering the energies in the waves. The energy in the resultant transmitted wave as it passes any section c, from [1] and [19], will be nearly

$$\frac{(\sqrt{r}\, f)^2 L_c}{k_c} = \frac{rf^2 L_c}{k_c} = \frac{\sqrt{\dfrac{m_c k_c}{m_a k_a}}\, f^2 \sqrt{\dfrac{k_c}{m_c}}\, t}{k_c} = \frac{f^2 \sqrt{\dfrac{k_a}{m_a}}\, t}{k_a} = \frac{f^2 L_a}{k_a}$$

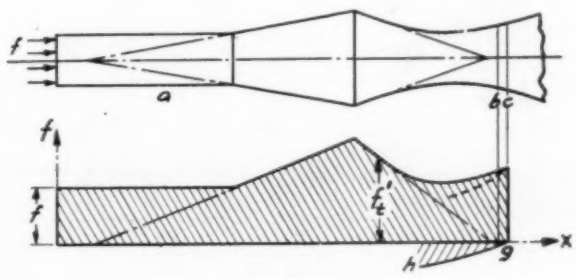

Fig. 23

which is the energy of the original wave starting at a. As the total energy cannot change, the energy in the resultant reflected wave must be small (it has been pointed out before that the energies of waves going in opposite directions can be calculated independently). It can be shown that the foregoing reasoning applies also to a series of short waves of *opposite* sign, such as are produced by a harmonic force of high frequency.

General Case of a Gradual Change

To study the problem in more detail we must use the differential equation of the rod. Let $f = (f_t + f_r)$ represent the total compression at any section, u the longitudinal displacement of the section, and t the time. In general f varies both with time and with x. The rate of variation along the length (that is with x) is represented by $\partial f/\partial x$. The difference between the compressions at the two ends of an elemental length of the bar, of length dx, is therefore $(\partial f/\partial x)dx$. This represents an unbalanced force acting on the element, which must equal the mass

[15] However, we are still making the approximate assumption that wave fronts are perpendicular to the axis of the rod.

[16] It will be the same whether the portion bc is alone or at the front of a long wave, because the effect of the portion of the wave behind section b cannot catch up with the portion bc.

of the element times its acceleration $(mdx)\frac{\partial^2 u}{\partial t^2}$. Hence, taking the direction in which x is measured as positive,

$$-\frac{\partial f}{\partial x}dx = mdx\frac{\partial^2 u}{\partial t^2}, \text{ or } -\frac{\partial f}{\partial x} = m\frac{\partial^2 u}{\partial t^2} \quad [20]$$

The unit strain is

$$\frac{\partial u}{\partial x} = -\frac{f}{k} \quad [21]$$

The negative sign is due to the fact that we have taken f as compression. In these equations m and k are of course no longer constants but are functions of x. From [21],

$$f = -k\frac{\partial u}{\partial x}$$

Differentiating with respect to x,

$$\frac{\partial f}{\partial x} = -k\frac{\partial^2 u}{\partial x^2} - \frac{dk}{dx}\cdot\frac{\partial u}{\partial x}$$

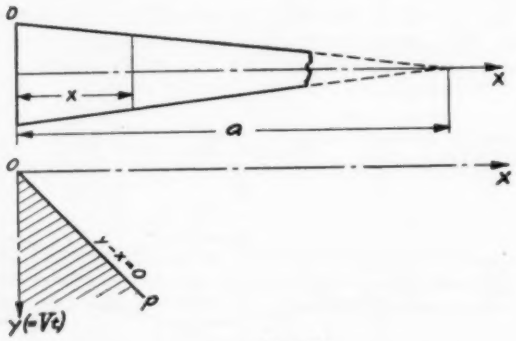

FIG. 24

and substituting this in [20] we have the general differential equation of the bar

$$k\frac{\partial^2 u}{\partial x^2} + \frac{dk}{dx}\cdot\frac{\partial x}{\partial x} = m\frac{\partial^2 u}{\partial t^2}$$

or

$$\frac{m}{k}\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2} + \frac{1}{k}\frac{dk}{dx}\cdot\frac{\partial u}{\partial x} \quad [22]$$

Also, from [21],

$$f_i + f_r = f = -k\frac{\partial u}{\partial x}$$

and using [6],

$$f_i - f_r = \sqrt{mk}\,v = \sqrt{mk}\frac{\partial u}{\partial t} \quad [23]$$

from which

$$f_i = -\frac{k}{2}\left(\frac{\partial u}{\partial x} - \sqrt{\frac{m}{k}}\frac{\partial u}{\partial t}\right)$$

$$f_r = -\frac{k}{2}\left(\frac{\partial u}{\partial x} + \sqrt{\frac{m}{k}}\frac{\partial u}{\partial t}\right)$$

CONICAL BAR

As an example of the application of these equations, consider the case of a conical bar of homogeneous material, dimensioned as shown in Fig. 24. If m_o and k_o are the constants at section o, then the constants at any other section will be[17]

$$m = \frac{(a-x)^2}{a^2}m_0 = \left(1-\frac{x}{a}\right)^2 m_0; \quad k = \left(1-\frac{x}{a}\right)^2 k_0. \quad [24]$$

In this case $V = \sqrt{\frac{k}{m}} = \sqrt{\frac{k_0}{m_0}}$ is a constant. Using the notation $y = Vt$, Equation [22] becomes:

$$\frac{\partial^2 u}{\partial y^2} = \frac{\partial^2 u}{\partial x^2} - \frac{2}{a-x}\frac{\partial u}{\partial x} \quad [25]$$

The general solution of this can be expressed as follows:

$$u = \frac{\phi(y-x) + \psi(y+x)}{1-\frac{x}{a}} \quad [26]$$

where ϕ and ψ are any functions; they must of course be determined to fit the other conditions. Using Equations [23],

$$f = -k\frac{\partial u}{\partial x} = k_o\left[\left(1-\frac{x}{a}\right)(\phi'-\psi') - \frac{1}{a}(\phi+\psi)\right] \quad [27]$$

$$v = \frac{\partial u}{\partial t} = V\frac{\partial u}{\partial y} = V\frac{\phi'+\psi'}{1-\frac{x}{a}} \quad [28]$$

$$f_i = -\frac{k}{2}\left(\frac{\partial u}{\partial x} - \frac{\partial u}{\partial y}\right) = k_o\left[\left(1-\frac{x}{a}\right)\phi' - \frac{1}{2a}(\phi+\psi)\right] \quad [29]$$

$$f_r = -\frac{k}{2}\left(\frac{\partial u}{\partial x} + \frac{\partial u}{\partial y}\right) = k_o\left[\left(\frac{x}{a}-1\right)\psi' - \frac{1}{2a}(\phi+\psi)\right] \quad [30]$$

where $\phi' = \frac{d\phi}{d(y-x)}$, $\phi'' = \frac{d^2\phi}{d(y-x)^2}$, etc.

Suppose for example that a constant compressive force f_o is applied at o. In determining the value of u in the resulting wave an xy diagram, such as shown in Fig. 24, is useful. This is similar to the xt diagrams used previously but here $y = Vt$ represents the distance traveled by the wave. If we start measuring the time when the force is applied then the line $y = x$ represents the position of the wave front at any instant. Points in the area xop represent points along the rod before the wave reaches them, that is, beyond the wave front. The portion in which we are interested is the shaded area poy, which represents points within the wave. There are no discontinuities within this region and we can avoid discussion of discontinuities by making use of our knowledge, previously obtained, of the conditions at the wave front—that is, along the line op. We need only satisfy the known conditions along the lines op and oy, and the condition for variation between; the latter condition, represented by [25], has already been satisfied by using [26]. The condition along oy—that is, at the end of the bar—is that $(f)_{x=o} = f_o$. From [19] the condition along op, at the wave front, is that $(f)_{y=x} = \frac{a-x}{a}f_0 = \left(1-\frac{x}{a}\right)f_0$. It is found that ψ may be zero in this case, so that these conditions become

$$k_0\left[\phi'(y) - \frac{\phi(y)}{a}\right] = f_0 \quad [31]$$

[17] The following analysis applies to any case where [24] holds whether the bar is actually conical or not. It is assumed, as before, that cross-sections and the rate of change, or angle of taper, are small.

$$k_0\left[\left(1-\frac{x}{a}\right)\phi'(o)-\frac{\phi(o)}{a}\right]=\left(1-\frac{x}{a}\right)f_o \quad \ldots\ldots [32]$$

Solving the differential Equation [31], and using [32] to determine the resulting constant of integration,[18]

$$\phi=\frac{f_0 a}{k_0}\left(e^{\frac{y-x}{a}}-1\right),\ \psi=0 \quad \ldots\ldots [33]$$

Substituting this in [24],

$$f=\left(1-\frac{x}{a}e^{\frac{y-x}{a}}\right)f_0$$

If a is made very large we approach the condition in a uniform bar, $f = f_0$.

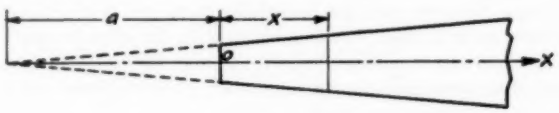

FIG. 25

If the force is removed after a length of time equal to L/V, this is equivalent to superimposing on the above wave a negative wave produced by a force $-f_0$, and having $(y - L)$ instead of y as the distance traveled by its wave front. This gives

$$(y-L)<x<y\ :f=\left(1-\frac{x}{a}e^{\frac{y-x}{a}}\right)f_0, \text{ as above}$$

$$0<x<(y-L)\ :f=\frac{x}{a}\left(e^{\frac{y-x-l}{a}}-e^{\frac{y-x}{a}}\right)f_0$$

The latter expression represents a sort of tail strung out behind the main part of the wave, due to reflections. All these waves are of course made up of two waves, one with compression f_i moving forward, and one with compression f_r moving backward. These can be investigated by substituting [33] in [29] and [30].

If a is negative we have the case shown in Fig. 25. The above formulas can be used for this case also, using a *negative* value for a.

WAVES IN MATERIALS WHICH DO NOT FOLLOW HOOKE'S LAW

Suppose that a uniform bar is made of a material such that, in a tensile or compressive test, we obtain a load vs. unit strain curve as shown in Fig. 26. The slope of this curve corresponds to our stiffness constant k. If a constant force f_1 is applied to the end of the bar, a wave with this compression will move along the bar with a velocity $V_1 = \sqrt{k_1/m}$. If now another force f_2 is superposed on f_1, the bar, being already under a compression f_1, will follow the load-strain curve with slope k_2, and the wave started by f_2 will move along the bar with the velocity $V_2 = \sqrt{k_2/m}$. If the two forces are applied at the same time the action will be the same, and the complete wave front will present the appearance shown in Fig. 26(*b*), with the gap between the two parts of the front increasing with time.

If we imagine k_2 gradually decreased we see that when it becomes zero the second portion of the wave, having zero velocity, will never get started. This means that, if a force exceeding the yield-point force is applied to a bar of steel having a sharp, horizontal yield point, a wave will move along the rod with a compression equal to the yield-point force only. The work done by the remainder of the force is obviously absorbed as plastic work around the point of application.

[18] It would ordinarily require two arbitrary constants to satisfy [32]; the fact that it can be done with only one is a check on our previous analysis of the conditions at the wave front.

If the load-strain curve of the material has a gradual decrease of slope with increasing stress (as in the case of cast iron, for example) it is evident, from the above reasoning, that the wave front will have a gradual backward slope, as in Fig. 27, increasing with time. Its exact shape will depend on the stress-strain diagram. The simplest result would be to have it a straight line, as indicated by the broken line in Fig. 27. In order for this to be the case the distance $\frac{t}{\sqrt{m}}\left(\sqrt{k_0}-\sqrt{k}\right)$ in the figure would have to be proportional to f as well as to t, as for instance,

$$\frac{t}{\sqrt{m}}\left(\sqrt{k_0}-\sqrt{k}\right)=\frac{Ct}{\sqrt{mk_0}}f \quad \ldots\ldots [34]$$

where C is a constant to be determined. Substituting $k = df/de$ in this equation, and integrating and determining the constant of integration from the condition $f = 0$, $e = 0$, we find:

$$f=\frac{k_0 e}{Ce+1} \quad \ldots\ldots [35]$$

This equation represents the experimental results obtained with such materials as cast iron and annealed copper very well.

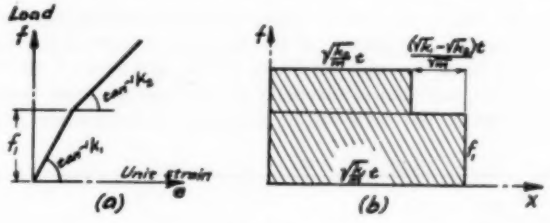

FIG. 26

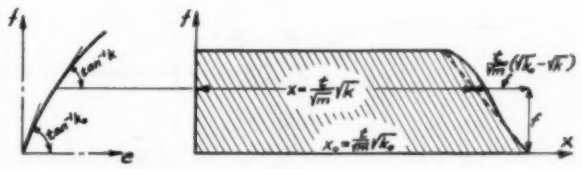

FIG. 27

The constants k_0 and C can be found from any two experimental values of f and e: f_1, e_1, and f_2, e_2 (where f_1 is preferably the largest load used and f_2 about half the largest). Substituting these in [35] and solving for k_0 and C,[19]

$$k_0=\frac{f_1 f_2(e_2-e_1)}{e_1 e_2(f_2-f_1)},\quad C=\frac{f_1 e_2-f_2 e_1}{e_1 e_2(f_2-f_1)} \quad \ldots\ldots [36]$$

Hence we may assume that in bars of such materials the wave produced by a suddenly applied constant force will have, on the f, x diagram, an inclined front, the slope of which is $Ct/\sqrt{mk_0}$ (from [34]), where k_0 and C are given by [36]. If, upon *unloading*, the material shows a straight load-strain line having the slope k_0—as seems to be approximately the rule—the rear of the wave will evidently be vertical in the f, x diagram and will move at the velocity $\sqrt{k_0/m}$, so that the total length of the wave will remain constant.

COMPRESSION WAVES IN HELICAL SPRINGS AND COLUMNS OF LIQUIDS

All the foregoing theory applies without change to longitudinal

[19] k_0 should be the slope of the experimental f, e curve at the bottom but it is difficult to measure this accurately.

waves in helical springs. The stiffness constant k in this case is the spring constant of a unit length of the spring.

That portion of the foregoing which deals with prismatical bars can be applied to longitudinal pressure waves in inclosed columns of gases and liquids, of uniform section. It also applies approximately to the longitudinal propagation of surface waves in liquids in long uniform tanks; in this case, however, the lateral motions involved at the ends of the waves produce a large frictional effect which modifies conditions at these points.

In the case of columns of gases in rigid pipes, k is the area of the cross-section times the modulus of volume elasticity. The latter

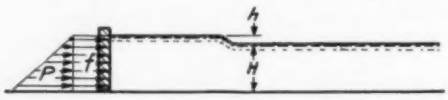

FIG. 28

for adiabatic conditions, is λp, where λ is the ratio of the specific heats of the gas under constant pressure and under constant volume ($\lambda = 1.4$ for air) and p is the unit pressure of the gas. For very long waves there will be some deviation from adiabatic conditions in the middle of the wave, which will complicate the problem.

In the case of columns of liquids in pipes, the flexibility of the walls must be considered. If p is the unit pressure of the liquid, α the ratio of the wall thickness to the diameter of the pipe, and E the modulus of elasticity of the wall material, then the hoop stress in the walls will be $p/2\alpha$ and the hoop strain $p/2\alpha E$.

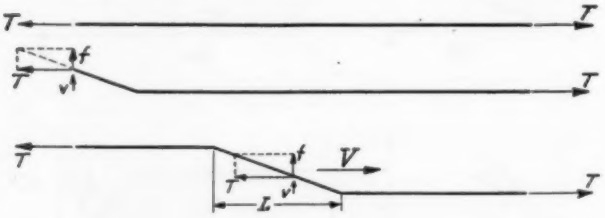

FIG. 29

This produces a unit increase in volume inside the pipe of

$$\left(1 + \frac{p}{2\alpha E}\right)^2 - 1 = \frac{p}{\alpha E}$$

approximately. This has the same effect as a unit decrease in volume of the liquid. This decrease must be added to that due to the compressibility of the liquid, which is p/E_v, where E_v is the modulus of volume elasticity of the liquid. The stiffness constant k, being the longitudinal force per unit longitudinal shortening, will be equal to the area of the cross-section times

$$\frac{p}{\frac{p}{E_v} + \frac{p}{\alpha E}} = \frac{E_v}{1 + \frac{E_v}{\alpha E}}$$

The inertia of the pipe walls and the stiffening effect of the portion of the pipe just outside the wave will modify conditions near the ends of the waves and will be of importance if the waves are very short.

The case of surface waves in long tanks is illustrated by Fig. 28. If a uniformly distributed longitudinal force f (superposed on the total static pressure, P) is exerted on the water at a certain point, say through a movable bulkhead as shown in the figure, the water will rise a distance h, such that

$$\frac{(h + H)^2}{H^2} = \frac{P + f}{P}$$

where H is the original depth. Assuming that the volume of water remains the same, there will be a unit shortening in the lengthwise direction, due to this increase in depth, of h/H. And k, the force per unit shortening, will be $f/(h/H)$. Using the above equation this reduces to $k = 2P$, approximately (if h/H is small).

Applications to Other Types of Waves

The foregoing theory can be applied also to the case of small *lateral* waves in a stretched chain or flexible rope. In this case f is to be taken as a lateral force acting on the rope, superposed on the initial constant tensile force T, and v is to be taken as the resulting lateral velocity of particles of the rope, as indicated in Fig. 29. The lateral displacement per unit length of rope can be taken as f/T, if f is small compared to T. In this case k, being the force per unit *lateral* displacement, is $f/(f/T) = T$. In this, as in all the preceding cases, m is the same as originally defined, the mass per unit length. It may be noted, in this last case, that superposing waves may be in different planes and must then be combined vectorially.

All the preceding theory can be applied to the case of torsion waves in bars of uniform or variable section (with even more exactitude than for the original case of longitudinal pressure waves, as there is no lateral expansion here to affect the conditions at the ends of waves). In this case f is to be interpreted as the torque applied to the bar (or the internal torque on sections within the wave) and v is to be interpreted as the resulting angular velocity of sections of the bar. For this case m must be taken as the moment of inertia of mass of the bar (about the longitudinal axis) per unit length of the bar; and k will be the torque required to twist unit length of the bar one radian, which can be determined by the usual methods.

Discussion

THOS. C. RATHBONE.[20] Professor Donnell has opened up a most fascinating subject which has practical application in many fields of mechanical engineering. The transmission of impulses in materials is usually associated with the case of relatively small parts involving extremely short periods of time. When these studies are applied to large central-station turbines, however, both the time intervals and distances become appreciable. For example, the distance between the bearings of a large generator rotor may reach 35 ft. or more, and a length of 75 ft. would not be unusual between the turbine thrust bearing and the outboard bearing. These units are normally mounted on a continuous steel foundation. Although the forces at the bearing due to unbalance in the rotor are usually considered as acting in a plane normal to the turbine axis, it is not unusual to find axial disturbances.

In his investigation of the vibration phenomena, the writer has made use of stroboscopic vibrometers to explore in some detail the characteristic of vibration of large installations as a whole, with particular regard to the phase relation between the vibratory motion and references on the rotor. These studies were directed toward arriving at a method of correcting unbalance on a complicated structure where the vibratory disturbances at the several bearings are transmitted throughout the unit and affect each other. On such an installation the motion observed at any bearing represents a composite which includes disturbances emanating from the other bearings.

Many unusual conditions were disclosed. For example, it was found that the same unbalance in a rotor would produce a

[20] Division Engineer, Central Station Turbine Division, Westinghouse Elec. & Mfg. Co., Lester, Pa. Mem. A.S.M.E.

given set of vibratory characteristics when rotating in the opposite direction at the same speed. It was also found that the so-called "angle of lag," between a point in the vibratory motion of the bearing and a datum on the rotating spindle, would vary through two full circles or more in going through a speed range up to 2000 r.p.m. These results are entirely at variance with the commonly accepted notion that the "angle of lag" at the critical speed is 90 deg., becoming 180 deg. at an infinite speed.

On these very large units the phase relation of the vibratory motion at the various bearings is affected by the length of time required for an impulse to travel from one point to another. For example, on an installation of the size mentioned, running at 1800 r.p.m., the spindle will turn through approximately 50 deg. during the time required for an impulse to travel from the thrust bearing, for example, to the outboard bearing. Such large angles are of course very appreciable when attempting to analyze the vibratory characteristics in order to determine the proper locations for balance corrector weights.

The velocity of propagation in steel is about one-third higher than in concrete. It is interesting to note that a disturbance at the thrust end of such a unit would reach the outboard end through the steel and iron turbine structure about 17 deg. ahead of the wave coming through the concrete foundation.

The study of resonances in a large turbine-generator installation from the viewpoint of reflections and standing waves offers an interesting field of investigation. The modes of vibration commonly encountered on such structures are very complex and cannot be predicted by ordinary methods.

Steady Forced Vibration as Influenced by Damping

An Approximate Solution of the Steady Forced Vibration of a System of One Degree of Freedom Under the Influence of Various Types of Damping

By LYDIK S. JACOBSEN,[1] STANFORD UNIVERSITY, CALIF.

In this paper the author presents a general method of obtaining approximate solutions of the steady forced vibration of a damped system of one degree of freedom for the case of sinusoidally varying disturbing forces.

The approximation consists in expressing all the damping terms of the original differential equation by a single equivalent damping term, proportional to the first power of the velocity of motion.

In the case of a system influenced by a centrifugal disturbing force and damped by constant friction and by friction proportional to the first power of the velocity, experimental evidence is in good agreement with the approximate solution.

While the paper deals solely with a system of one degree of freedom, there is no reason aside from complexity why the approximate solution cannot be applied to systems of several degrees of freedom.

THE analytical treatment of forced vibrations occurring in mechanical structures usually assumes that the dissipative forces can be regarded as being proportional to the first power of the velocity of motion. By making this postulate, the investigator arbitrarily limits his analysis to apply to physical problems of a special class, but he gains a commensurate amount of ease and comfort in his mathematical expression for the resulting vibratory motions. If, however, the problem is to investigate the forced vibrations of structures in which only a small proportion of the dissipated energy is due to viscous forces, it becomes necessary to make approximations in such a way that actual physical conditions are simulated and that the resulting differential equations of motion do not defy easy solutions.

The experimental records of free vibrations of mechanical structures very fortunately furnish us with information about the type of dissipative forces that predominate in particular cases. An examination of a free-vibration record will disclose the extent to which viscous damping occurs, it will indicate whether or not constant dissipative forces are in action, and it will, if closely scrutinized, betray the existence of damping forces proportional to the nth power of the velocity of motion. At any rate, it will usually be possible to fit an empirical curve to the free-vibration curve if combinations of constant friction, viscous friction, and friction proportional to the nth power of the velocity be at our disposal.

As examples involving the three types of damping, the following may be mentioned:

a Constant friction occurs in nearly all mechanical structures; the greater the number of friction joints, the more predominant the constant-friction term in the equation of motion.

b Viscous friction, proportional to the first power of the velocity, is usually present to a greater or smaller extent in all mechanical structures. Air damping at small velocities belongs to this type.

c Friction, proportional to the nth power of the velocity, occurs in hydraulic systems and in air-damped systems where the velocity of motion is relatively large.

Historical Notes

While the solution of the free vibration of a system with constant friction is well known, the problem of the forced vibration of the same system involves so much difficulty that a rigorous analytical solution has not been obtained until very recently. A paper by Herr W. Eckolt[2] considers in detail, but from a semi-graphical point of view, the wave shape of a forced vibration with constant damping. His method involves a great number of steps that are not sufficiently obvious, or well explained, to be of practical use for engineering purposes. During the summer of 1929, after the first draft of this paper had been made, and submitted to Dr. S. Timoshenko for criticism, the author learned that Dr. J. P. Den Hartog[3] had just succeeded in obtaining an exact analytical solution of the forced vibration with constant friction and also of the forced vibration with constant friction and with first-power-velocity damping. It is, indeed, very fortunate for the approximate method developed in this paper that Dr. Den Hartog's exact solution is available. A comparison of the results obtained by applying the exact and the approximate method to four special cases discloses the fact that there is excellent numerical agreement between them. Moreover, the exact as well as the approximate solution is in good accord with experimental evidence for the four special cases mentioned above.

The solution of the free vibration with damping proportional to the square of the velocity is well known, though not very simple. Professor Milne's tables,[4] recently finished, give a complete and rigorous solution of the problem. The case of damping proportional to the nth power of the velocity has not yet been solved analytically; it is, however, as is pointed out by Professor Milne, possible to get a solution for a certain region by considering a combination of first- and second-power-velocity damping.

Simplifying Assumptions

An approximate solution of a physical problem usually requires that uneven emphasis be placed upon a trustworthy

answer to the various aspects of the physical problem. In the following approximate solution of steady forced vibrations, primary interest will be attached to the question of amplitude of the resulting motion. It is, of course, realized that the question of wave form enters in and, in the case of large damping, may influence the amplitude appreciably, but as a first approximation it will be assumed that a displacement of sinusoidal form will yield results that cannot, except in extreme cases, be much at variance with actual phenomena.

The approximate solution centers on the simple and well-known solution of a vibrating system of one degree of freedom, influenced by a sinusoidally varying disturbing force and by a viscous friction proportional to the first power of the velocity of motion. In considering other types of damping it will be assumed that they all can be reduced to an equivalent viscous damping involving the term dx/dt and a coefficient which is a function of the maximum displacement and the angular velocity of the motion. The reason for doing this is obviously simplicity; its justification as an approximation lies in the fact that we are considering the steady state of the forced vibration, so that the coefficient of dx/dt becomes a constant for the constant value of the maximum displacement and the angular velocity under observation.

In defining the term "equivalent viscous damping," it is necessary to state the criterion upon which equivalence is established. It must be admitted that it is somewhat arbitrary to say that the criterion of equivalent dissipative work done during a cycle is a better criterion than, for instance, that of equivalent time average of the damping force. Intuitively, however, we recognize the great importance of having a general reckoning in regard to work done at the end of every cycle, so we feel warranted in pdstulating as a criterion of equivalence of viscous damping force the equality of dissipative work done during a cycle by the real force and by the equivalent viscous force. Before this criterion had been adopted, the approximate solution of the forced vibration of a system with constant friction and velocity damping had been carried out for four special cases on three different criteria of equivalent viscous damping force. The results were then compared to experimental evidence, with the remarkable outcome that the three criteria gave approximately the same agreement with experiment in all regions of the frequency-amplitude plane, with the exception of the one of resonance. At or near resonance the criterion of dissipative work done during a cycle was far superior to the other two in regard to numerical agreement with experiment. Furthermore, a comparison of Mr. Den Hartog's exact solution with the approximate one gave a very gratifying agreement, provided that the criterion of dissipative work was used for establishing the equivalent viscous damping.

I--THEORETICAL WORK

Derivation of the General Equation

Consider a vibrating system of one degree of freedom. The mass is m, and the spring factor is k. Let the system be acted upon by a sinusoidally varying disturbing force of the constant circular frequency ω, and of a constant maximum magnitude Q. If the system be influenced by a viscous damping equal to a constant c multiplied by the velocity dx/dt, the differential equation of motion is:

$$m\frac{d^2x}{dt^2} + c\frac{dx}{dt} + kx = Q\sin\omega t \quad \ldots\ldots\ldots\ldots [1]$$

The solution of this equation is simple and well known. Since we are limiting this investigation to the steady forced vibration, we are interested in the particular integral only. This integral is:

$$x = \frac{Q}{\sqrt{(k - m\omega^2)^2 + c^2\omega^2}}\sin(\omega t - \psi) = X\sin(\omega t - \psi) \quad \ldots [2]$$

where

$$\tan\psi = \frac{c\omega}{k - m\omega^2}$$

Let us now consider a slightly different case where the same system is influenced by a damping force which is proportional to the nth power of the velocity; the equation of motion is then:

$$m\frac{d^2x}{dt^2} \pm c_n\left(\frac{dx}{dt}\right)^n + kx = Q\sin\omega t \quad \ldots\ldots\ldots [3]$$

The plus or minus sign before the damping term indicates that the force always opposes the motion. In other words, the sign of the damping term must always be the same as that of dx/dt. Let us now replace the damping term in Equation [3] by an equivalent viscous damping term

$$c_1\frac{dx}{dt}$$

where c_1 is to be determined by the criterion of equivalent dissipative work done during a cycle,

$$w = 4c_n\int_0^{\frac{\pi}{2\omega}}\left(\frac{dx}{dt}\right)^n dx = 4c_1\int_0^{\frac{\pi}{2\omega}}\frac{dx}{dt}\,dx$$

If we retain our previous assumption that the effect of the friction on the wave shape of the displacement is negligible, we can perform the integration above since

$$x = X\sin(\omega t - \psi)$$

Consequently

$$c_n\int_0^{\frac{\pi}{2\omega}} X^{n+1}\,\omega^{n+1}\cos^{n+1}\omega t\,dt = c_1\int_0^{\frac{\pi}{2\omega}} X^2\omega^2\cos^2\omega t\,dt$$

giving

$$c_n X^{n-1}\,\omega^{n-1}\int_0^{\frac{\pi}{2\omega}}\cos^{n+1}\omega t\,dt = \frac{\pi}{4}c_1$$

The integral above is most generally expressed as follows:

$$\int_0^{\frac{\pi}{2\omega}}\cos^{n+1}\omega t\,dt = {}^1/_2\sqrt{\pi}\,\frac{\Gamma\left(\frac{n+2}{2}\right)}{\Gamma\left(\frac{n+3}{2}\right)}$$

where $\Gamma(n)$ means the gamma function for the value n. The equivalent friction coefficient is therefore

$$c_1 = c_n\frac{2}{\sqrt{\pi}}\,\frac{\Gamma\left(\frac{n+2}{2}\right)}{\Gamma\left(\frac{n+3}{2}\right)}\,X^{n-1}\,\omega^{n-1} = c_n\gamma X^{n-1}\,\omega^{n-1} \quad \ldots [4]$$

Fig. 1 gives in curve form the value of γ for values of n between zero and four.

Equation [3] can be replaced by

$$m\frac{d^2x}{dt^2} + (c_n\gamma X^{n-1}\,\omega^{n-1})\frac{dx}{dt} + kx = Q\sin\omega t \quad \ldots\ldots [5]$$

Since, as before, we are interested in the steady forced vibration only, X as well as ω is a constant, and the particular integral, in accordance with Equation [2], becomes:

$$x = \frac{Q}{\sqrt{(k - m\omega^2)^2 + c_n^2\gamma^2X^{2n-2}\omega^{2n}}} \sin(\omega t - \psi)$$
$$= X \sin(\omega t - \psi) \ldots\ldots [6]$$

where

$$\tan \psi = \frac{c_n\gamma X^{n-1}\omega^n}{k - m\omega^2}$$

In case n is equal to unity, this result coincides with the exact solution of the vibrating system with damping proportional to the first power of the velocity. If n be greater than zero but different from one, we have approximate solutions, the approximation being very close for values of n near unity, and less close for values of n near zero and for values of n somewhat greater than unity.

Fig. 2 shows a family of equivalent damping-force curves as

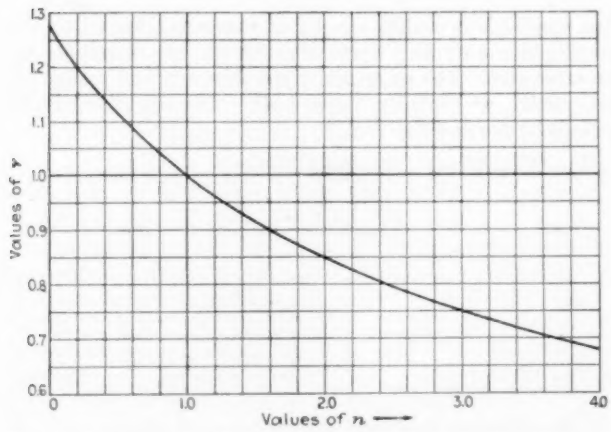

FIG. 1 SHOWING THE EQUIVALENCE FACTOR γ AS A FUNCTION OF THE VELOCITY-DAMPING POWER n

functions of time, assuming that the work per cycle is the same for each value of n. The curve $n = 1$ is the simple sine curve for which we have the exact solution of the equation of motion. As n decreases, the peak of the curve is lowered until, for $n = 0$, the curve degenerates into a straight line parallel to the time axis. This case corresponds to constant friction independent of the velocity. If the constant friction force be F, it is seen that

$$c_1 = \frac{4}{\pi} c_0 X^{-1}\omega^{-1} = \frac{4}{\pi} FX^{-1}\omega^{-1}$$

For values of n greater than unity, the peaks of the curves increase, so that for the limiting case of $n = \infty$ the curve becomes a straight line perpendicular to the time axis. For the case of damping proportional to the second power of the velocity, the following relation exists between the coefficient of the actual damping term, c_2, and the coefficient of the equivalent damping term, c_1,

$$c_1 = \frac{8}{3\pi} c_2 X\omega$$

AN ARBITRARY CRITERION OF VALIDITY

Before the physical significance of the above approximate solutions of the steady forced vibration is discussed, let us consider the criterion for a free periodic motion of a system of one degree of freedom and with damping proportional to the first power of the velocity. In this case the condition for a system having a periodic free vibration requires that:

$$\frac{k}{m} \geqq \frac{c_1^2}{4m^2} \ldots\ldots [7]$$

In the approximate solution of the steady forced vibration, the equivalent damping factor c_1 varies with the amplitude and the angular velocity. This means that, in the general case of n different from unity, the condition for a periodic free vibration cannot be satisfied for all regions of the frequency-amplitude plane. Interpreted physically, this fact indicates that there

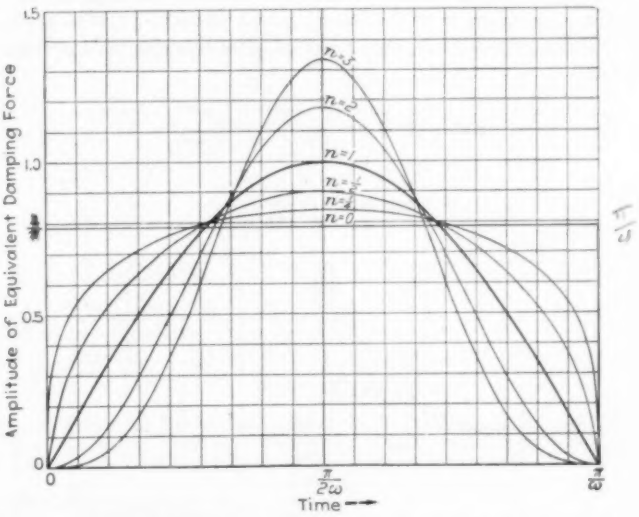

FIG. 2 SHOWING TIME-AMPLITUDE CURVES OF THE EQUIVALENT DAMPING FORCE FOR DIFFERENT VALUES OF THE VELOCITY-DAMPING POWER n

will be regions where our approximately equivalent dynamical vibrating system is not a free vibrating system. Manifestly, in these regions we must be careful in interpreting the results of the approximate solution. Thus, for the case of constant friction when n is zero, the value of c_1 will be large for simultaneously small values of the amplitude and the frequency; the condition of free periodicity will therefore not be fulfilled at small values of ω unless the damping factor F is extremely small. We therefore infer that in the general case an orderly motion, expressible by our approximate solution, will not occur until ω has reached a finite value dictated by the criterion of free periodicity expressed in Equation [7]. For values of n greater than zero but smaller than one, the same characteristics of the free-periodicity criterion prevail. At $n = 1$, our solution is, as said before, exact, and we have nothing unusual to be concerned about. When n is greater than unity, the aperiodic condition is sometimes reached for simultaneously large values of the amplitude and the angular frequency.

APPLICATIONS OF THE THEORY

In the following applications of the above-explained theory, it will be advisable to distinguish between two types of sinusoidal disturbing forces, the one of constant magnitude Q, and the one of a variable magnitude $P\omega^2$. The practical importance of considering the variable or the "centrifugal" disturbing force is derived from the fact that this type of disturbing force is realized approximately in a rotating, unbalanced machine, whose unbalanced mass moment is P, when the amplitude of the forced vibration is small compared to the radius of the unbalanced

moment. To facilitate a discussion as well as to make the curves applicable to similar vibrating systems with different physical constants, it will be found desirable to express all the constants by ratios. Let:

$$\left.\begin{aligned} &\frac{Q}{k} = q; \quad \frac{P}{m} = s; \quad \frac{k}{m} = \omega_c; \quad \frac{\omega}{\omega_c} = \tau \\ &f_n = c_n \gamma_n \omega_c{}^n k^{-n} Q^{n-1} \\ &h_n = c_n \gamma_n \omega_c{}^{2n-2} k^{-n} P^{n-1} \end{aligned}\right\} \quad \ldots\ldots\ldots [8]$$

γ_n to be found from Fig. 1.

The general Equation [6] for the maximum displacement and the phase angle ψ of the steady forced vibration, due to a disturbing force $Q \sin \omega t$, then becomes, after squaring and rearranging:

$$X^{2n} + X^2 \frac{q^{2n-2}(1-\tau^2)^2}{f_n{}^2 \tau^{2n}} - \frac{q^{2n}}{f_n{}^2 \tau^{2n}} = 0 \qquad (9)$$

$$\tan \psi = \frac{f_n \tau^n X^{n-1}}{q^{n-1}(1-\tau^2)}$$

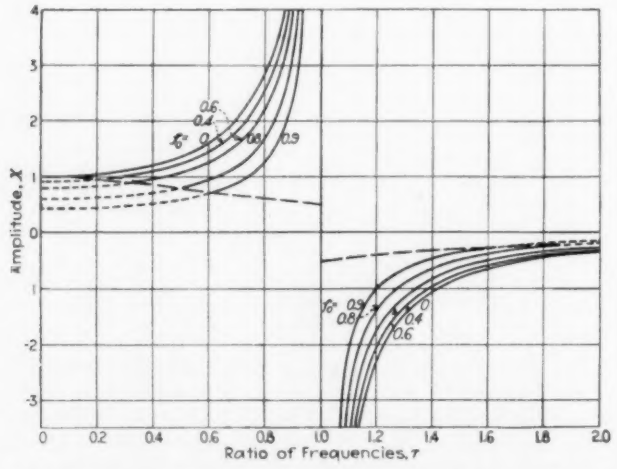

FIG. 3 SHOWING FREQUENCY-AMPLITUDE CURVES OF THE FORCED VIBRATION WITH COULOMB DAMPING AND "CONSTANT" DISTURBING FORCE, FOR DIFFERENT VALUES OF THE DAMPING FACTOR f_0

The arbitrary condition of free periodicity, Equation [7], requires that

$$4km \geqq c_n{}^2 \gamma_n{}^2 X^{2n-2} \omega^{2n-2} \text{ or } X\tau \leqq q \sqrt[n-1]{\frac{2}{f_n}}$$

If, instead of the "constant" disturbing force, the "centrifugal" disturbing force be used, the general equation assumes the form:

$$X^{2n} + X^2 \frac{s^{2n-2}(1-\tau^2)^2}{h_n{}^2 \tau^{2n}} - \frac{s^{2n}\tau^4}{h_n{}^2 \tau^{2n}} = 0 \qquad (10)$$

$$\tan \psi = \frac{h_n \tau^n X^{n-1}}{s^{n-1}(1-\tau^2)}$$

with the arbitrary free periodicity condition of

$$4km \geqq c_n{}^2 \gamma_n{}^2 X^{2n-2} \omega^{2n-2} \quad \text{or} \quad X\tau \leqq S \sqrt[n-1]{\frac{2}{h_n}}$$

In the general cases where n is greater than zero, Equations [9] and [10] must, of course, be solved by trial.

Let us see what the general equations become when different values are assigned to n.

Case I—A System With Viscous Damping

If $n = 1$, we have a system with damping proportional to the first power of the velocity; in other words, the solution is exact. From Fig. 1 we see that $\gamma = 1$.

(*a*) "Constant" Disturbing Force:

$$f_1 = c_1 \omega_c k^{-1} = \frac{c_1}{m\omega_c}$$

The general Equation [9] then becomes

$$\left.\begin{aligned} &X^2 + X^2 \frac{(1-\tau^2)^2}{f_1{}^2\tau^2} - \frac{q^2}{f_1{}^2\tau^2} = 0 \\ &X = q[f_1{}^2\tau^2 + (1-\tau^2)^2]^{-\frac{1}{2}} \\ &\tan \psi = \frac{f_1 \tau}{1-\tau} \end{aligned}\right\} \quad \ldots\ldots\ldots [11]$$

The amplitude is q when $\tau = 0$; at resonance when $\tau = 1$, the amplitude is q/f_1; as τ approaches infinity, the amplitude approaches zero. The phase angle ψ is zero, $\pi/2$, and π when τ is zero, unity, and infinity, respectively. The condition of free periodicity requires that $f_1 \leqq 2$.

(*b*) "Centrifugal" Disturbing Force:

$$h_1 = c_1 \omega_c k^{-1} = \frac{c_1}{m\omega_c}$$

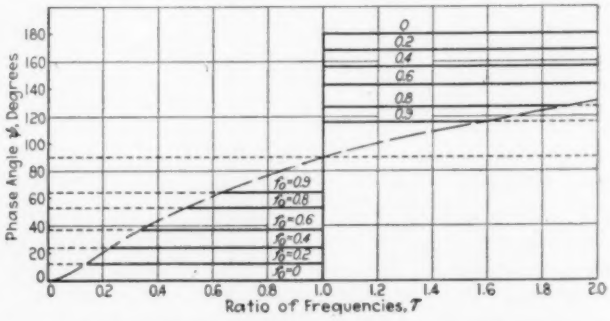

FIG. 4 SHOWING FREQUENCY-PHASE-ANGLE CURVES CORRESPONDING TO THE AMPLITUDE CURVES IN FIG. 3

The general Equation [10] then becomes

$$\left.\begin{aligned} &X^2 + X^2 \frac{(1-\tau^2)^2}{h_2{}^2\tau^2} - \frac{s^2\tau^4}{h_1{}^2\tau^4} = 0 \\ &X = s\tau^2[h_1{}^2\tau^2 + (1-\tau^2)^2]^{-\frac{1}{2}} \\ &\tan \psi = \frac{h_1 \tau}{1-\tau^2} \end{aligned}\right\} \quad \ldots\ldots\ldots [12]$$

showing that the amplitude is zero, s/h_1, and $-s$, when τ is zero, unity, and infinity, respectively. The phase angle shows the same characteristics as before. Also, the condition of free periodicity requires that $h_1 \leqq 2$.

The results stated under case I are so well known that it has been deemed unnecessary to draw curves exhibiting the characteristics.

Case II—A System With Coulomb Damping

If $n = 0$, we have the case of a system with constant friction.

Our solution by means of the general equations is, of course, only approximate. From Fig. 1 we see that $\gamma = 4/\pi$.

(*a*) "Constant" Disturbing Force:

$$f_0 = c_0 \frac{4}{\pi} Q^{-1} = \frac{4}{\pi} \frac{F}{Q}$$

The general Equation [9] then becomes,

$$1 + X^2 \frac{q^{-2}(1 - \tau^2)^2}{f_0^2} - \frac{1}{f_0^2} = 0$$

$$X = q \frac{(1 - f_0^2)^{\frac{1}{2}}}{1 - \tau^2}$$

$$\tan \psi = \frac{f_0 X^{-1}}{q^{-1}(1 - \tau^2)} = \frac{f_0}{(1 - f_0^2)^{\frac{1}{2}}}$$

The arbitrary condition of free periodicity requires that

$$X\tau \leqq \frac{f_0}{2} q$$

giving

$$f_0 \geqq 2\tau[(1 - \tau^2)^2 + 4\tau^2]^{-\frac{1}{2}}$$

to which corresponds a minimum amplitude of

$$X_{\text{min.}} = q[(1 - \tau^2)^2 + 4\tau^2]^{-\frac{1}{2}}$$

The above results are shown in Fig. 3 where a family of curves has been drawn for q equal to unity and for different values of f_0. Infinite amplitude occurs at resonance when $\tau = 1$; as τ approaches infinity, the amplitude approaches zero from the negative side. The arbitrary condition of free periodicity is shown by the dotted part of the curves; thus when $f_0 = 0.8$, the system does not emerge from the aperiodic state until τ is greater than 0.5; moreover, at a value of $\tau = 1.85$ approximately, the system returns to the aperiodic state. This does not mean that no motion takes place except when τ lies between the two values, but it means that our approximate solution cannot be expected to give very trustworthy results except for the range of $\tau = 0.5$ to $\tau = 1.85$. Fig. 4 shows the corresponding phase angles. They are constant until $\tau = 1$, at which point they change suddenly to other constant values, symmetrically distributed about $\pi/2$. The condition of free periodicity cuts off certain parts of the curves as shown by the dotted lines.

(*b*) "Centrifugal" Disturbing Force:

$$h_0 = c_0 \frac{4}{\pi} \omega_c^{-2} P^{-1} = \frac{4}{\pi} \frac{F}{P\omega_e^2}$$

The general Equation [10] then becomes,

$$\left.\begin{aligned} 1 + X^2 \frac{s^{-2}(1 - \tau^2)^2}{h_0^2} - \frac{\tau^4}{h_0^2} &= 0 \\ X = s \frac{(\tau^4 - h_0^2)^{\frac{1}{2}}}{1 - \tau^2} & \\ \tan \psi = \frac{h_0 X^{-1}}{s^{-1}(1 - \tau^2)} = \frac{h_0}{(\tau^4 - h_0^2)^{\frac{1}{2}}} & \end{aligned}\right\} \quad \ldots\ldots [14]$$

The condition of free periodicity requires that

$$X\tau \leqq \frac{h_0}{2} s$$

giving

$$h_0 \geqq 2\tau^3[(1 - \tau^2)^2 + 4\tau^2]^{-\frac{1}{2}}$$

to which corresponds a minimum amplitude of

$$X_{\text{min.}} = s\tau^2[(1 - \tau^2)^2 + 4\tau^2]^{-\frac{1}{2}}$$

Fig. 5 shows a family of amplitude curves, constructed for different values of h_0 and for s equal to unity. The frequency-amplitude plane is divided into four regions by the zero ordinate and by the abscissa for $\tau = 1$; two of these regions are used for plotting the real values of the amplitudes; in the other two regions the amplitude is imaginary and has no physical significance. It is interesting to note that, unless h_0 is zero, the amplitude is imaginary and negative at start when $\tau = 0$. If, for instance, h_0 be 0.4, the curve starts at minus imaginary 0.4, it crosses the zero axis at right angles when $\tau = 0.633$, and enters the region of real values. On account of the arbitrary criterion of free periodicity, the curve is still shown dotted until $\tau = 0.66$ approximately; from then on the amplitude increases rapidly and becomes infinite at the resonance value of τ. For values of τ greater than unity, the amplitude is real and negative, approaching the limit $-s$ as τ approaches infinity. When h_0 is greater than unity, the amplitude curve has no positive real values. Thus, for $h_0 = 2$, the curve starts at minus imagi-

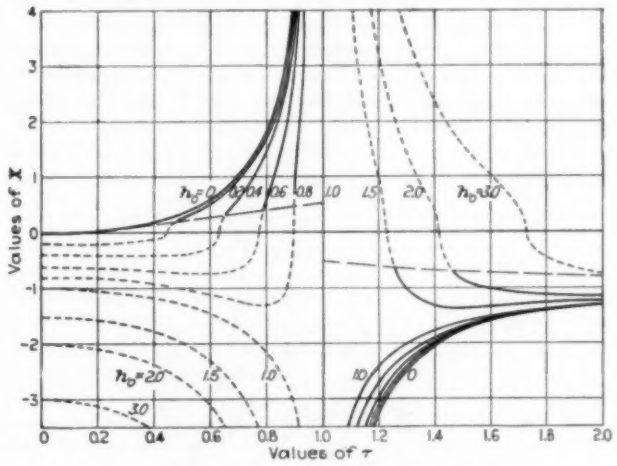

FIG. 5 SHOWING FREQUENCY-AMPLITUDE CURVES OF THE FORCED VIBRATION WITH COULOMB DAMPING AND "CENTRIFUGAL" DISTURBING FORCE FOR DIFFERENT VALUES OF THE DAMPING FACTOR h_0

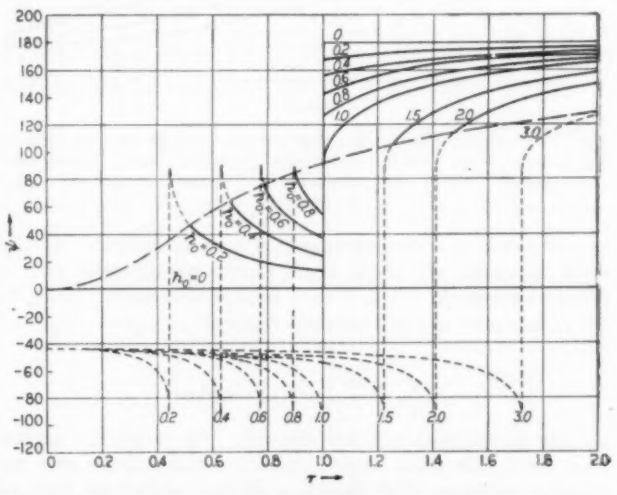

FIG. 6 SHOWING FREQUENCY-PHASE-ANGLE CURVES CORRESPONDING TO THE AMPLITUDE CURVES IN FIG. 5

nary 2, at $\tau = 1$ the amplitude is plus or minus imaginary infinite, and the first zero value is reached when $\tau = \sqrt{2}$; from then on the curve enters the region of negative real values of the amplitude, and overcomes the requirement of the condition for free periodicity when $\tau = 1.46$ approximately. The limit $-s$ is approached from the zero side as τ approaches infinity. The interesting characteristic shown by this family of curves is that no motion occurs until the frequency of the "centrifugal" disturbing force has reached the value $\omega_c\sqrt{h_0}$; further increases in the frequency result, first in forced vibrations in the aperiodic realm, and then in forced vibrations in the free periodic realm for which our approximate solution gives usable results.

The phase angles ψ corresponding to the amplitude curves in Fig. 5 are given in Fig. 6. The ordinate $\psi = 0$ divides the frequency-phase-angle plane into two regions, the upper being used for real values, the lower for imaginary values of ψ. All the curves, with the exception of the one for $h_0 = 0$, start at minus imaginary $\pi/4$; they then decrease to minus imaginary $\pi/2$

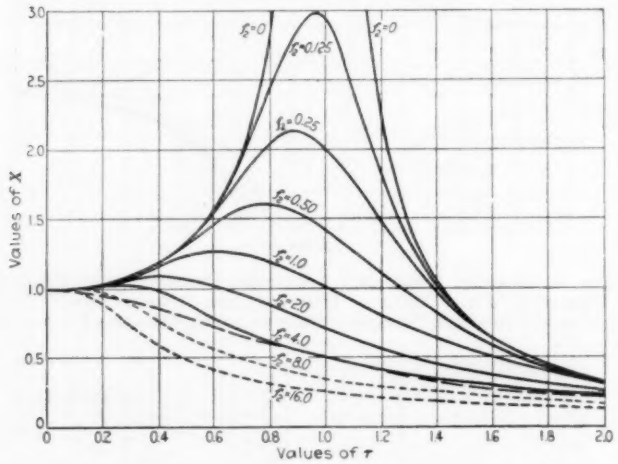

FIG. 7 SHOWING FREQUENCY-AMPLITUDE CURVES OF THE FORCED VIBRATION WITH VELOCITY-SQUARE DAMPING AND "CONSTANT" DISTURBING FORCE, FOR DIFFERENT VALUES OF THE DAMPING FACTOR f_2

at the value of τ corresponding to zero amplitude. At this point, however, the phase angle is also positive real $\pi/2$; a further increase in τ will, if h_0 is smaller than unity, make the curve drop until at $\tau = 1$ the finite angles of

$$\psi = \tan\left[\pm \frac{h_0}{(1 - h_0^2)^{\frac{1}{2}}}\right]$$

equally spaced from $\pi/2$, are reached. For values of τ greater than unity, the phase angle approaches the value π as τ approaches infinity. The condition of free periodicity cuts off certain parts of the curves in the region of real values of the phase angle.

Case III—A System With Velocity-Square Damping

If $n = 2$, we have the case of a system influenced by friction proportional to the second power of the velocity. The application of the general equations to this problem will also give approximate solutions. From Fig. 1 it is seen that $\gamma = 8/3\pi = 0.847$.

(*a*) "Constant" Disturbing Force:

$$f_2 = c_2 \frac{8}{3\pi} \omega_c^2 k^{-2} Q = \frac{\frac{8}{3\pi} c_2 Q}{m^2 \omega_c^2}$$

The general Equation [9] becomes

$$X^4 + X^2 \frac{q^2(1 - \tau^2)^2}{f_2^2\tau^4} - \frac{q^4}{f_2^2\tau^4} = 0$$

$$X = \frac{q}{\sqrt{2}\, f_2\tau^2} \left[\left\{(1 - \tau^2)^4 + 4f_2^2\tau^4\right\}^{\frac{1}{2}} - (1 - \tau^2)^2\right]^{\frac{1}{2}}$$

$$\tan\psi = \frac{f_2\tau^2 X}{q(1 - \tau^2)} = \frac{1}{\sqrt{2}}\left[\left\{1 + \frac{4f_2^2\tau^4}{(1 - \tau^2)^4}\right\}^{\frac{1}{2}} - 1\right]^{\frac{1}{2}}$$

The arbitrary condition of free periodicity requires that

$$X\tau \leqq \frac{2}{f_2} q$$

giving

$$f_2 \leqq \left[16 + \frac{4(1 - \tau^2)^2}{\tau_2}\right]^{\frac{1}{2}}$$

which tells us that for free periodicity the maximum value of f_2 is 4 and occurs at resonance. It therefore appears that only in the case of very high values of c_2 the vibrating system with velocity-square damping is likely to fall into the category of free aperiodic systems.

The limiting value of the amplitude as τ approaches zero is

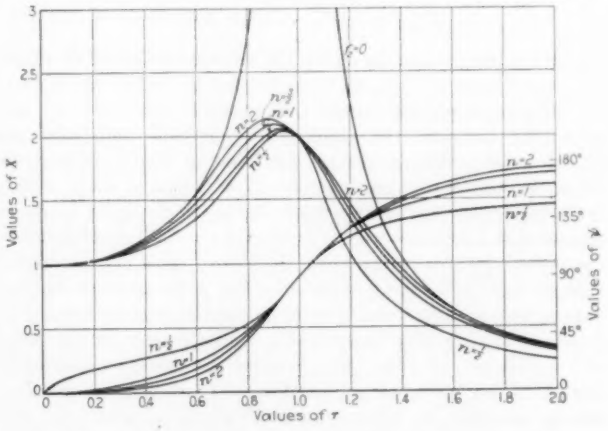

FIG. 8 SHOWING FREQUENCY-AMPLITUDE AND FREQUENCY-PHASE-ANGLE CURVES FOR THE FORCED VIBRATION WITH "CONSTANT" DISTURBING FORCE AND FOR DIFFERENT VALUES OF THE VELOCITY-DAMPING POWER n

easily shown to be q, just as in the system where n is unity. At resonance the amplitude becomes $q/\sqrt{f_2}$. As τ approaches infinity, the limiting value of the amplitude is zero or imaginary q/f_2, which means, physically speaking, that it is zero. The phase angle behaves qualitatively as the phase angle for the case of first-power velocity damping.

Fig. 7 shows a family of curves for different values of f_2. With the exception of the resonance range, the curves follow the zero friction curve more closely than the frequency amplitude curves for a system with first-power velocity damping. The maxima of the curves are shifted a considerable distance toward the lower frequencies. In order to illustrate the peculiar conditions for free periodic motion, three curves for large values of the damping factor f_2 have been drawn. The curve for $f_2 = 4$ becomes tangent to the boundary curve for the free periodic realm at the resonance point. The curve for $f_2 = 8$ enters the aperiodic region when $\tau = 0.28$ approximately; it leaves that region (not shown on curves) when $\tau = 3.5$ approximately. Similarly, the amplitude curve for $f_2 = 16$ plunges into the region

of free aperiodic motion when $\tau = 0.13$, and leaves it when $\tau = 7.8$. It is doubtful, however, whether or not this criterion of free periodicity has much physical significance for our approximate solution of systems whose damping terms are proportional to powers of the velocity higher than the first.

(*b*) "Centrifugal" Disturbing Force:

$$h_2 = c_2 \frac{8}{3\pi} \omega_c{}^4 k^{-2} P = \frac{\frac{8}{3\pi} c_2 P}{m^2}$$

The general Equation [10] becomes,

$$X^4 + X^2 \frac{s^2(1-\tau^2)^2}{h_2{}^2\tau^4} - \frac{s^4\tau^4}{h_2{}^2\tau^4} = 0$$

$$X = \frac{s}{\sqrt{2h_2\tau^2}} \left[\left\{ (1-\tau^2)^4 + 4h_2{}^2\tau^8 \right\}^{\frac{1}{2}} - (1-\tau^2)^2 \right]^{\frac{1}{2}}$$

$$\tan \psi = \frac{h_2\tau X}{s(1-\tau^2)} = \frac{1}{\sqrt{2}} \left[\left\{ 1 + \frac{4h_2{}^2\tau^8}{(1-\tau^2)^4} \right\}^{\frac{1}{2}} - 1 \right]^{\frac{1}{2}}$$

The condition of free periodicity requires that

$$X\tau \leqq \frac{2}{h_2} s$$

giving

$$h_2 \leqq \frac{1}{\tau^2} \left[16 + \frac{4(1-\tau^2)^2}{\tau^2} \right]^{\frac{1}{2}}$$

As τ increases, the critical value of h_2 decreases from infinity to zero. Thus, when $\tau = 1$, $h_2 = 4$; when $\tau = 2$, $h_2 = 1.25$; and when $\tau = \infty$, $h_2 = 0$.

No curves are drawn for this case, as it is clear that they will resemble those of Fig. 7 in all important deviations from the ones of first-power velocity damping. When $\tau = 0$, the amplitude will be zero; at resonance the amplitude will be $s/\sqrt{h_2}$; when τ approaches infinity, this system will, unlike its first-power-velocity relative, have a limiting value of the amplitude of:

$$-s \frac{\left(\sqrt{h_2{}^2 + \frac{1}{4}} - \frac{1}{2} \right)^{\frac{1}{2}}}{h_2}$$

For smaller values of n, i.e., for $0 < n < 2$, the limiting value of the amplitude is $-s$; for $n > 2$, the limiting value of the amplitude will be zero.

Comparison of Systems With *n*th-Power Velocity Damping

In order to make clear the influence of changing the exponent of the velocity-damping term on the amplitude curve, a set of curves has been drawn in Fig. 8. The curves have been drawn so as to give the same resonance amplitude of $2q$. Since the exponents are $^1/_2$, 1, $^2/_3$, and 2, the requirement of equal resonance amplitude necessitates that the friction factors f be 0.707, 0.500, 0.353, and 0.250, respectively. It is seen that there is a considerable change in the shape of the amplitude curves as the exponent of the friction term is varied. The phase-angle curves show a flattening-out tendency accompanying a decrease in the value of n; the limiting form of the phase-angle curve for $n = 0$ is, as shown in Fig. 4, a straight line parallel to the abscissa.

Case IV—Systems With Composite Damping

Let us now consider the case where the damping is proportional to a sum of terms, each one involving the velocity to some power. It is interesting that also in this very general case our approximate method will give results.

The differential equation of motion, before we have applied our approximations, may look like this:

$$m \frac{d^2x}{dt^2} \pm c_{n1} \left(\frac{dx}{dt} \right)^{n1} \pm c_{n2} \left(\frac{dx}{dt} \right)^{n2} + \ldots . kx = Q \sin \omega t . \quad [17]$$

By the criterion of equivalent dissipative work done during a cycle, we obtain:

$$\frac{1}{4} W = c_{n1} \int_0^{\frac{\pi}{2\omega}} \left(\frac{dx}{dt} \right)^{n1} dx + c_{n2} \int_0^{\frac{2\pi}{\omega}} \left(\frac{dx}{dt} \right)^{n2} dx + \ldots .$$

$$= c_1 \int_0^{\frac{\pi}{2\omega}} \frac{dx}{dt} \, dx$$

From which it follows that

$$c_1 = c_{n1} \gamma_{n1} x^{n_1 - 1} \omega^{n_1 - 1} + c_{n2} \gamma_{n2} X^{n_2 - 1} \omega^{n_2 - 1} + \ldots \quad [18]$$

If this value of c_1 be inserted in the solution for the simple system, involving first-power velocity damping only, an expression results which, in the general case, can be solved by successive approximations.

Due to the frequent occurrence of constant friction and first-power velocity damping in engineering structures, let us see what the approximate solution gives in this case.

Case V—A System With Coulomb and Viscosity Damping

Since $n_1 = 0$ and $n_2 = 1$, we find, by means of Fig. 1 that

$$\gamma_{n1} = \frac{4}{\pi} \qquad \gamma_{n2} = 1$$

Inserting this into Equation [18]

$$c_1 = c_0 \frac{4}{\pi} X^{-1} \omega^{-1} + c = \frac{4}{\pi} F X^{-1} \omega^{-1} + c$$

Substitution of this value of c_1 into the general solution, Equation [2], will yield

$$x = \frac{Q}{\sqrt{(k - m\omega^2)^2 + \left(\frac{4}{\pi} F X^{-1} \omega^{-1} + c \right)^2 \omega^2}} \sin(\omega t - \psi)$$

$$= X \sin(\omega t - \psi)$$

$$\tan \psi = \frac{\left(\frac{4}{\pi} F X^{-1} \omega^{-1} + c \right) \omega}{k - m\omega^2}$$

Squaring both sides and rearranging terms, the following quadratic equation in X is obtained:

$$X^2 + \frac{\frac{8}{\pi} cF}{c^2\omega^2 + (k - m\omega^2)^2} X + \frac{\frac{16}{\pi^2} F^2 - Q^2}{c^2\omega^2 + (k - m\omega^2)^2} = 0$$

from which

$$X = \frac{\left[Q^2 \left\{ c^2\omega^2 + (k - m\omega^2)^2 \right\} - \frac{16}{\pi^2} F^2 (k - m\omega^2)^2 \right]^{\frac{1}{2}} - \frac{4}{\pi} cF\omega}{c^2\omega^2 + (k - m\omega^2)^2}$$

. . . . . [19]

For the sake of simplicity and generality, let us use the ratio symbols that were employed before, Equation [8]; then

$$f_0 = \frac{4}{\pi}\frac{F}{Q} \qquad f_1 = \frac{c}{m\omega_c}$$

and Equation [19] becomes

$$X = \frac{q[\{f_1^2\tau^2 + (1 - f_0^2)(1 - \tau^2)^2\}^{\frac{1}{2}} - f_0 f_1 \tau]}{f_1^2\tau^2 + (1 - \tau^2)} \quad \ldots [19a]$$

$$\tan\psi = \frac{f_1\tau + f_0 X^{-1}}{1 - \tau^2}$$

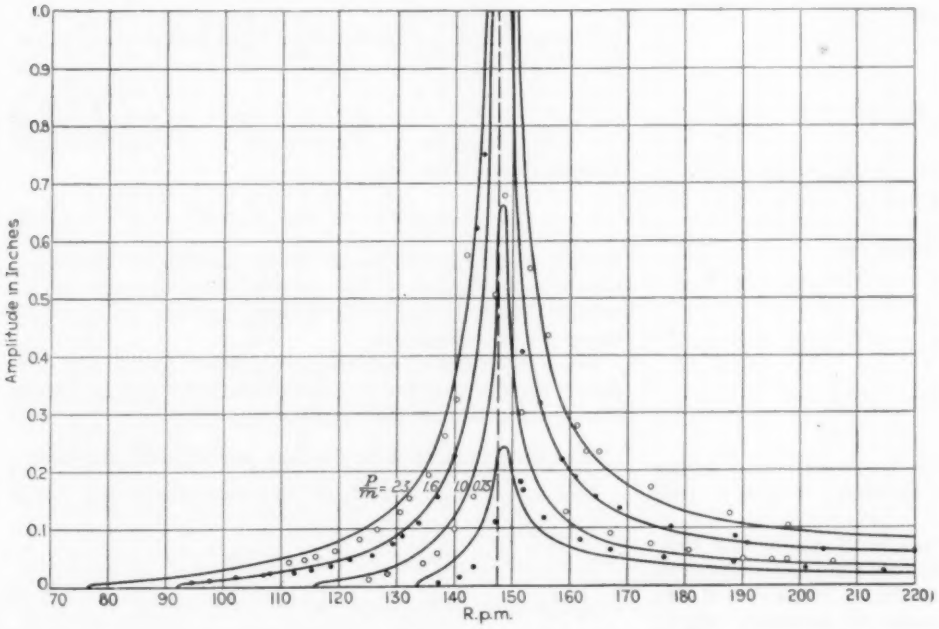

FIG. 9 SHOWING FREQUENCY-AMPLITUDE CURVES OF THE FORCED VIBRATION WITH A COMBINATION OF COULOMB AND VISCOUS DAMPING AND "CENTRIFUGAL" DISTURBING FORCE FOR DIFFERENT VALUES OF THE RATIO P/m (POINTS DETERMINED EXPERIMENTALLY)

It is seen that the motion is similar to the one depicted in Figs. 3 and 4, with the exception that the resonance amplitude is limited to $q(1 - f_0)/f_1$, and that the phase angle does not change abruptly at the resonance point. If, instead of a "constant" disturbing force, a "centrifugal" disturbing force be assumed, the results become

$$\left.\begin{aligned} X &= \frac{\left[P^2\omega^4\{c^2\omega^2 + (k - m\omega^2)^2\} - \frac{16}{\pi^2}F^2(k - m\omega^2)^2\right]^{\frac{1}{2}} - \frac{4}{\pi}cF\omega}{c^2\omega^2 + (k - m\omega^2)^2} \\ \tan\psi &= \frac{c\omega + \frac{4}{\pi}FX^{-1}}{k - m\omega^2} \end{aligned}\right\} \quad [20]$$

At values of ω for which the expression $P^2\omega^2$ is smaller than $(4/\pi)F$, the above equation has no physical meaning; in other words, motion does not begin until

$$\omega = \sqrt{\frac{\frac{4}{\pi}F}{P}}$$

This is in agreement with the results shown in Fig. 5, namely, that the forced vibration with constant friction and "centrifugal" disturbing force requires a certain minimum angular velocity of the disturbing force in order to show any motion at all. At resonance, the value of the amplitude is:

$$X = \pm\left(\frac{P\omega_c}{c} - \frac{\frac{4}{\pi}F}{c\omega_c}\right)$$

It is interesting to note that the amplitude depends not only on P and c, but also on F, a characteristic which is easily recognized in experiments. Above resonance, when ω approaches infinity, the amplitude approaches the asymptotic value of $-P/m$.

In regard to the phase angle, it is seen that, at the value of ω for which motion begins, the amplitude is zero and consequently $\psi = \pi/2$. As ω increases toward the resonance value, the magnitude of the displacement increases with the effect that the expression for $\tan\psi$ first decreases and then increases, giving a minimum somewhere between ω_0 and ω_c. At resonance, ψ is seen to be $\pi/2$, and as ω approaches infinity, the phase angle approaches the value π.

Expressing the motion by ratio symbols, Equation [8], we obtain:

$$h_0 = \frac{4}{\pi}\frac{F}{P\omega_c^2}; \quad h_1 = \frac{c}{m\omega_c}$$

giving

$$X = \frac{s[\{h_1^2\tau^2 + (\tau^4 - h_0^2)(1 - \tau^2)^2\}^{\frac{1}{2}} - h_0 h_1\tau]}{h_1^2\tau^2 + (1 - \tau^2)^2} \quad \ldots [20a]$$

$$\tan\psi = \frac{h_1\tau + h_0 X^{-1}}{1 - \tau^2}$$

The free-periodicity condition gives

$$X\tau \geqq \frac{sh_0}{2 - h_1} = \text{a constant}$$

a requirement which can easily be superimposed on the curves after they have been constructed.

Fig. 9 shows a series of four amplitude curves for the following values of s or P/m: 2.3, 1.6, 1.0, and 0.75. The points plotted on the same figure are the experimental results. Neglecting for the present these points, we notice that the theoretical curves start with finite slopes at definite angular frequencies or r.p.m. The arbitrary condition of free periodicity cuts off a small part of the curves at start. It is noticeable that the resonance amplitudes of the curves are not simply proportional to P/m, being 2.84 in., 1.665 in., 0.665 in., and 0.249 in., respectively. Attention should be called to the fact that the r.p.m. scale does not start at zero but at 70 cycles per minute, or approximately at $\tau = 0.5$. Fig. 10 shows the phase-angle curves corresponding to the amplitude curves of Fig. 9. Here again the criterion of free periodicity discredits our faith in the physical approximation of our method for the

part of the curves shown dotted. Minimum phase angles are obtained at approximately 133, 136, 138, and 142 cycles per minute; they amount to approximately 21.5, 31, 46, and 67 deg. Above the resonance frequency, all the curves approach π as a limit.

II—EXPERIMENTAL WORK

Description of Apparatus Employed

In order to test the foregoing conclusions concerning the steady forced vibration of a system under the influence of constant friction and first-power velocity damping, a series of experiments was performed on a large vibrating table[5] belonging to the School of Engineering at Stanford University. Fig. 11 shows a sketch of the table. The following dimensions and properties of the table have been measured or disclosed by free-vibration tests:

Weight of vibrating mass	19,800 lb.
Spring characteristic	12,320 lb. per in.
Constant friction force	114 lb.
Coefficient of first-power velocity damping	9.3 lb. per in. per sec.
Resonance frequency	148 cycles per min.

The disturbing force was produced by the centrifugal reaction of a rotating unbalanced flywheel, mounted rigidly on the table. Four different unbalanced moments of the flywheel were used: 890 lb-in., 620 lb-in., 390 lb-in., and 290 lb-in. The unbalances as well as the friction constants were determined with an accuracy of ± 3 per cent. A continuous record of the amplitude and the phase angle was obtained by means of a simple recording mechanism.

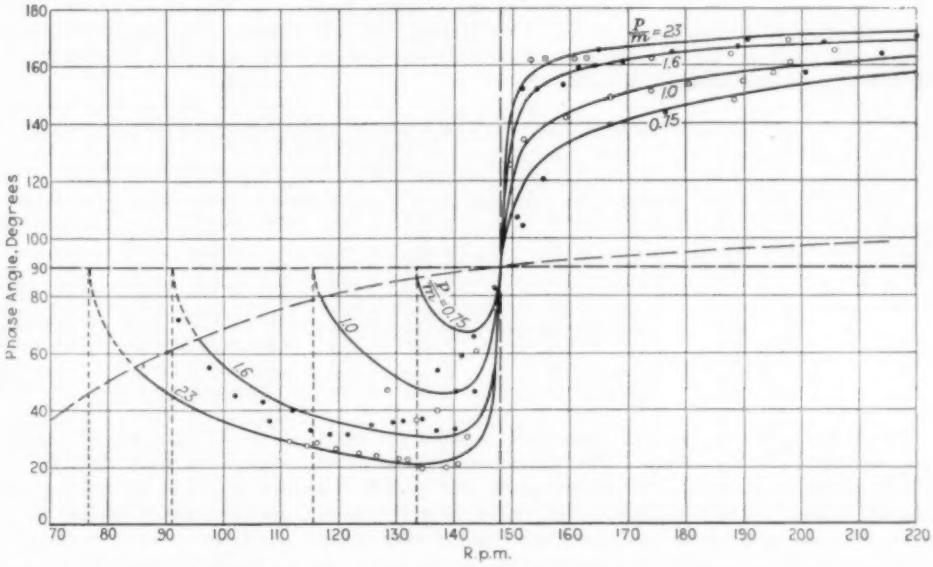

Fig. 10 Showing Frequency-Phase-Angle Curves Corresponding to the Amplitude Curves in Fig. 9

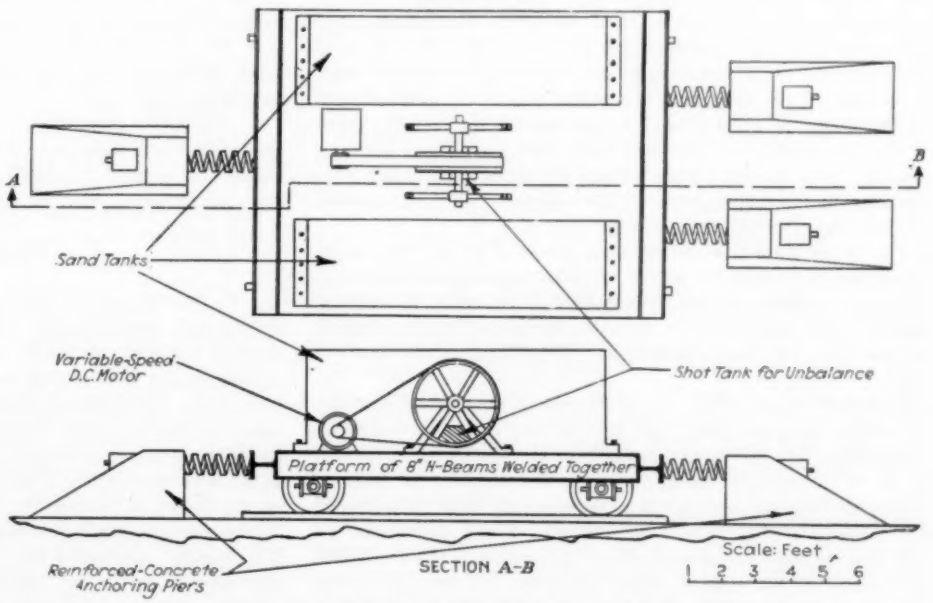

Fig. 11 Diagrammatic Sketch of Vibrating Table at Stanford University

Discussion of Experimental Results

Referring to Fig. 9, it will be seen that the experimentally determined points follow the theoretical, approximate curves very closely. As the unbalance is decreased, the experimental points seem to shift slightly to the right of the curves. This is quite easily explained by a small variation of the spring constant, a thing very likely to happen as the four curves were not obtained on the same day. Near resonance it was found very difficult to keep the frequency of the impressed force constant, especially so when the unbalance was large, hence very few points were obtained at 148 cycles per minute. Considering that the constant friction force is rather large compared to the first-power velocity damping coefficient, one is impressed with the agreement of experimental data and approximate theory.

The phase angles shown in Fig. 10 are also, considering their capricious nature, in good agreement with the approximate theory. All the records, with the exception of those at the starting frequencies, show wave shapes that approximate the sinusoid very closely. The phase angles were determined with reference to the zero-amplitude time position.

[5] For a detailed description of the vibrating table, see author's paper on "Vibration Research at Stanford University," *Bulletin of Seismological Society of America*, March, 1929.

Comparison of the Den Hartog Exact Theory and the Approximate Theory

It was stated earlier in this paper that, fortunately for the approximate theory, an exact theory for the case of constant friction and first-power velocity damping had been developed. The four special cases, for which experimental evidence had been obtained, were computed by Mr. Den Hartog, and his results are given in Table 1 for comparison with the results obtained by the approximate theory.

TABLE 1 COMPARISON OF THE RESULTS OBTAINED BY THE EXACT THEORY AND BY THE APPROXIMATE METHOD

	$P/m = 2.3$			$P/m = 1.6$			$P/m = 1.0$			$P/m = 0.75$

148	2.840	2.840	0	1.660	1.665	0	0.660	0.665	+1	0.242	0.249	+3
151	0.964	0.903	−6	0.618	0.588	−5	0.303	0.298	−2	0.146	0.153	+5
156	0.433	0.420	−3	0.288	0.279	−3	0.154	0.151	−2	0.088	0.089	+1
164.5	0.227	0.226	0	0.152	0.153	0	0.086	0.086	0	0.053	0.055	+2
174	0.157	0.157	0	0.106	0.107	+1	0.061	0.062	+1	0.040	0.041	+2
185	0.122	0.121	−1	0.083	0.083	0	0.049	0.049	0	0.033	0.034	+3

The table shows an excellent agreement between the exact and the approximate theory. The difference is greatest at start; this is to be expected, inasmuch as the assumption of a sinusoid wave form of the displacement cannot be a very good approximation until the motion has reached a fair magnitude; in some cases the difference amounts to about 15 per cent. At resonance the two methods give practically the same results, and, above the resonance point, the error of the approximate method may be said to be within 5 per cent. Considering that the agreement is as satisfactory in this case where the values of n are zero and unity, the term with $n = 0$ being the predominant, it is easy to see that in other cases, where the predominant friction term is proportional to powers of the velocity near unity, the approximate method must give even closer approximations than recorded here. Even the case of damping proportional to the second power of the velocity should be expected to give very close approximations.

Let us consider the assumptions involved in the theoretical treatment of system for which we have experimental evidence; they are constant friction independent of the velocity, constant spring characteristic, and a vibrating system of just one degree of freedom. Of these assumptions let us examine the first one only.

Experiments on coefficients of friction of dry and of partially lubricated surfaces have been carried out by many early investigators with the general result that the coefficient of friction is never completely independent of the velocity of motion. Professor Fleming Jenkin,[6] in experimenting with velocities in the range of 0.0024 to 0.12 in. per sec., found that there did not seem to exist a discontinuity in the value of the coefficient of friction at rest and at small velocities. If this be so, the free-vibration tests will give average values of the coefficient of friction, but the averages will, of course, be higher the smaller the amplitudes of the free vibration. It is therefore very likely that the assumption of a constant friction force is not in complete harmony with experiment, and one invariably asks the question if, from a pragmatic point of view, an approximate theory might not give as accurate results as an exact theory? From an academic point of view, however, the exact theory, even if based on assumptions that are not strictly physical realities, is vastly superior to an approximate theory or solution; in fact, it is the only one that has any claim to recognition.

[6] Proceedings of the Royal Society, March, 1877.

Conclusions

1 A general method of obtaining approximate solutions of the steady forced vibration of a damped system of one degree of freedom has been developed for the case of sinusoidally varying disturbing forces.

2 The approximation consists in expressing all the damping terms of the original differential equation by a single equivalent damping term, proportional to the first power of the velocity of motion.

3 The criterion of equivalence is taken to be the amount of dissipative work done per cycle. If in addition to this it be assumed that the friction does not change the wave shape of the displacement from that of a sinusoid, the equivalent damping coefficient is easily evaluated.

4 In the case of a system influenced by a centrifugal disturbing force and damped by constant friction and by friction proportional to the first power of the velocity, experimental evidence is in good agreement with the approximate solution.

5 Mr. Den Hartog's exact solution for the above system is in good agreement with the experimental results and with the approximate solution.

6 While this paper has dealt solely with a system of one degree of freedom, there is no reason why the approximate solution cannot be applied to systems of several degrees of freedom; such applications will, of course, become relatively involved.

Discussion

J. P. Den Hartog.[7] The paper solves in one stroke and with very simple mathematics a number of problems of which the solution has been wanted for many years.

Since in the general case no exact solution is available to compare with, the question naturally arises whether we can form some qualitative ideas regarding the accuracy of the procedure. In this respect it is noted first that in Fig. 2 the sine curve ($n = 1$) is the first term in the Fourier development of any of the other curves shown in that figure. There is a definite reason for this. The author has made the assumption of pure harmonic motion. The energy dissipated by a non-harmonic periodic force in combination with a pure harmonic motion of the same frequency can be shown to be due to the fundamental component of the force only, while its higher harmonics do not perform any work during a complete cycle.

The author has replaced the curves of Fig. 2 by the particular curve $n = 1$, thus neglecting the higher harmonics of the damping force. As said before, this does not affect the energy relations. The main influence of these higher harmonics will then consist of a distortion of the wave form of the motion.

Let us try to extend the process somewhat by dropping the assumption of a harmonic motion, but by retaining a damping

[7] Research Laboratories, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

force, determined by the curves of Fig. 2, which will be correct only for harmonic motion.

Then let us investigate how this damping force distorts the motion. On account of their symmetry the curves of Fig. 2 can be expressed by sine series with odd components only. The differential equation of the motion thus becomes:

$$m\ddot{x} + kx = Q \cos(\omega t + \varphi) + \sum_{n=1,3,5\ldots} a_n \sin n\omega t \ldots\ldots [21]$$

where φ is as yet undetermined and the a_n's are the Fourier coefficients of the damping curve in Fig. 2. The steady-state solution of this equation is:

$$x = \frac{Q}{k - m\omega^2} \cos(\omega t + \varphi) + \sum_{n=1,3,5\ldots} \frac{a_n \sin n\omega t}{k - n^2 m\omega^2} \ldots [22]$$

It is seen that the first two terms have the period ωt. In the neighborhood of resonance these terms are large on account of the $k - m\omega^2$ in the denominator. The remaining terms with periods $3\omega t$, $5\omega t$, etc., are smaller and represent the distortion in the motion. Therefore, comparing the accuracies of the results of the paper for the various cases of Fig. 2, it can be roughly said that the Fourier coefficients a_3, a_5, etc., of the various curves give an estimate of the error committed. The Fourier expansions for the two principal cases are:

$$\text{For } n = 0: \quad \frac{4}{\pi}\left[\sin \omega t + \frac{1}{3}\sin 3\omega t + \frac{1}{5}\sin 5\omega t \ldots\right] \ldots [23a]$$

$$\text{For } n = 2: \quad \frac{8}{3\pi}\left[\sin \omega t - \frac{1}{5}\sin 3\omega t - \frac{1}{35}\sin 5\omega t \ldots\right]. \quad [23b]$$

Therefore, the conclusion seems justified that the approximation in the neighborhood of resonance is even better for the square velocity damping case than for the Coulomb damping case.

An examination of [22] leads to yet another fact. It is seen that near one-third, one-fifth, etc., of the resonant frequency, the corresponding term in the series becomes large, so that the motion is very much distorted. Near such frequencies, therefore, the approximation given should be poor. Indeed the exact solution for the Coulomb case shows that stops in the motion occur at those frequencies even for infinitesimal small damping. Happily, however, these cases are of little practical importance.

A third interesting property of Equation [22] is that it enables us to arrive at an exact solution in series form for the case of Coulomb friction as long as no stops occur during the cycle. In this case, the magnitude of the damping force is independent of the velocity, that is of the wave form, so that [21] is the true differential equation.

In the Fourier expansion of the damping curve the origin of time was taken at the left-hand side of Fig. 2, at the moment that the damping force passes through zero. This means that at this moment the motion must be at its maximum or minimum position, and the velocity must be zero. Differentiating [22], after substituting the series [23a] for the a_n in it, we obtain:

$$\dot{x} = \frac{-Q\omega}{k - m\omega^2} \sin(\omega t + \varphi) + \frac{4F}{\pi} \sum_{n=1,3,5\ldots} \frac{\omega \cos n\omega t}{k - n^2 m\omega^2}$$

By equating this to zero for $t = 0$, a condition for φ is found:

$$(\dot{x})_{t=0} = 0 \quad \frac{-Q\omega}{k - m\omega^2} \sin\varphi + \frac{4F}{\pi} \sum_{1,3,5\ldots} \frac{\omega}{k - n^2 m\omega^2}$$

or

$$\sin\varphi = \frac{4}{\pi}\frac{F}{Q}\left(\frac{k}{m} - \omega^2\right) \sum_{n=1,3,5\ldots} \frac{1}{k/m - n^2\omega^2} \ldots\ldots [24]$$

The maximum amplitude X also occurs at $t = 0$; then the entire series in [22] vanishes:

$$X = \frac{Q}{k - m\omega^2} \cos\varphi \ldots\ldots\ldots\ldots\ldots [25]$$

It is seen that [24] and [25] constitute an exact solution of the amplitude and phase angle, while [22] gives the wave form.

It is appreciated that this is true only when the series in [21] actually represents the damping force. When the friction becomes so large that stops occur during the motion this ceases to be correct, so that the solution is limited to motions without stops.

It is evident that when [24] and [25] are restricted to only the first term of the series, the result:

$$X = \frac{Q}{k - m\omega^2} \sqrt{1 - \left(\frac{4}{\pi}\frac{F}{Q}\right)^2}$$

coincides with the solution given in the paper.

The solution [24], [25] naturally gives the same numerical results as the exact solution obtained before,[8] though the latter appears in the finite form:

$$X = \frac{Q}{k} \sqrt{\left(\frac{\beta^2}{\beta^2 - 1}\right)^2 - \left(\frac{F}{Q}\right)^2 \left(\frac{\beta \sin \beta\pi}{1 + \cos \beta\pi}\right)^2} \ldots [26]$$

where

$$\beta = \frac{1}{\omega}\sqrt{\frac{k}{m}}$$

A comparison of [25] with [26] incidentally leads to the interesting series:

$$\sum_{n=1,3,5\ldots} \frac{1}{n^2 - \beta^2} = \frac{\pi}{4} \frac{\sin \beta\pi}{\beta(1 + \cos \beta\pi)} \ldots\ldots\ldots [27]$$

which is true for all values of β and which would probably be difficult to prove mathematically, without having recourse to the physical problem from which it was derived.

Summarizing, the following statements can be made:

1. For any n not larger than 2, the results obtained by the approximate method are more accurate than those for the case $n = 0$, at least in a sufficiently broad region near resonance. Since for $n = 0$ the error is very small, the method is reliable for all practical cases.

2. Larger errors are to be expected at frequencies near one-third, one-fifth, etc., of the natural frequency. Since these cases are of no practical importance, it does not affect the usefulness of the solution.

3. For the special case of Coulomb damping ($n = 0$) the method employed in the paper can be extended to give an exact solution in series form for friction forces sufficiently small to permit motions without periodic stops.

E. O. Waters.[9] The author's analysis is a most interesting extension of the theory of vibrations, and the formulations are simple enough to be within the reach of most engineers who have to do with vibration problems. It is indeed un-

[8] *Phil. Mag.*, 1930, p. 803.

[9] Associate Professor of Mechanical Engineering, Yale University, New Haven, Conn. Assoc-Mem. A.S.M.E.

fortunate that only one particular type of vibration—that with viscous damping—should lend itself to an easy and at the same time rigorous mathematical treatment, because the tendency has been to concentrate attention upon this type to the exclusion of others which may be of quite as common physical occurrence. In most of the elementary analyses of the forces and stresses in machines, the friction force is assumed constant; but as soon as periodic motion is encountered, the engineer has not had the means at his disposal to determine the effect of this kind of friction even approximately.

From an abstractly mathematical point of view, there is nothing difficult about the solution of the equations for steady forced vibrations with Coulomb damping, or a combination of viscous and Coulomb damping; the trouble comes in trying to get numerical results. On account of the + sign appearing before the damping term, there is a discontinuity each time the velocity passes through zero, and the constants of integration have to be evaluated anew at each such point. But these constants are contained in the transient portion of the complete expression for the motion, whereas it is only the steady state in which we are interested. Mr. Den Hartog and Professor Milne have shown that the problem can be solved both for the case of constant damping and that of velocity-square damping, but a perusal of their papers leads one to the conclusion that the method outlined in the present paper, with its simplifying assumptions, is better adapted to practical numerical computation. This is especially true for composite Coulomb and viscous damping, for which Table 1 shows a very good agreement between the approximate and the exact theory. It would be interesting to know whether an equally good correlation holds for the case of velocity-square damping.

As the author states, his method does not reveal anything regarding possible complications in the wave shape, and simply assumes that it is sinusoidal. It may be of interest to know that the actual wave shape may be found quite easily, with any desired degree of accuracy, for a given combination of Coulomb and viscous damping. The method is based upon the use of a Fourier series for the damping, and the solution of the equation of motion by the well-known method of undetermined coefficients, together with the condition that $c_0 = 0$ when $x = 0$.

If the friction is constant in magnitude, but varies principally in sign, it may be expressed as

$$\frac{4s_0}{\pi}\left[\sin\omega t + \frac{1}{3}\sin 3\omega t + \frac{1}{5}\sin 5\omega t + \ldots\ldots\right]$$

Four terms give a mean value better than 97 per cent of c_0 and a correspondingly low root-mean-square deviation. The equation of motion is

$$mx - \frac{4c_0}{\pi}\left[\sin\omega t + \frac{1}{3}\sin 3\omega t + \frac{1}{5}\sin 5\omega t + \ldots\right] + bx = Q\sin(\omega t - \psi)$$

the solution of which is (neglecting transients)

$$x = -\frac{4c_0}{\pi}\left(\frac{1}{k - qm\omega^2} + \frac{1}{k - 25m\omega^2} + \ldots\right)\sin\omega t + \sqrt{\left(\frac{Q}{k - m\omega^2}\right)^2 - \frac{16c_0^2}{\pi^2}\left(\frac{1}{k - m\omega^2} + \frac{1}{k - qm\omega^2} + \frac{1}{k - 25m\omega^2}\right)^2}\cos\omega t + \frac{4c_0}{\pi}\left(\frac{\sin 3\omega t}{3(k - qm\omega^2)} + \frac{\sin 5\omega t}{5(k - 25m\omega^2)} + \ldots\right)$$

This becomes identical with the author's solution for a "constant" disturbing force when the higher harmonic terms and corrective coefficients are dropped. At first sight it would seem that there are an infinite number of critical speeds, but an analysis of the cosine term shows that there is only the one critical speed $\omega_c = \sqrt{k/m}$, and a number of aperiodic regions which are reached whenever any of the terms $1/(k - qm\omega^2)$, $1/(k - 25m\omega^2)$, etc., become so large that the coefficient of cos ωt is imaginary.

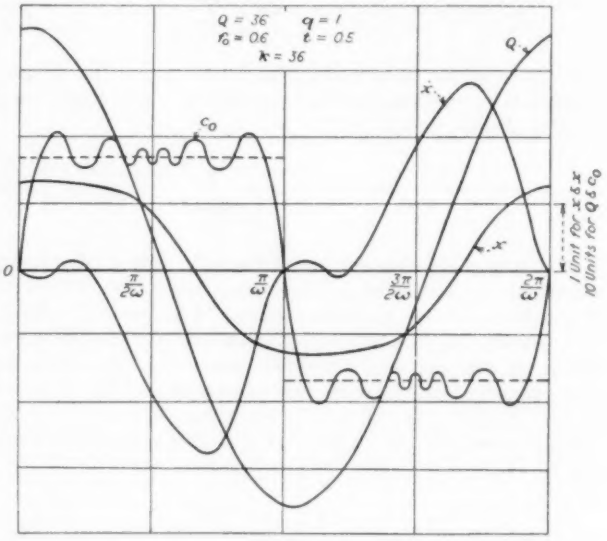

FIG. 12

Fig. 12 illustrates the results for a sample problem, with constants taken close to the aperiodic region as shown in Fig. 3 of the paper. The small oscillations of x about the X-axis are of course incompatible with the damping force as indicated; possibly the inclusion of more harmonics in the analysis, or a choice of constants further from the aperiodic boundary, would iron them out. At any rate, it is evident that the motion is practically composed of sinusoidal swings from one extreme position to the other, interrupted by brief pauses for about one-eighth of a cycle at each end of the travel of the vibrating body.

The foregoing method may be extended to problems in combined Coulomb and viscous damping; it is also applicable to nth-power velocity damping, provided the assumption be made that the damping force is proportional to the nth power of the velocity wave.

A. L. KIMBALL.[10] The author has presented a method of finding the amplitude of a forced vibration at any frequency for any law of damping which he wishes to assume. The method is not exact, but it is near enough so as to be of great value in practical work. He makes the approximation of assuming the vibratory motion to be exactly sinusoidal, regardless of the character of the damping friction. Since the departure from sinusoidal motion is usually very small, the error in this method is correspondingly unimportant.

The paper is of considerable interest to the writer because vibration damping due to internal friction in elastic bodies is a specialty of his. It is interesting that he has used the same method as that used by the author for the particular case of the damping of forced vibrations with "solid friction."[11]

The paper, in the writer's opinion, is outstanding, and it is to be hoped that it will receive a full share of appreciation.

[11] A. L. Kimball, "Vibration Damping, Including the Case of Solid Friction," Trans. A.S.M.E., paper APM-51-21, pp. 227–236.

Author's Closure

After his paper had been written and submitted to the Committee on Publications of the Applied Mechanics Division of the Society, the author was much interested to learn from Mr. Kimball that he had used a particular case of the general problem dealt with in the paper for expressing the damping due to "solid friction." It is very gratifying for the general problem that the approximation in the case of "solid friction" is found to be satisfactory.

The discussions by Dr. Den Hartog and by Professor Waters are valuable contributions to the paper. If no stops occur in the motion, the exact solution for $n = 0$ is obtainable in series form or in the finite form given by Dr. Den Hartog in his original paper. Of especial interest to the author is Dr. Den Hartog's investigation of the question of the degree of approximation involved when the exponent n is varied.

The author wishes to acknowledge his indebtedness to Prof. L. H. Donnell of the University of Michigan for presenting the paper, and to express his thanks to those who have taken part in the discussion.

APM-52-16

Automotive Brakes With Servo-Action

By DR. F. LOEWENBERG,[1] BERLIN-CHARLOTTENBURG, GERMANY

The retardation produced in braking automotive vehicles results from the pressing of a fixed body against a moving surface. This paper discusses a method in which the friction forces themselves produce higher pressure. This has been called "self-actuation" or "self-energization." Various conditions and arrangements are discussed, and the forces developed are worked out mathematically.

THE design of brakes for automotive vehicles is based on the decelerative effect of friction forces produced by pressing a fixed body against a moving surface. In the case of buses and trucks the physical power of a human being has been found to be insufficient to exert the pressure required for proper brake action. Of course, the power of the driver can be largely increased by using levers, but the leverage is limited by the allowable travel of the pedal. From the total motion of the pedal a sufficient amount has to be deducted for taking up the slack in the brake rigging and the clearance between shoe and drum and to allow for wear of the lining; otherwise, serious difficulties arise in service such as dragging brakes and the necessity of frequent brake adjustments. Only a fraction of the travel can therefore be used for real brake action, which results in a rather definite maximum leverage. Various methods are in use in order to increase or replace the force of the driver, using either the suction of the engine or other means as a source of power. This paper is concerned with another method consisting in the use of the friction forces themselves to produce higher pressure. This has been termed "self-actuation" or "self-energization" and has been used to a certain extent not only in straight mechanical but also in power brakes. It is only in modern brake design, however, that the possibilities of this method have been fully realized.

In order to make clear the meaning of self-actuation and the way it has been used in different brake designs, the basic principle is shown in Fig. 1 in a simplified manner. Here a block is pressed against a straight moving surface, the reaction of the friction forces being taken up by a fixed block with a straight or inclined surface. While this deviates far from the actual design, it gives an idea of the action without the use of formulas, and most of the actual designs can be classified under one of the cases shown. In case (*a*) the reaction of the friction forces has apparently no effect on the pressure between block and moving face (no self-actuation). In case (*b*) the pressure is increased by the reaction of the friction (positive self-actuation), while in case (*c*) it is decreased (negative self-actuation). Under (*d*) an inclined face of very small angle is drawn in order to show that the principle of self-actuation can be brought to the point where the block "wedges itself in," which means that the smallest force exerted upon the block results in a theoretically unlimited pressure between block and moving face. In this case the brake is "grabbing."

The three following cases represent designs with two brakeshoes. In (*e*) two brakeshoes are shown, each having positive self-actuation; in (*f*) and (*g*) one brakeshoe has positive and one negative self-actuation, while (*f*) represents the case in which the force exerted by the brake rigging is equally divided between the two shoes. It can be easily proved that in this case the advantage gained on one shoe exceeds the disadvantage caused by the negative self-actuation of the other shoe, so that the two shoes taken as a whole have positive self-actuation. In case (*g*) the two blocks are connected with the rigging in such a way that the travel of both blocks is equal. This is obtained in actual design, for instance, by a symmetrical fixed cam, and results in the pressure on the sliding face being equal on both blocks. A simple calculation shows that in this case the positive and the negative self-actuation of the two shoes just balance each other, so that the net self-actuation is zero.

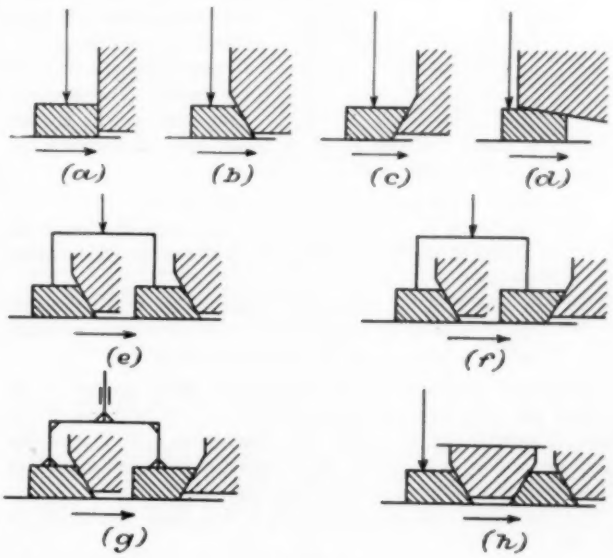

FIG. 1

The principle of another brake design is shown at (*h*), Fig. 1. In this case the pedal pressure acts upon one of the two brakeshoes only. The reaction of the friction forces of this shoe is not taken up by a fixed face, but is transferred to the second shoe, which is actuated by it. Each of the two brakeshoes can be self-actuating in itself, but at the same time we have the action of the "primary" shoe upon the "secondary" shoe, which action is called "servo-action" and forms the main subject of the present paper.

BRAKESHOE WITH FIXED ANCHOR PIN

In actual brake design the self-actuation is not produced by wedge effect as has been assumed thus far for the sake of simplicity. Fig. 2 gives an example of a self-actuating shoe. The

[1] Allgemeine Elektrizitäts Gesellschaft Oberleitung. Dr. Loewenberg was graduated in 1922 from the Technical Institute, Berlin-Charlottenburg, with the degree of Diplom-Ingenieur. He received the degree of Doctor of Engineering in 1924, also in Berlin. From 1925 to 1927 he was connected with the American Locomotive Works, Schenectady, N. Y., and later was for two years associated with the Delling Motors Co., West Collingswood, N. J. He is at present engaged in development work on motor coaches for the subsidiary companies of the German General Electric Company.

Contributed by the Applied Mechanics Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

shoe swings around a fixed anchor pin G and is pressed against the drum by a force P exerted, for instance, by a cam. F_1 denotes the friction force acting upon the brake drum at a certain point, while F_2 is the reaction of this force upon the brakeshoe. It is obvious from the figure that the reactions of the friction forces in all points of the brakeshoe have a tendency to turn the shoe in the same direction in which it is turned by the action of the cam. They contribute, therefore, to the pressure existing between brakeshoe and drum, and make the shoe self-actuating. This, however, is only true for the drum turning in the direction shown by the arrow. If the drum rotates in the opposite direction the reactions of the friction forces counteract the cam force P. For this direction of rotation the shoe has therefore negative self-actuation. For the brakeshoe shown in Fig. 2, L. C. Huck has developed a formula[2] giving the relation between the cam force P and the total amount of all pressures between shoe and drum. The assumptions on which Huck's formula is based are the same as those used in deriving the equations of this paper, and are as follows:

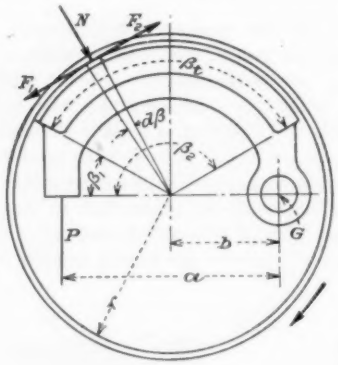

FIG. 2

1 Brake drum and brakeshoe are not flexible
2 The brake is "worn in," i.e., in applying the brake all points of the brake lining touch the drum at the same moment
3 In applying the brake the lining is being compressed, the compression being in proportion to the pressure which is exerted on the lining (Hooke's law).

With these assumptions, Huck's formula gives the sum of all normal pressures between shoe and drum (ΣN) in terms of the force P exerted by the cam, the dimensions a, b, r, and the angles β_1 and β_2 as shown in Fig. 2, and the coefficient of friction f between shoe and drum (see Appendix No. 1).

For the sum of all friction forces acting upon the drum we obtain

$$\Sigma F = f\Sigma N$$

In the case of no-friction, i.e., for $f = 0$, we obtain from Equation [2], Appendix No. 1,

$$\Sigma N' = P\frac{aE}{bB}$$

The negative sign in Equation [2] is valid for the rotation according to the arrow in Fig. 2. In this case $\Sigma N > \Sigma N'$, as our definition of self-actuation called for. For rotation in the opposite direction we have to use the positive sign of the equation and we obtain $\Sigma N < \Sigma N'$. In comparing the self-actuation of different brakeshoes Huck makes use of a certain self-actuation factor giving the self-actuation as a percentage and an actuation constant which is constant for a given brakeshoe. This has not been found to be practical for the calculations which follow. The author will therefore use only one self-actuation factor, which gives the ratio between the sum of all pressures exerted on the drum under the action of the friction forces to the sum of all pressures which would result from the cam force if there were no friction whatsoever. This factor $\Sigma N/\Sigma N'$ is not constant for a given brakeshoe but varies with the coefficient of friction. With the value of ΣN given in Equation [2], Appendix No. 1, we obtain for the brakeshoe swinging around a fixed anchor pin

$$\frac{\Sigma N}{\Sigma N'} = \frac{1}{1 - \frac{f}{B}\left(A + \frac{r}{b}E\right)}$$

This expression becomes infinite when

$$f = \frac{B}{A + \frac{r}{b}E}$$

this being the value of the friction coefficient at which the brake first grabs.

In Fig. 3 the factor of self-actuation is plotted against the coefficient of friction, for a symmetrical brakeshoe in which $b = 7.125$ and $r = 8.45$. The figure shows the curves for different values of $\beta_t = \beta_2 - \beta_1$, the total angle covered by the brakeshoe. In Fig. 4 similar curves are plotted, the difference being that the brakeshoe is here assumed to be symmetrical with respect to a radius drawn at 70 deg. and at 110 deg. to the line connecting the anchor pin and the center of the brake.

The curves show that any amount of self-actuation can easily be obtained, but they show at the same time that the higher the self-actuation the more sensitive is the brake to changes in the friction coefficient. Therefore, if too high a degree of self-actuation is used in a brake design, the brake is liable to grab in some cases, while it will not hold sufficiently in other cases. That is why it is much more important to obtain a brake lining which is affected as little as possible by temperature, moisture, speed, etc., than to obtain one with a high frictional coefficient. Outside of this the curves show that moving the brakeshoe either toward the anchor pin or away from the anchor pin tends to decrease the self-actuation. Lengthening the brakeshoe seems to decrease the self-actuation in most cases, while in a few cases it increases it. There seems to be no way of judging the self-actuation of a brakeshoe or of comparing the self-actuation of two shoes of different design without computation according to Huck's formula.

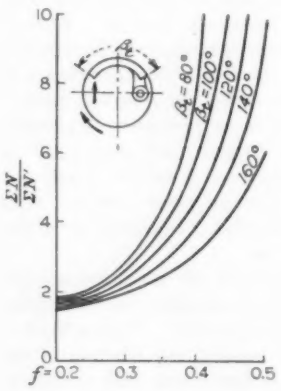

FIG. 3

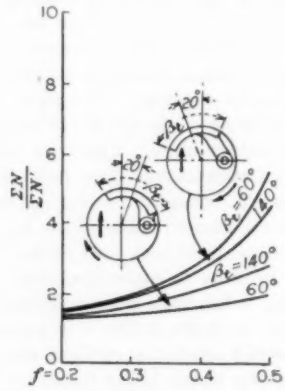

FIG. 4

SERVO-ACTION

Two different designs will be dealt with here. In one design the primary shoe, or the shoe upon which the cam pressure is exerted, is directly connected to the secondary shoe by a pin, the secondary shoe swinging around a fixed anchor pin (Fig. 5). In this case there are only two members between the cam and

[2] *Trans. S.A.E.*, 1926, part 1.

the anchor pin. In the other design (Figs. 10 and 14) both shoes are connected by a link, so that there are three members between the cam and the anchor pin.

Shoes Directly Connected

Referring to Fig. 5, we can apply Huck's formula to the secondary shoe because it swings around the fixed anchor pin G. The primary shoe swings around pin H, which in turn describes a circle around G. In the design shown in Fig. 5 the points G and H are located almost diametrically opposite each other. This means that the motion of point H around G deviates but little from the circular motion around the center of the brake. Consequently the primary shoe can also be considered as swinging around a fixed anchor pin, because a circular motion of point H around the brake center has no effect on the compression of the brake lining of the primary shoe. It would be quite possible to dispense with this approximation and to solve the problem for a primary brakeshoe whose motion is composed of swinging around H and G. The calculations, however, would become far more involved, and it does not seem likely that any brake design could be used successfully in which the points G and H are not located diametrically opposite each other, because it would necessarily result in very unequal wear of the linings of the two shoes.

Huck's formula will therefore be applied to the primary brake-

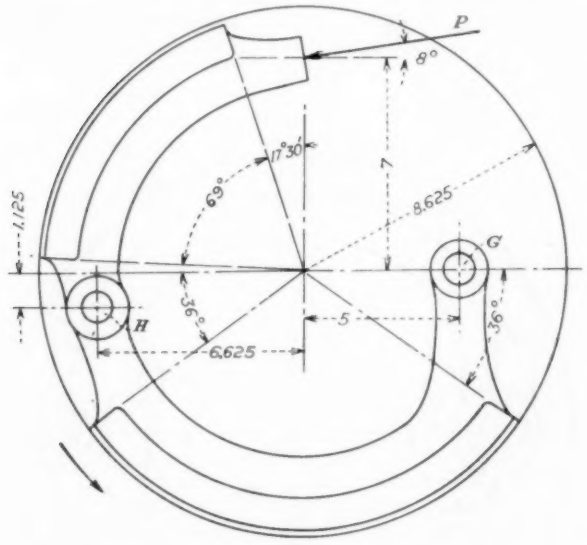

Fig. 5

shoe. However, this formula gives only a means of calculating the sum of all pressures exerted upon the drum and the amount of self-actuation of this shoe. In order to obtain the self-actuation of the total brake, comprising both primary and secondary shoe, it is necessary to determine the force acting upon point H, because it is this force which actuates the secondary shoe. This force can only be calculated from the static equations of the primary brakeshoe.

Referring to Fig. 6, in which the primary brakeshoe is drawn separately, a line is drawn through point H and the center of the brake, and the forces are resolved into their components either parallel or normal to this line. This gives two static equations, while a third equation is obtained from the moments around the center of the brake drum. (See Appendix No. 2.) From these three equations formulas are derived which give the force acting upon the pin H in terms of the cam force P, the coefficient of friction f, and the dimensions of the brake. (Eq. [6] and [7], App. No. 2.) By substituting $f = 0$ in these equations we obtain the relation of these forces in the case of no-friction. Furthermore a coefficient of friction can be computed for which the force on the pin becomes infinite, i.e., for which the brake grabs due to the servo-action. With the force on

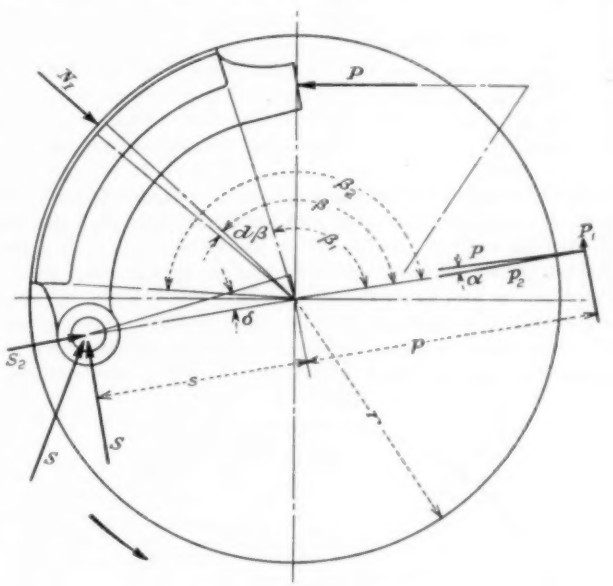

Fig. 6

the pin and the force on the cam we can use Huck's formula to determine the sum of all pressures between the primary shoe and the drum ΣN_{I}, and between the secondary shoe and the drum, ΣN_{II}, and we can furthermore compute these pressures for the case of no-friction, $\Sigma N_{\mathrm{I}}'$ and $\Sigma N_{\mathrm{II}}'$. (Eq. [6a], [6b], [7a], [7b], App. No. 2.) The relation between the sum of all normal pressures for friction and for no friction gives the factor of self-actuation; it is to be noted, however, that the expression $\Sigma N_{\mathrm{II}}/\Sigma N_{\mathrm{II}}'$ found in this way is not the same as if the self-actuation of the secondary shoe had been calculated separately, because it contains at the same time the influence of the servo-action. If now ΣN and $\Sigma N'$ denote the sum of all pressures of the total brake, we have

$$\Sigma N = \Sigma N_{\mathrm{I}} + \Sigma N_{\mathrm{II}}$$
$$\Sigma N' = \Sigma N_{\mathrm{I}}' + \Sigma N_{\mathrm{II}}'$$

and the total self-actuation is

$$\frac{\Sigma N}{\Sigma N'}$$

Example. From the dimensions shown in Fig. 5 the following values can be calculated:

Primary Shoe (Fig. 6):

$p = 264$ $s = 6.75$ $r = 8.625$
$\alpha = 1° 30'$ $\beta_1 = 98°$ $\beta_2 = 167°$
$A = -0.465$ $B = 0.641$ $E = 0.835$

Secondary Shoe (Fig. 7):

$a = 11.625$ $a' = 1.125$
$b = 5$ $r = 8.625$
$\epsilon = 9° 30'$ $\beta_1 = 36°$ $\beta_2 = 144°$
$A = 0$ $B = 1.419$ $E = 1.618$

TABLE 1

		Values of f

3	$\Sigma N_I/\Sigma N_I'$	...	1.15	1.33	1.54	1.8
4	S_1	...	1.43	1.72	2.1	2.6
5	S_2	...	0.22	0.36	0.45	0.56
6	$S = \sqrt{S_1^2 + S_2^2}$	...	1.45	1.76	2.15	2.66
7	S_1'	1.025	..	...	...	....
8	S_2'	0.225	..	...	...	....
9	$S' = \sqrt{S_1'^2 + S_2'^2}$	1.05	..	...	...	....
10	S/S'	...	1.38	1.68	2.05	2.53
11	ΣN_{II}	...	5.07	8.4	19.3	290
12	$\Sigma N_{II}'$	2.01	..	...	...	...
13	$\Sigma N_{II}/N_{II}'$	...	2.52	4.18	9.6	71
14	ΣN	...	6.65	10.22	21.4	292
15	$\Sigma N'$	3.38	..	...	...	....
16	$\Sigma N/\Sigma N'$	...	1.97	3.03	6.35	86

With these values and by using the above formulas Table 1 has been calculated. In this table all forces are given in multiples of the cam force P. In Fig. 8 the factors of self-actuation are plotted against the coefficient of friction for primary and secondary shoe as well as for the total brake. Fig. 9 shows the sum of all brakeshoe pressures and the force at the connecting pin H. It is found that the self-actuation of the primary shoe is rather low and very little affected by changes in the frictional

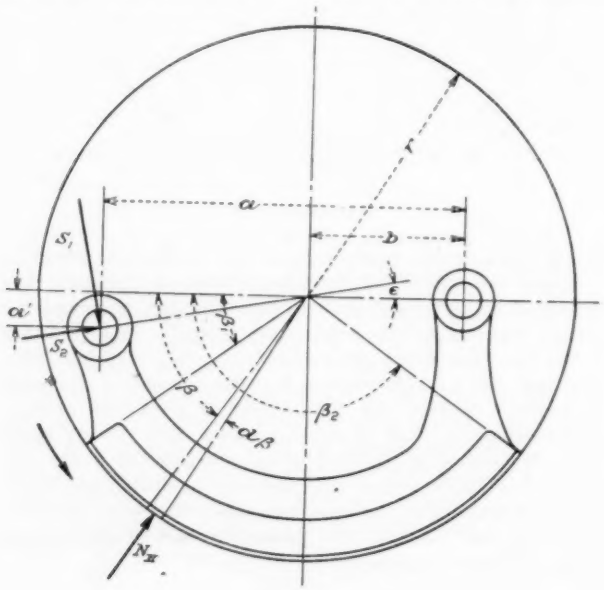

FIG. 7

coefficient. Equally, the servo-action is not influenced much by the friction. The self-actuation of the secondary shoe is very high and correspondingly subjected to great changes. In fact, the secondary shoe is very close to the point of grabbing. According to the curves, one would expect that the lining of the secondary shoe would show most of the wear.

BRAKESHOES CONNECTED BY LINK

Figs. 10 and 14 show brake designs in which a link is inserted between the primary and secondary shoes. The calculation of the primary shoe in this design is essentially different from the one dealt with in the foregoing, because no simplifying assumption can be made regarding the motion of the shoe under the action of the cam force.

In Fig. 11 a primary shoe is shown separately. We shall assume as before that the lining of the shoe touches the drum at all points at the same moment. We shall furthermore consider that point as being the center of the brakeshoe which coincides with the center of the drum when the shoe just touches the drum. If now the shoe is pressed harder against the drum, the center of the shoe will move away from the center of the drum, e denoting the magnitude and γ the direction of this displacement. By resolving all forces into their horizontal and vertical components we obtain three static equations (App. No. 3). After eliminating e and γ a relation between the cam force P and the force in the link S can be found (Eq. [11], App. No. 3). By substituting $P/S = 0$ in this equation we find an equation for that value of the frictional coefficient for which grabbing occurs due to the servo-action. This equation is of the second degree and does not always give a solution, thus indicating that in certain designs grabbing due to the servo-action cannot occur no matter which value of friction prevails.

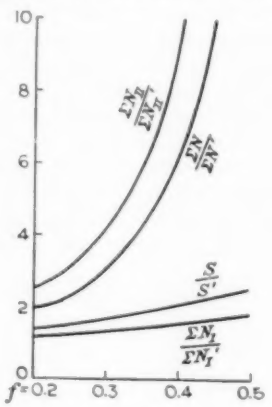

FIG. 8

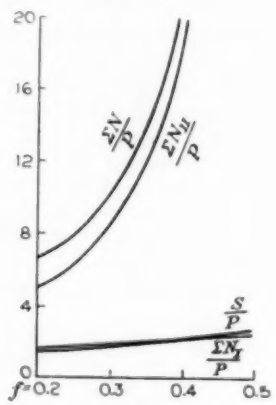

FIG. 9

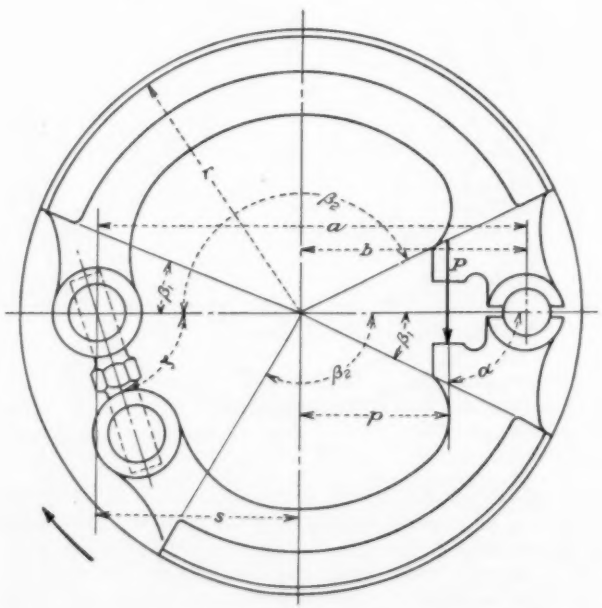

FIG. 10

ΣN_I can be determined in the usual way (Eq. [12], App. No. 3). If we desire to compare the force in the link and the sum of the drum pressures under certain frictional conditions with those which would prevail if there were no friction at all, we easily find a relation between P and S' (Eq. [13], App. No. 3). But we cannot find $\Sigma N_I'$ by substituting $f = 0$ in Eq. [12] because the right-hand member of the equation becomes indefinite. In order to determine $\Sigma N_I'$ we have to go back to the static equations for the case of $f = 0$. The value of the direction

of the displacement for $f = 0$ is given in Eq. [15] (App. No. 3) and $\Sigma N_I'$ in Eq. [14] (App. No. 3).

With these equations the self-actuation of the primary shoe and the force in the connecting link for friction and for no-friction can be determined. The self-actuation of the secondary shoe and its brake-drum pressures can be found in the way already described because the secondary shoe swings around a fixed anchor pin.

Example I (Fig. 10):

PRIMARY SHOE:

p	= 4.625	s	= 6.5625			r	= 8.45
α	= 90°	ζ	= 72°	β_1	= 26° 30′		
A	= 0.28	B	= 1.224	β_2	= 119° 30′	C	= 0.396
D	= 0.424	E	= 1.387				

SECONDARY SHOE:

a	= 13.685	b	= 7.125	r	= 8.45
β_1	= 22°	β_2	= 153°		
A	= 0.033	B	= 1.524	E	= 1.818

With these values Table 2 has been calculated.

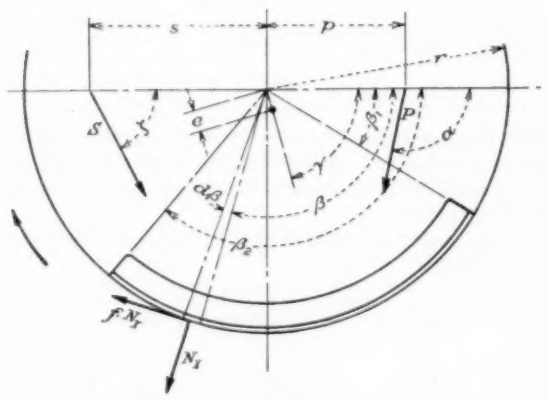

FIG. 11

TABLE 2[a]

		Values of f				
		0	0.2	0.3	0.4	0.5
1	ΣN_I	...	2.44	2.92	3.23	3.45
2	$\Sigma N_I'$	1.88	...	...	...	...
3	$\Sigma N_I/N_I'$	...	1.3	1.55	1.72	1.83
4	S	...	1.4	1.92	2.48	3.07
5	S'	0.735	...	...	...	...
6	S/S'	...	1.91	2.61	3.38	4.18
7	ΣN_{II}	...	4.27	7.32	12.7	23.7
8	$\Sigma N_{II}'$	1.59	...	...	...	...
9	$\Sigma N_{II}/N_{II}'$	...	2.67	4.6	7.95	14.8
10	$\Sigma N = \Sigma N_I + \Sigma N_{II}$	...	6.71	10.24	15.93	27.15
11	$\Sigma N' = \Sigma N_I' + \Sigma N_{II}'$	3.47	...	...	...	...
12	$\Sigma N/\Sigma N'$	...	1.93	2.96	4.6	7.85

[a] All forces in multiples of the cam force P.

Example II (Fig. 14):

PRIMARY SHOE:

p	= 5.25	s	= 5.875	r	= 1	β_1	= 40°
α	= 90°	ζ	= 90°			β_2	= 164°
A	= —0.169	B	= 1.458	C	= 0.702		
D	= —0.367	E	= 1.727				

In this particular instance the equation for P/S cannot be used because the right-hand member of the static Equation [9] disappears for $\alpha = 90°$ and $\zeta = 90°$. The static equations have to be solved for these special conditions. Eq. [16] (App. No. 3) gives the general solution, and with the values given above we obtain:

$$\frac{P}{S} = \frac{4.14 f^2 - 8.05 f + 5.85}{6.92 f^2 + 8.05 f + 5.22}$$

P/S', ΣN_I, and $\Sigma N_I'$ can be calculated in the usual way.

SECONDARY SHOE:

a	= 11.76	b	= 5.62	r	= 1
β_1	= 32° 45′	β_2	= 156° 45′	e	= 16° 45′
A	= —0.068	B	= 1.488	E	= 1.76

The values in Table 3 were then obtained.

Self-actuation and brake-drum pressure are plotted against the coefficient of friction in Figs. 12, 13, 15, and 16. In both cases, but especially in Example I, Figs. 12 and 13, the drum pressure of the primary shoe is considerably higher than in the case of the directly connected shoes (Figs. 8 and 9), while the self-actuation of the secondary shoe is smaller. This seems to be a very desirable condition because, first, it has the result of distributing the wear of the lining more evenly over the two

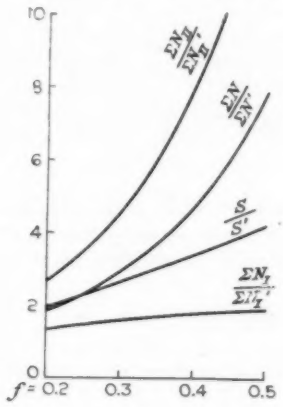

FIG. 12

[a] All forces in multiples of the cam force P.

shoes, and second, the self-actuation of the primary shoe shows much less tendency to rise suddenly with increasing coefficient of friction. Equally the servo-action seems comparatively little affected by changes in the friction coefficient. In order to obtain reliable and constant brake action, therefore, the aim of the

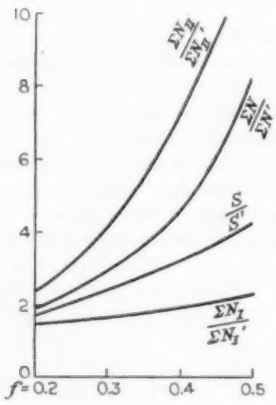

FIG. 15

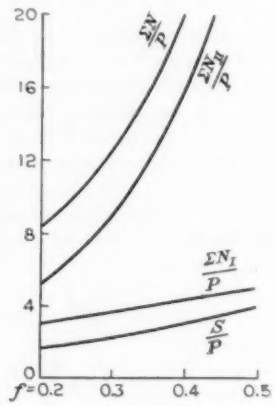

FIG. 16

design should be to have a high self-actuation of the primary shoe and a high servo-action, but to keep the self-actuation of the secondary shoe far enough away from the grabbing point.

Appendix No. 1

For use in this paper Huck's formula has been given the following shape:

$$\Sigma N = P \times \frac{a \int_{\beta_1}^{\beta_2} \sin \beta d\beta}{b \int_{\beta_1}^{\beta_2} \sin^2 \beta d\beta \mp f\left(b \int_{\beta_1}^{\beta_2} \cos \beta \sin \beta d\beta + r \int_{\beta_1}^{\beta_2} \sin \beta d\beta\right)} \quad \ldots\ldots [1]$$

in which ΣN = sum of all normal pressures between shoe and drum
P = force exerted by the cam
a, b, r, β_1 and β_2 = dimensions and angles shown in Fig. 2, and
f = coefficient of friction between shoe and drum.

The integrals can easily be evaluated and the formula can be written in the form

$$\Sigma N = P \times \frac{aE}{bB \mp f(bA + rE)} \quad \ldots\ldots [2]$$

where $A = \int_{\beta_1}^{\beta_2} \cos \beta \sin \beta d\beta = -\frac{1}{4}(\cos 2\beta_2 - \cos 2\beta_1)$

$B = \int_{\beta_1}^{\beta_2} \sin^2 \beta d\beta = -\frac{1}{4}(\sin 2\beta_2 - \sin 2\beta_1) + \frac{1}{2}\beta_2 - \frac{1}{2}\beta_1$

$E = \int_{\beta_1}^{\beta_2} \sin \beta d\beta = -(\cos \beta_2 - \cos \beta_1)$

The formulas become somewhat simpler if the brakeshoe is symmetrical with respect to a line drawn through the center of the drum and normal to the line connecting the center with the anchor pin. In this case $\beta_1 = 2\pi - \beta_2$, $A = 0$, $B = \pi - \beta_1 + \frac{1}{2}\sin 2\beta_1$ and $E = 2 \cos \beta_1$.

Appendix No. 2

The following notation will be used (see Fig. 6):

P, P_1, P_2 = cam force and its components
S, S_1, S_2 = force acting upon pin H and its components
S', S_1', S_2' = same forces for "no-friction"
N_1 = normal force acting between shoe and drum at any point
N_1' = same for "no-friction"
ΣN_1, $\Sigma N_1'$ = sum of all forces N_1 and N_1'
p, s, r = dimensions shown in Fig. 6
w = width of the shoe
α, β, β_1, β_2 = angles shown in Fig. 6
f = coefficient of friction
δ = small angle giving the amount of swing of the shoe when the cam pressure is applied
c = coefficient giving the pressure in lb. per sq. in. which would compress the lining 1 in.

We then have

$$N_1 = wrcs\delta \sin \beta d\beta$$

and we obtain the following three static equations:

$$P_1 + S_1 = wrcs\delta \left(\int_{\beta_1}^{\beta_2} \sin^2 \beta d\beta - f \int_{\beta_1}^{\beta_2} \sin \beta \cos \beta d\beta\right) \quad [3]$$

$$P_2 - S_2 = -wrcs\delta \left(\int_{\beta_1}^{\beta_2} \sin \beta \cos \beta d\beta + f \int_{\beta_1}^{\beta_2} \sin^2 \beta d\beta\right) \quad [4]$$

$$P_1 p - S_1 s = -wrcs\delta r \int_{\beta_1}^{\beta_2} \sin \beta d\beta \quad \ldots\ldots [5]$$

In these equations the expression $wrcs\delta$ can be eliminated and S_1 and S_2 calculated in terms of the cam force P for any given frictional coefficient f, the values of β_1, β_2, p, s, and r being dimensions of the design.

With the substitutions as used in connection with Huck's formula we obtain

$$S_1 = \frac{pB - f(pA - rE)}{sB - f(sA + rE)} P \sin \alpha \quad \ldots\ldots [6]$$

$$S_2 = \left(\cos \alpha + \frac{(p + s)(fB + A)}{sB - f(sA + rE)} \sin \alpha\right) \times P \quad \ldots\ldots [7]$$

For the case of no-friction we have

$$S_1' = \frac{p}{s} \sin \alpha P$$

$$S_2' = \left(\cos \alpha + \frac{(p + s)A}{sB} \sin \alpha\right) P$$

At the same time we find that S_1 and S_2 may become infinite, meaning that grabbing may occur due to excessive servo-action. This would happen when

$$f \geqq \frac{sB}{sA + rE}$$

The sum of all pressures exerted on the drum can be calculated from the three equations. We obtain

$$\Sigma N_1 = wrcs\delta \int_{\beta_1}^{\beta_2} \sin \beta d\beta$$

$$= \frac{(p + s)E}{sB - f(sA + rE)} P \sin \alpha \quad \ldots\ldots [6a]$$

$$\Sigma N_1' = \frac{(p + s)E}{sB} P \sin \alpha \quad \ldots\ldots [6b]$$

Knowing the values for S_1 and S_2 we can now proceed to determine the sum of all pressures exerted by the secondary shoe and the amount of its self-actuation. In Fig. 7 the secondary

brakeshoe is drawn separately. With the notation of that figure and by using Huck's formula we obtain

$$\Sigma N_{II} = (S_1 \cos \epsilon a + S_1 \sin \epsilon a' + S_2 \cos \epsilon a' - S_2 \sin \epsilon a) \frac{E}{bB - f(bA + rE)} \quad [7a]$$

$$\Sigma N_{II}' = (S_1' \cos \epsilon a + S_1' \sin \epsilon a' + S_2' \cos \epsilon a' - S_2' \sin \epsilon a) \frac{E}{bB} \quad [7b]$$

Appendix No. 3

The following notation will be used (Fig. 11):

P = cam force
S = force in the link
N_1 = normal force between shoe and brake drum at any point
$\alpha, \zeta, \beta, \beta_1, \beta_2, \beta, \gamma$ = angles as shown in Fig. 11
p, s, r, e = dimensions as shown in Fig. 11
w = width of the shoe
f = coefficient of friction
c = coefficient of elasticity of the lining in lb. per sq. in. per inch of compression.

N_1', S', ΣN_1, and $\Sigma N_1'$ will be used in the same sense as before.

We then have

$$N_1 = wrce \cos(\beta - \gamma) d\beta$$

and the three static equations:

$$P \sin \alpha + S \sin \zeta = wrce \left[\int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \sin \beta d\beta - f \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \cos \beta d\beta \right] \quad [8]$$

$$P \cos \alpha + S \cos \zeta = wrce \left[\int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \cos \beta d\beta - f \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \sin \beta d\beta \right] \quad [9]$$

$$-Pp \sin \alpha + Ss \sin \zeta = wrcefr \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) d\beta \quad [10]$$

In these equations the expression $wrce$ as well as the angle γ can be eliminated and S can be calculated in terms of P and the values of f, p, s, r, α, ζ, β_1, and β_2. The following substitutions will be used:

$$A = \int_{\beta_1}^{\beta_2} \cos \beta \sin \beta d\beta = -\tfrac{1}{4}(\cos 2\beta_2 - \cos 2\beta_1)$$

$$B = \int_{\beta_1}^{\beta_2} \sin^2 \beta d\beta = -\tfrac{1}{4}(\sin 2\beta_2 - \sin 2\beta_1) + \tfrac{1}{2}\beta_2 - \tfrac{1}{2}\beta_1$$

$$C = \int_{\beta_1}^{\beta_2} \cos^2 \beta d\beta = \tfrac{1}{4}(\sin 2\beta_2 - \sin 2\beta_1) + \tfrac{1}{2}\beta_2 - \tfrac{1}{2}\beta_1$$

$$D = \int_{\beta_1}^{\beta_2} \cos \beta d\beta = \sin \beta_2 - \sin \beta_1$$

$$E = \int_{\beta_1}^{\beta_2} \sin \beta d\beta = -(\cos \beta_2 - \cos \beta_1)$$

After eliminating $wrce$ we obtain the following two equations:

$$\frac{A - fC + \tan \gamma (B - fA)}{C + fA + \tan \gamma (A + fB)} = \frac{P \sin \alpha + S \sin \zeta}{P \cos \alpha + S \cos \zeta}$$

$$\frac{C + fA + \tan \gamma (A + fB)}{rf(D + \tan \gamma E)} = \frac{P \cos \alpha + S \cos \zeta}{-Pp \sin \alpha + Ss \sin \zeta}$$

from which the following relation between P and S can be obtained:

$$\frac{\frac{P}{S}[C \sin \alpha - A \cos \alpha + f(A \sin \alpha + C \cos \alpha)] + f(A \sin \zeta + C \cos \zeta) + C \sin \zeta - A \cos \zeta}{-\frac{P}{S}[A \sin \alpha - B \cos \alpha + f(B \sin \alpha + A \cos \alpha)] - f(B \sin \zeta + A \cos \zeta) + B \cos \zeta - A \sin \zeta} =$$

$$\frac{\frac{P}{S}[Cp \sin \alpha + f(Ap \sin \alpha + rD \cos \alpha)] + f(rD \cos \zeta - As \sin \zeta) - Cs \sin \zeta}{-\frac{P}{S}[Ap \sin \alpha + f(Bp \sin \alpha + rE \cos \alpha)] - f(rE \cos \zeta - Bs \sin \zeta) + As \sin \zeta}$$

In this form the equation appears to be very involved. In order to obtain P/S a still more complicated equation of the second degree would have to be solved. An essential simplification, however, can be made if instead of dividing the forces into their horizontal and vertical components the axis of the system is chosen in such a way that $\alpha = 90°$. We then have $\sin \alpha = 1$ and $\cos \alpha = 0$ and obtain:

$$\frac{\frac{P}{S}[C + fA] + f(A \sin \zeta + C \cos \zeta) + C \sin \zeta - A \cos \zeta}{-\frac{P}{S}[A + fB] - f(B \sin \zeta + A \cos \zeta) + B \cos \zeta - A \sin \zeta} =$$

$$\frac{\frac{P}{S}[Cp + fAp] + f(rD \cos \zeta - As \sin \zeta] - Cs \sin \zeta}{-\frac{P}{S}[Ap + fBp] - f(rE \cos \zeta - Bs \sin \zeta) + As \sin \zeta} \quad [11]$$

In developing this equation the members containing $(P/S)^2$ disappear and an equation of the first degree is obtained for P/S.

Grabbing of the brake due to excessive servo-action occurs when $P/S = 0$. By substituting $P/S = 0$ in the equation above we obtain an equation of the second degree for f, from which the magnitude of the friction coefficient which will cause grabbing can be calculated. The sum of all brake-drum pressures can be calculated from Equation [10]. We have

$$\Sigma N_1 = wrce \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) d\beta = \frac{Ss \sin \zeta - Pp \sin \alpha}{rf} \quad [12]$$

In order to compare the force in the link and the sum of the drum pressures under certain frictional conditions with those which would prevail if there were no friction at all, we have to find P/S, and $\Sigma N_1'$. It is evident from Fig. 11 that

$$Pp \sin \alpha = S's \sin \zeta \quad [13]$$

In order to determine $\Sigma N_1'$, however, we have to go back to the static equations, which have the following form for $f = 0$ and $\alpha = 90°$.

$$P + S' \sin \zeta = wrce \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \sin \beta d\beta \quad [8a]$$

$$S' \cos \zeta = wrce \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \cos \beta d\beta \quad [9a]$$

$$Pp = S's \sin \zeta \quad [10a]$$

We then can write [9a] in the following way:

$$\Sigma N_1' =$$

$$wrce \int_{\beta_1}^{\beta_2} \cos(\beta - \gamma)\, d\beta = S' \cos\zeta \frac{\int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) d\beta}{\int_{\beta_1}^{\beta_2} \cos(\beta - \gamma) \cos\beta d\beta}$$

With the usual substitution we obtain

$$\Sigma N_1' = S' \cos\zeta \frac{D + \tan\gamma\, E}{C + \tan\gamma\, A} \quad \ldots\ldots\ldots\ldots [14]$$

In order to make use of this expression we have to find $\tan\gamma$ for $f = 0$. By eliminating *wrce* in Equations [8*a*] and [9*a*] we obtain the following value:

$$\tan\gamma = \frac{\frac{P}{S'}C + C\sin\zeta - A\cos\zeta}{-\frac{P}{S'}A + B\cos\zeta - A\sin\zeta} \quad \ldots\ldots\ldots [15]$$

For $\alpha = 90°$ and $\zeta = 90°$ the static equations give the following solution:

$$\frac{r\left(1 + \frac{P}{S}\right)}{s - p\frac{P}{S}} = \frac{(A^2 - BC)(1 + f^2)}{f(DA - EC) + f^2(DB - EA)} \quad \ldots [16]$$

Discussion

L. H. Donnell.[3] This very interesting paper shows how comparatively simple analytical methods can greatly clarify a problem which has given considerable difficulty when attacked in a purely empirical manner.

At first thought it appears that in the charts showing the variation of the factor of self-actuation with the coefficient of friction, the ideal condition would be a horizontal line, i.e., no variation with the coefficient of friction. It is interesting to point out that, as a matter of fact, to have the ideal condition of uniform response to a given brake pressure under all conditions, these curves would have to have a *downward* slope to the right, so that a decrease in the coefficient of friction would be made up for by an increase in self-actuation.

All these charts would be clearer if a horizontal line with *unit* ordinate were shown, as this, rather than the line with zero ordinate, represents the real "zero" of self-actuation.

The theory presented in this paper starts with the assumption, first given by Huck, that after the brake lining is worn-in it touches simultaneously at all points and that on further movement the distribution of pressure can be calculated as a statically indeterminate problem, assuming that the brake lining follows Hooke's law and that all other parts are rigid. It seems to the writer that this assumption is likely to be approximately true when the brake lining is nearly new, but that as the brake lining wears there is a strong tendency for the normal pressure to become uniform all over the lining; for if the pressure is greater at some points than it is at others under average brake load, these points will certainly wear faster, and this must tend to relieve the pressure at these points and give a more uniform distribution, under average conditions. It would seem safe to assume that actual conditions will in general lie somewhere between two extremes, one the assumption given in the paper, and the other an assumption of uniformly distributed normal pressures.

[3] University of Michigan. Mem. A.S.M.E.

Author's Closure

The author cannot agree with Mr. Donnell regarding the effect of unequal pressure at different points of the lining. There is a distinct difference between a lining which is worn-in and one which is not. With "worn-in" it is meant that the lining touches the drum in all points at the same time when the brake is being applied. There is very little chance that the lining will do that as long as it is new. There are variations in the curvature of the shoe and in the thickness of the lining. Furthermore, with a fixed anchor pin, there always will be a certain error in the swinging motion of the shoe. Now, as long as this condition exists, in applying the brakes those points which touch the drum first will be subjected to a higher pressure than those which touch later. In this case the author perfectly agrees with Mr. Donnell that the points which carry the higher pressure will wear down faster than the others. This is just what the author calls "wearing-in," and after a certain time it must result in all points touching at the same time.

Now, if this stage is reached, Mr. Donnell believes that the pressure in all points must be and remain equal. This, however, is not the case, just as the pressure at different points of a bearing is not equal even though it may fit the shaft quite snugly and just as the balls of a ball bearing carry different loads at a certain moment. Now, one should not expect that on account of this difference in pressure the lining will begin once more to touch the drum at different moments. The lining will wear down unequally according to the difference in pressure at different points, but it will wear down so that the outside curvature of the lining remains always true with respect to the durm. A simple geometrical analysis shows that this may very well be the case, and this is just what is implied when the matter is calculated as a statically indeterminate problem.

So, as long as it is assumed that the lining follows Hooke's law and that the shoe and the drum are rigid, the calculation seems to be correct. Whether these assumptions are true or not does not depend upon whether or not the lining is worn-in. It will be approximately correct when the brake is applied slightly, and the error will be greater the more flexible all parts are and the harder the brake is applied. Every flexibility will tend to decrease the pressure at all points in which it is high according to the calculation and will increase it correspondingly in other points giving a more uniform distribution. So, while the author cannot agree with Mr. Donnell as regards the effect of the wear, for other reasons, i.e., on account of the flexibility of the parts, he agrees with Mr. Donnell that the actual conditions will lie somewhere between the uniform distribution of pressure and the distribution which is obtained from the foregoing calculations.

On the Mechanics of the Plastic State of Metals

By A. NADAI,[1] EAST PITTSBURGH, PA.

This paper is a study of the mechanical conditions under which plastic flow in metals occurs. Rules relative to the stresses and the deformation when the stresses reach the limit of plasticity are discussed. Some cases of plastic flow with rotational symmetry around an axis in cylinders are considered. As examples, the case of a bar in combined tension and torsion and that of a hollow cylinder subjected to a high internal pressure and axial forces are treated. The cases of pure bending of a bar with a rectangular cross-section and of pure torsion of a bar with a circular cross-section are discussed, assuming a general law of deformation. Also application of this theory is made to the hollow cylinder subjected to internal pressure. Methods of finding the residual stresses after severe plastic deformation are discussed, and the results obtained in the study should throw light on the problem of these stresses.

I—Consideration of the Various Types of Plastic Material With Respect to the Mechanical Conditions of Plastic Flow in Metals

AS IS GENERALLY known, the terms "solid" and "fluid" which serve in mechanics, physics, and chemistry to differentiate the states of aggregation of matter are in some cases insufficient, especially if the behavior of matter under high pressures acting from all directions or under elevated temperatures is considered. Cases frequently arise in which a gradual change from the solid state into another state can be observed, and the bodies change their shape permanently and continuously to a considerable amount without appreciable increase in the forces at work. In other cases—a common example is found among the ductile metals—bodies undergo permanent changes in shape at normal temperatures. The ductile metals may be bent, drawn, hammered, rolled, etc. On the other hand, certain substances—for example, bituminous solids—are known which have no definite melting point and which gradually change in shape at temperatures at which they usually are considered as solids. Even very small forces are capable of deforming such substances by considerable amounts. Thus, hard asphalt may flow out of an overturned barrel if sufficient time is allowed for the action of the weight of the mass to accelerate the particles thereof. Thus a solid mass flows like a fluid, which would flow out of the barrel under its own weight.

From these observations it must be concluded that all solid materials—even the strongest metals, like steel, or brittle materials, like marble or sandstone—without exception, may, under favorable mechanical conditions, be brought into a new state—the plastic state—in which permanent deformations of considerable magnitude may be produced in them.

It is an interesting problem of mechanics which has many important applications in science and in engineering practice, to try to describe the principal rules which govern the slow movements of the small particles within solid bodies in the plastic state. In the following an attempt is made to analyze some simple cases of plastic flow, and to describe the deformation and the distribution of internal stress in bars or in bodies of simple geometric form which take place when the material is stressed beyond the limit of plasticity.

The first attempts to establish equations for the plastic state of metals, which must be mentioned here, were those of St. Venant.[2] Using as a basis the tests made by Tresca with ductile metals, St. Venant worked out at the beginning of the seventh decade of the last century a theory of the two-dimensional plastic flow of metals and of the plastic deformations of a twisted bar.[3] Later, Duguet[4] extended the theory of the twisted bar under the assumption of a more general stress-strain relation for pure shear.[5]

While the engineer interested in questions of analysis of stress or deformation relies upon a mathematical theory which has been well established and long ago more or less completely worked out when he confines himself to purely elastic deformation, the case is different where plastic flow occurs in parts of stressed bodies or throughout the entire mass of the material. The main reason for this seems to be that the mechanical properties of our principal materials of construction in the plastic state apparently do not follow so general mechanical rules or laws as do the deformations of an isotropic, perfectly elastic body. A step further in the development of rules for the plastic state seems to be to concede this and to try to work out cases under special assumptions as to the mechanical properties of the substances while they are in a plastic state. The newer development of the mechanics of the plastic state of matter has followed these lines. In recent years H. Hencky,[6] Th. v. Kármán,[7] and L. Prandtl[8] have revived the theory of St. Venant, presenting it in many new aspects and extending it to several new cases,[9] while R. v. Mises[10] has mathematically formulated a theory of the plastic state which has proved very valuable. The mechanics of another group of plastic materials, namely, wet, earthy masses, wet clay, etc., has been especially considered by K. v. Terzaghi.[11]

[9] The most complete study of the plastic deformations of single metallic crystals is due to G. T. Taylor (Proc. Roy. Soc., London, vol. 102, Bakerian lecture, 1923) and to his pupils. P. W. Bridgman has made very complete investigations of the physical and chemical properties of single crystals.

[10] Göttingen *Nachrichten*, 1913.

[11] "*Erdbaumechanik*," Leipzig, 1925.

One important point should now be mentioned. The question arises whether a body deformed plastically has to be treated under the assumption that all the forces acting on it form a system which is in static equilibrium, or whether the small particles of the body move in a way similar, for example, to that in which the particles of a viscous fluid do; in other words, whether to treat plastic flow in a body as a question of statics or as one of dynamics. If the latter, it would be necessary to assume that the stresses in the body depend in some way on the rate of change of shape. That is, that the components of stress depend on the velocity with which the corresponding components of unit strain change during the deformation. There is no doubt that in certain cases of plastic flow (an example of the plastic flow of amorphous masses other than asphalt under ordinary temperatures is the flow of glass under elevated temperatures) the movement of the small particles of the mass resembles the flow of the so-called viscous fluids as described in hydrodynamics. Taking the first viewpoint, it would be necessary to assume that the stresses in the small element of a plastic mass are in equilibrium, just as in all problems of the statics of perfectly elastic masses.

Take for example the simple case of a straight, cylindrical bar of a ductile (polycrystalline) metal, for instance, mild steel, stretched under two equal forces acting in opposite directions along its axis. If the longitudinal stresses exceed a certain limit, namely, the yield point of the material, the bar will begin to extend permanently. As tests show, in some kinds of low-carbon steel no appreciable increase in the stress is observed within the first two to three per cent of unit elongation when plastic flow begins to spread throughout the length of the bar.[12] At greater unit elongations, however, the stress in the bar will slowly increase with plastic deformation. The rate of increase of the stress with unit elongation will be the higher the lower the temperature of the metal being stretched. From the first point of view, the stress does not depend on the rate of change of length with time or on the velocity with which the bar is stretched. Under ordinary temperatures, tests show that the yield stress of ductile metals such as mild steel or copper changes but little with the velocity of deformation. But at elevated temperatures, this statement of the facts may not be quite sufficient. The same low stress which may not produce any appreciable permanent elongation during an ordinary tensile test at room temperature, may in a polycrystalline metal produce considerable permanent set or creep when the metal is exposed to sufficiently high temperatures. To observe such creep, it may be necessary to stretch the bar under such conditions during a long period of time, i.e., make long-time tests of the bar. Hence not only is the limit of plasticity lowered with increasing temperatures, but a new fact is introduced, that the stresses now depend on the rate of change of shape.

As R. Becker,[13] M. Polanyi and E. Schmid,[14] and others have shown, two principal modes of plastic flow in solids must be distinguished: the plastic flow of single crystals and that of amorphous (non-crystalline) substances. The mechanism of the plastic flow seems to be different in both cases. In crystalline masses plasticity consists in a certain gliding movement: parts of the crystals glide along certain definite planes or directions with respect to each other, these planes and directions having well-defined positions with respect to the crystalline axis. The velocity of this gliding movement or slip in the crystal planes does not seem to be affected much by the shearing stresses under which plasticity starts within the crystal. Schmid and Polanyi have shown that slip in single metal crystals occurs at the lowest temperatures which could be produced and which were close to the absolute zero of the temperature scale, where the thermal agitation of the atoms in the lattices vanishes. On the other hand, the stresses in amorphous plastic substances such as glass or asphalt are known to depend considerably on the velocity of deformation, especially at high temperatures. Obviously, the mechanism of the plastic flow in such substances is quite different from the mechanism of plasticity in crystalline substances. Within the range of softening temperatures of these substances the stress depends on the rate of change of shape, and the coefficient of viscosity which expresses this fact is a pronounced function of the temperature.

The only conclusion which should be drawn from these remarks is that in a great variety of cases of practical importance it is justifiable to treat the plastic flow of polycrystalline substances as a slow movement during which the forces may be considered to remain in equilibrium. This is especially the case when the temperature is comparatively low, that is, when it is a comparatively small fraction of the melting temperature of the substance. Under these conditions, in many cases, the stresses may be determined by considering the substance to be in equilibrium. On the basis of this assumption, as will be shown in the following section, it will now be necessary to consider, in addition, some special mechanical conditions under which plastic flow occurs in materials.

II—Mechanical Rules Concerning the Slow Stationary Plastic Flow in Metals—The Condition of Plasticity

Some observations relative to the magnitude of the deformation are now in order. Several cases may be distinguished:

a The deformation, or the unit strains during plastic flow, is of the same order of magnitude as the elastic deformation. As the latter in most cases of practical importance remains only small in comparison with the smallest dimension of the stressed piece, this means that we can use for the unit elongations and unit shears, which determine the state of deformation at an arbitrary point of the mass, the same mathematical expressions as those used in the theory of elasticity. If we use rectangular coordinates x, y, z, the state of deformation is determined by the three unit elongations ϵ_x, ϵ_y, ϵ_z parallel, respectively to the axes x, y, z, and the three unit shears γ_{xy}, γ_{yz}, γ_{zx}. These six components of strain are given by the following expressions in which ξ, η, ζ are the components of the displacement of the point x, y, z:

$$\left.\begin{aligned} \epsilon_x = \frac{\partial \xi}{\partial x},\ \epsilon_y = \frac{\partial \eta}{\partial y},\ \epsilon_z = \frac{\partial \zeta}{\partial z} \\ \gamma_{xy} = \frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x},\ \gamma_{yz} = \frac{\partial \eta}{\partial z} + \frac{\partial \zeta}{\partial y},\ \gamma_{zx} = \frac{\partial \zeta}{\partial x} + \frac{\partial \xi}{\partial z} \end{aligned}\right\} \quad \ldots\ldots [1]$$

b A more important case is where, during plastic flow, the unit elongations and shears remain small but may become large if compared to the elastic elongations and shears. Take for example a bent or twisted bar of mild steel in which the permanent unit extension or shear at the most severely stretched fibers may amount to from 2 to 4 per cent. The plastic extension is then from 20 to 40 times as large as the maximum elastic extension which could be produced in the material. In such cases it is justifiable to use for the six components of strain ϵ_x, ϵ_y, ϵ_z, γ_{xy}, γ_{yz}, γ_{zx} the same formula [1] as above, but to neglect, if necessary, the *elastic* parts of the strains. If we can confine the deformation to amounts of this order of magnitude, we can furthermore introduce another important simpli-

[12] As is well known, in certain low-carbon steels the stress necessary to maintain the plastic flow when it has once started is even considerably smaller than the stress under which yield first developed in the bar.

[13] *Zeit. f. Physik*, 1927. Also *Zeit. f. Tech. Physik*, vol. 7, 1926, p. 547.

[14] Several papers in *Zeit. f. Physik* (1928).

fication. We can replace the stress-strain diagram for pure tension or compression or for pure shear for a variety of materials by two straight lines as shown in Fig. 1. A good example of a metal with such a stress-strain diagram would be low-carbon steel; another, a metal such as copper or aluminum which has undergone severe cold work, if stressed again in the same sense. Fig. 1 especially represents the behavior of all materials or ductile metals which have a perfect elastic range and a well-defined yield point at which plastic deformation begins. For some other kinds of steel, as is well known, the stress-strain curve does not always change in direction so abruptly as in Fig. 1. But even for such materials, in many cases it will greatly simplify calculation of the stresses to assume that their stress-strain diagrams are similar to that of Fig. 1.

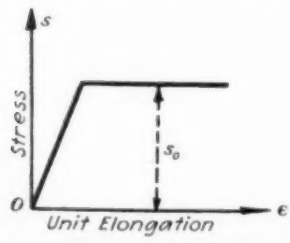

FIG. 1 IDEALIZED STRESS-STRAIN DIAGRAM FOR PLASTIC FLOW

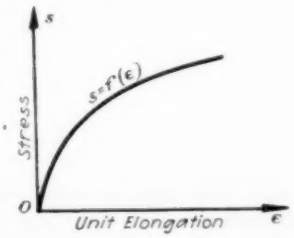

FIG. 2 STRESS-STRAIN DIAGRAM

For such substances it will be possible to distinguish within the stressed body in general an *elastic part* (in which the stresses are below the limit of plasticity), and one or more *plastic parts* where the stresses have reached the yield point.

c A third and more general case would be where the yield stress depends to a considerable extent on the plastic deformation. A well-known example is the stress-strain diagram (for pure tension or compression) for annealed copper or aluminum. It is known that such materials do not possess a limit of plasticity when they are stressed the first time, and that both the elastic and the plastic deformations are at first (under low stresses) of the same magnitude. Such materials show a gradual increase of the stress with deformation (Fig. 2). In such cases the stress in the diagram must be considered as a function of the unit elongation ϵ:

$$s = f(\epsilon) \quad \ldots\ldots [2]$$

which may be determined by means of an ordinary tensile or a compression test or may be assumed in the form of an analytical expression. In this case the deformation may not be limited in amount to some few per cent. It should be noted that if the unit elongations or unit shears exceed certain amounts, the simple relations [1] will no longer be sufficient. These latter will become gradually less exact and the establishment of new expressions will be necessary for the larger deformations. Some examples will be given later in Sections VII and VIII.

While in certain cases of plastic flow it may be advantageous to assume that the yield stress is independent of deformation (as was assumed under *a*), it is necessary to emphasize that this does not mean that no relations exist which would connect the expressions for the components of strain with those for the components of stress. During plastic flow these components depend on each other in a manner which will now be determined. If we use the rectangular coordinates x, y, z, and denote by ϵ_x, ϵ_y, ϵ_z the unit elongation which the material undergoes in the direction parallel to the x, y, and z axes and by γ_{xy}, γ_{yz}, γ_{zx} the corresponding unit shears, then, if we call s_x, s_y, s_z the components of normal stress and s_{xy}, s_{yz}, s_{zx} the three components of shearing stress (the six components of stress which determine the state of stress in a small element at a point with the coordinates x, y, z are shown by the arrows in Fig. 3), the stress components are connected with the strain components in an elastic isotropic material by Hooke's law or by the following six equations:

$$\left.\begin{aligned} \epsilon_x &= \frac{1}{E}(s_x - \nu s_y - \nu s_z); \quad \gamma_{xy} = \frac{s_{xy}}{G} \\ \epsilon_y &= \frac{1}{E}(s_y - \nu s_z - \nu s_x); \quad \gamma_{yz} = \frac{z_{yz}}{G} \\ \epsilon_z &= \frac{1}{E}(s_z - \nu s_x - \nu s_y); \quad \gamma_{zx} = \frac{s_{zx}}{G} \end{aligned}\right\} \quad \ldots\ldots [3]$$

In these equations two independent constants of elasticity enter, namely, Young's modulus of elasticity E and Poisson's ratio ν, while the third constant, the modulus of rigidity G, is given by the former two and is equal to

$$G = \frac{E}{2(1+\nu)}$$

The question arises, by what expressions in the case of plastic flow must these preceding stress-strain relations be replaced?

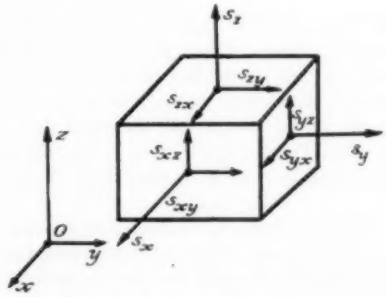

FIG. 3 STRESS COMPONENTS

In general, strain components such, for example, as ϵ_x will have an elastic portion such as ϵ_x' and a plastic (permanent) portion such as ϵ_x'', and the total strain will be equal the sum:

$$\epsilon_x = \epsilon_x' + \epsilon_x'' \quad \ldots\ldots [4]$$

In many cases it may be necessary to deal with these complete expressions for ϵ_x, ϵ_y, ... In other cases, especially for the proposed analysis of stress in a body completely transformed into the plastic state, it will be quite sufficient to neglect the elastic portions of the strains. Under such conditions we may introduce another simplification by neglecting also the small possible elastic changes in volume of the stressed body as well as also some possible small permanent changes therein. Permanent changes of volume have been observed in substances like the metals after plastic flow, but in most of the ductile metals such changes are only perceivable under severe cold working and after great plastic deformation. Under ordinary circumstances (some few per cent of unit elongations) they can be neglected. In other words, we can assume for the sake of simplicity that the volume of the material remains unchanged during or after the plastic deformation. A mathematical expression for this experimental fact is that, for small amounts of deformation, the sum of the unit elongations for the three perpendicular directions x, y, z is zero, or

$$\epsilon_x + \epsilon_y + \epsilon_z = 0 \quad \ldots\ldots [5]$$

In the mechanics of the plastic state of metals it is convenient to use the principal values for strain and stress, denoting them by the subscripts 1, 2, and 3; thus:

ϵ_1, ϵ_2, ϵ_3 are the three principal unit elongations, and
s_1, s_2, s_3 are the corresponding three principal stresses.

In terms of principal elongation, Equation [5] can also be expressed as follows:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \ldots\ldots\ldots\ldots\ldots\ldots [5a]$$

A first set of three relations may be obtained for the six quantities ϵ_1, ϵ_2, ϵ_3, s_1, s_2, s_3, by making use of the experimental fact that the three directions of principal strain within a plastic mass

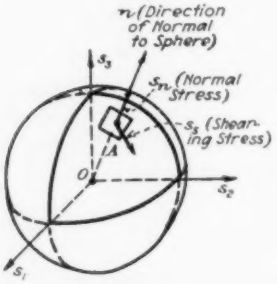

FIG. 4

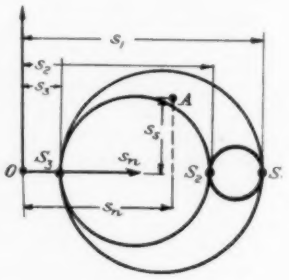

FIG. 5

must always coincide with the corresponding three directions of the principal stresses. The general expressions for these three relations will not be written down here as in general they are fairly complicated (they have been used in the theory of plasticity by M. Lévy), but it will be noted that in the special cases of stress distribution given later, these expressions become simplified considerably. In some important cases they are of a trivial form.

A further relation which, for the sake of brevity, we can perhaps call the *rule of plastic flow*, can be expressed in the simplest way by using Mohr's diagram for the representation of stress and strain.[15]

In general, the position of any plane at the point x, y, z, for which the normal and the shearing stresses s_n and s_s are to be found, can be represented by a plane tangential to a sphere of unit radius or by the normal n thereto (see Fig. 4). The state of stress at the same point of the body can be represented by Mohr's diagram in plotting the normal stress s_n and the shearing stress s_s acting in the plane defined by its normal n in Fig. 4 as the abscissa and the ordinate of a certain point A in Fig. 5. Since to each point A on this sphere (Fig. 4) (that is, to each plane parallel to the corresponding tangent plane of the sphere in the stressed body) there corresponds a certain point A in the stress figure (Fig. 5), to a given curve which may be drawn on the surface of the sphere there will also correspond a certain curve in the plane s_n, s_s. Mohr has shown that to the three principal circles on the sphere, connecting poles for the principal directions, correspond the three principal circles 11, 22, 33. The points of intersection s_1, s_2, s_3 of the three principal circles in Fig. 5 with the s_n-axis determine the principal stresses s_1, s_2, s_3. It should be mentioned that the graphical representation given by Mohr's diagram for stress is also valid for strain. In this case all that is necessary is merely to replace the words "normal stress" and symbol s_n by the words "unit elongation" and symbol ϵ_n, and the words "shearing stress" and symbol s_s by the words "one-half of the unit shear" and symbol $\gamma/2$. We can therefore represent any given state of stress or strain at a point in a plastic mass by the three corresponding principal circles in Mohr's stress or strain diagram.

[15] See S. Timoshenko and J. M. Lessells, "Applied Elasticity," p. 13, 1925; or A. Nadai, "Der bildsame Zustand der Werkstoffe," Springer, Berlin, 1927.

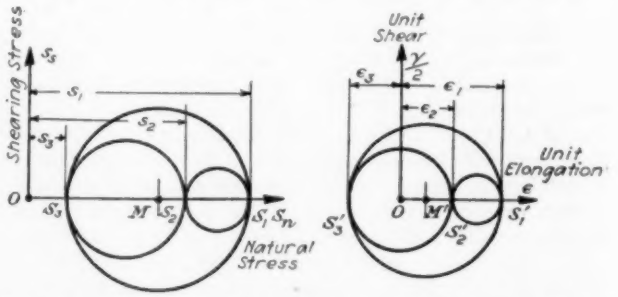
We can now express the "rule of plastic flow" mentioned above as follows:

> During plastic flow, the figure consisting of the three principal stress circles in Mohr's diagram must always remain geometrically similar to the figure consisting of the three principal strain circles.

This is shown by Figs. 6 and 7. From the geometrical proportions of these figures we may obtain the following relations:

$$\mu = \frac{\overline{MS_2}}{\overline{MS_1}}, \quad \nu = \frac{\overline{M'S_2'}}{\overline{M'S_1'}}$$

$$\mu = \nu \quad \text{or} \quad \frac{s_2 - \frac{s_1 + s_3}{2}}{\frac{s_1 - s_3}{2}} = \frac{\epsilon_2 - \frac{\epsilon_1 + \epsilon_3}{2}}{\frac{\epsilon_1 - \epsilon_3}{2}},$$



or

$$\frac{s_2 - s_1 + s_2 - s_3}{s_1 - s_3} = \frac{\epsilon_2 - \epsilon_1 + \epsilon_2 - \epsilon_3}{\epsilon_1 - \epsilon_3} \ldots\ldots\ldots [6]$$

which must hold at every point of a plastic mass. It is not difficult to explain the physical meaning of this equation. Neglecting the elastic part of the deformation, compare, for example, the mode of deformation of a small cube cut out from a plastic mass in the following three cases: namely, pure tension, pure compression, and pure shear. It is well known from observation how a small cube will be deformed if subjected to the distributions of stress just mentioned. For example, if a tensile stress acts on two parallel planes of the cube in a direction perpendicular to these planes, the cube will be extended in this direction and will contract in all perpendicular directions by the same amount. Hence the unit contraction in both lateral directions must be equal to half the extension in the direction of the stress, and must be of opposite sign if the volume of the cube is not to be changed. We see that for pure tension $s_1 = s$, $s_2 = s_3 = 0$, $\epsilon_2 = \epsilon_3 = -\epsilon_1/2$, and the quantities defined above, $\mu = -1$, $\nu = -1$, must be equal. In a similar way it can easily be shown that for pure compression we must have $s_1 = -s$, $s_2 = s_3 = 0$, $\epsilon_2 = \epsilon_3 = -\epsilon_1/2$, and $\mu = +1$, $\nu = 1$; and finally for pure shear $s_1 = s$, $s_2 = -s$, $s_3 = 0$, $\epsilon_1 = -\epsilon_2$, $\epsilon_3 = 0$ and $\mu = 0$, $\nu = 0$. We see at once that for all three special cases of stress distribution just mentioned,

$$\mu = \nu \ldots\ldots\ldots\ldots\ldots\ldots [6a]$$

The rule mentioned above assumes now that this condition holds for every kind of stress distribution. Expressed in other words, we can also say that the material yields in such a way that the excess of the intermediate principal stress s_2 over the average value of the two other principal stresses is proportional to the

FIGS. 6 AND 7 MOHR'S CIRCLE DIAGRAMS FOR STRESS AND STRAIN

excess of the intermediate principal strain ϵ_2 over the average value of the two other principal strains.

The three conditions mentioned first, together with those expressed in Equations [5] and [6], that is, a total of five conditions for plastic flow, are equivalent to the six equations which express the stress-strain conditions of an elastic body (Hooke's law). As a total of six quantities must be determined, a sixth equation is necessary. This last equation will express the experimental fact that the stresses have reached the limit of plasticity of the substance. The form for this last condition, which we shall call the "condition of plasticity," has been under investigation for a long time by engineers and physicists in many countries. The more recent tests seem to indicate that in this condition for certain ranges of stress and for certain materials as a first approximation, only the principal stresses enter. O. Mohr's conception that the condition of plasticity would not contain the intermediate principal stress s_2 seems not to have been verified for certain materials, especially the ductile polycrystalline metals. A symmetrical expression of the second degree,

$$(s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_3 - s_1)^2 = 2s_0^2 \quad [7]$$

was found to represent the results of tests in a satisfactory manner. In this equation s_0 is the yield stress in pure tension and, for a certain range of deformation, a constant. This expression was proposed by R. v. Mises. Many tests made by W. Lode[16] and Ros. and Eichinger[17] have verified this condition. In some cases it practically coincides with the expression of an older conception with regard to the yielding of plastic materials, that is, that yield should take place when the maximum shear reaches a certain value (maximum-shear theory); in other cases it differs. These points having been briefly considered, some applications of the foregoing rules will now be discussed.

III—Plastic Flow With Rotational Symmetry Around Axis

Under this heading are comprised all such cases of plastic flow in cylindrical bodies in which the components of stress and of strain are dependent only on a single variable coordinate, namely, the distance r of a point in the body from an axis. As examples may be mentioned the cases of plastic flow in a round bar in pure torsion; in a cylindrical bar of uniform cross-section which has been overstressed through twisting moments; in a round bar subjected to the combined action of tension and torsion; the stress distribution in thick, hollow cylinders or tubes subjected to a high internal (or external) pressure combined with an axial tension or compression or with twist; and the stress distribution in a long cylinder rotating around its axis with a uniform angular speed, if the material has been stressed beyond the yield point.

Taking the axis of the cylinder as the z-axis, in the case of rotational symmetry it is necessary to introduce as the components of normal stress

The radial stress s_r
The tangential stress s_t
The axial stress s_z

Of the three components of the shearing stresses only one has a value other than zero, and this component will be denoted by s_s. The shearing stress s_s acts in the planes perpendicular to the axis of the cylinder in a direction tangential to the circles r = const. The direction of these stress components can be seen in Fig. 8, in which a small element of the cylinder is shown. This element has as boundaries two parallel planes z = const. and $z + dz$ = const., two neighboring concentric cylinders r = const. and $r + dr$ = const., and two planes meeting in the axis of the cylinder and forming a small angle $d\alpha$.

In this case of rotational symmetry the radial normal stress s_r is a principal stress. The two other principal stresses are given by the expressions

$$\left.\begin{aligned} s_1 &= \frac{s_z + s_t}{2} + \sqrt{\frac{(s_z - s_t)^2}{4} + s_s^2} \\ s_2 &= \frac{s_z + s_t}{2} - \sqrt{\frac{(s_z - s_t)^2}{4} + s_s^2} \end{aligned}\right\} \quad [8]$$

It is convenient to use instead of the principal stresses two new stress variables s and s', defined as follows:

$$s = \frac{s_z + s_t}{2} - s_r, \qquad s' = \frac{s_z - s_t}{2} \quad [9]$$

In terms of these stress variables and of the shearing stress s_s the principal stresses can be now expressed as follows:

$$\left.\begin{aligned} s_1 &= s + s_r + \sqrt{s'^2 + s_s^2} \\ s_2 &= s + s_r - \sqrt{s'^2 + s_s^2} \\ s_3 &= s_r \end{aligned}\right\} \quad [10]$$

Hence the stress differences are:

$$\left.\begin{aligned} s_1 - s_2 &= 2\sqrt{s'^2 + s_s^2} \\ s_2 - s_3 &= s - \sqrt{s'^2 + s_s^2} \\ s_1 - s_3 &= s + \sqrt{s'^2 + s_s^2} \end{aligned}\right\} \quad [11]$$

The condition of plasticity (Equation [7])

$$(s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_3 - s_1)^2 = 2s_0^2 \quad [12]$$

takes with these variables the simpler form

$$s^2 + 3(s'^2 + s_s^2) = s_0^2 \quad [13]$$

A set of formulas analogous to [8], [9], and [10] can be written down for the strain components, using the expressions for the principal strains.

Let ϵ_r, ϵ_t, ϵ_z be the unit elongations in the radial, tangential, and axial directions, and γ be the unit shear. Then the three principal strains are given by

$$\left.\begin{aligned} 2\epsilon_1 &= \epsilon_z + \epsilon_t + \sqrt{(\epsilon_z - \epsilon_t)^2 + \gamma^2} \\ 2\epsilon_2 &= \epsilon_z + \epsilon_t - \sqrt{(\epsilon_z - \epsilon_t)^2 + \gamma^2} \\ \epsilon_3 &= \epsilon_r \end{aligned}\right\} \quad [14]$$

Using in analogy to [9] as new strain variables

$$\left.\begin{aligned} \epsilon &= \epsilon_z + \epsilon_t - 2\epsilon_r \\ \epsilon' &= \epsilon_z - \epsilon_t \end{aligned}\right\} \quad [15]$$

and the unit shear γ, the principal strains become

$$\left.\begin{aligned} 2\epsilon_1 &= \epsilon + 2\epsilon_r + \sqrt{\epsilon'^2 + \gamma^2} \\ 2\epsilon_2 &= \epsilon + 2\epsilon_r - \sqrt{\epsilon'^2 + \gamma^2} \\ \epsilon_3 &= \epsilon_r \end{aligned}\right\} \quad [16]$$

[16] "Der Einfluss der mittleren Hauptspannung auf das Fliessen der Metalle." V.D.I. Forschungsarbeiten, Heft 303, 1928.

[17] Proc. 2. International Congress of Applied Mechanics, Zurich, 1926.

and hence the principal strain differences are

$$\left.\begin{aligned} \epsilon_1 - \epsilon_2 &= \sqrt{\epsilon'^2 + \gamma^2} \\ \epsilon_2 - \epsilon_3 &= \frac{\epsilon}{2} - \frac{1}{2}\sqrt{\epsilon'^2 + \gamma^2} \\ \epsilon_1 - \epsilon_3 &= \frac{\epsilon}{2} + \frac{1}{2}\sqrt{\epsilon'^2 + \gamma^2} \end{aligned}\right\} \quad \ldots\ldots\ldots [17]$$

It is now necessary to express the special conditions of plastic flow in a cylinder, which will satisfy the conditions of symmetry. It must be recalled that all the points of the cylinder can move only (1) radially (all points situated on a circle r = const. are displaced by equal amounts), and (2) axially (all points situated in a plane which is perpendicular to the axis of the cylinder are displaced by equal amounts parallel to the axis of the cylinder). To these two deformations must be added the twist around the axis of the cylinder. If ρ is the radial displacement (the change of the radii r in the radial direction), then the tangential and radial unit elongations ϵ_t, ϵ_r are given by

$$\epsilon_t = \frac{\rho}{r}; \qquad \epsilon_r = \frac{d\rho}{dr} \quad \ldots\ldots\ldots [18]$$

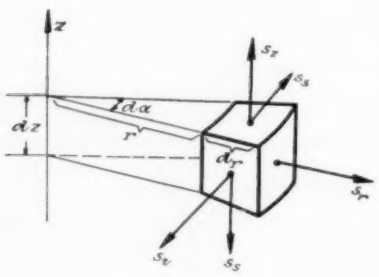


FIG. 8

FIG. 9

The condition of compatibility of these two relations involves

$$\frac{d(r\epsilon_t)}{dr} - \epsilon_r = 0 \quad \ldots\ldots\ldots [19]$$

Taking in account the fact that the volume of the small element (Fig. 8) will not be changed by the plastic flow,

$$\epsilon_r + \epsilon_t + \epsilon_z = 0 \quad \ldots\ldots\ldots [20]$$

In this last equation and in all later relations the axial unit elongation ϵ_z must be considered as a constant, as all cross-sections of the cylinder remain plane. From [19] and [20] we find by integration the expressions of the radial and tangential unit elongations as functions of r:

$$\left.\begin{aligned} \epsilon_r &= -\frac{\epsilon_z}{2} - \frac{c_1}{r^2} \\ \epsilon_t &= -\frac{\epsilon_z}{2} + \frac{c_1}{r^2} \end{aligned}\right\} \quad \ldots\ldots\ldots [21]$$

Here c_1 is a constant of integration. For a hollow cylinder c_1 in general will not be zero, but for a solid cylinder it must be taken equal to zero. Finally we have to express the fact that the cross-sections of the cylinder turn around its axis through a uniform angle of twist. If ϑ is the twist per unit of length, the unit shear at the distance r from the axis will be

$$\gamma = \vartheta r \quad \ldots\ldots\ldots [22]$$

Using the expressions [15], [21], and [22], condition [6] takes the form:

$$\epsilon' = \frac{3\epsilon_z}{2} - \frac{c_1}{r^2}$$

$$\epsilon = \frac{3\epsilon_z}{2} + \frac{3c_1}{r^2}$$

$$\frac{s - 3\sqrt{s'^2 + s_z^2}}{s + \sqrt{s'^2 + s_z^2}} = \frac{\epsilon - 3\sqrt{\epsilon'^2 + \gamma^2}}{\epsilon + \sqrt{\epsilon'^2 + \gamma^2}} \quad \ldots\ldots\ldots [23]$$

But as

$$\frac{A - 3B}{A + B} = \frac{A' - 3B'}{A' + B'}$$

is equivalent to

$$\frac{B}{A + B} = \frac{B'}{A' + B'}$$

[23] can be also expressed as

$$\frac{s^2}{s'^2 + s_z^2} = \frac{\epsilon^2}{\epsilon'^2 + \gamma^2} \quad \ldots\ldots\ldots [24]$$

Finally the coincidence of the principal directions for the stress s, and for the unit elongation ϵ_t must be expressed. This will be the case if

$$\frac{s_z - s_t}{2s_z} = \frac{\epsilon_z - \epsilon_t}{\gamma} \quad \ldots\ldots\ldots [25]$$

or by using s, s' (cf. [9] and [15]) and ϵ_t, ϵ',

$$\frac{s'}{s_z} = \frac{\epsilon'}{\gamma} \quad \ldots\ldots\ldots [26]$$

It is worth while to note that we thus obtain three *finite* equations for the three unknown quantities s,s',s_z, namely, [13], [24], and [26]. To sum up the preceding, we shall write down again these three equations as follows:

$$s^2 + 3(s'^2 + s_z^2) = s_0^2 \quad \ldots\ldots\ldots [27]$$

$$\frac{s^2}{s'^2 + s_z^2} = \frac{\epsilon^2}{\epsilon'^2 + \gamma^2} \quad \ldots\ldots\ldots [28]$$

$$\frac{s'}{s_z} = \frac{\epsilon'}{\gamma} \quad \ldots\ldots\ldots [29]$$

The right-hand members of the last two equations are to be considered as known functions of the independent variable r and given if we use the expressions found in [21] and [22] for $\epsilon_r,\epsilon_t,\gamma$. To solve these three equations we write

$$\delta^2 = \epsilon^2 + 3(\epsilon'^2 + \gamma^2) \quad \ldots\ldots\ldots [30]$$

and find that the three unknown stress variables s,s',s_z are given by the simple expressions:

$$s = \pm s_0 \frac{\epsilon}{\delta}; \qquad s' = \pm s_0 \frac{\epsilon'}{\delta}; \qquad s_z = \pm s_0 \frac{\gamma}{\delta} \quad \ldots [31]$$

Finally the axial and tangential normal stresses s_z,s_t are found:

$$\left.\begin{aligned} s_z &= s + s_r + s' \\ s_t &= s + s_r - s' \end{aligned}\right\} \quad \ldots\ldots\ldots [32]$$

and the radial stress is given by the differential equation

$$\frac{r ds_r}{dr} = s_t - s_r \quad \ldots\ldots\ldots [33]$$

by which the equilibrium of the small element in Fig. 8 is expressed. The last equation leads to

$$\frac{r ds_r}{dr} = s - s' \quad \ldots\ldots [34]$$

which serves for the calculation of the radial stress. In the next section some applications of the preceding formulae to special cases are given.

IV—Plastic Flow in Cylindrical Bar Under Combined Action of Axial Tension and of Torsion (Fig. 9)[17a]

As already mentioned, for a solid cylinder the integration constant c_1 must be taken equal to zero. Hence the radial and the tangential unit elongations in such a bar must be equal to half of the axial unit elongation ϵ_z.

$$\epsilon_r = \epsilon_t = -\frac{\epsilon_z}{2} \quad \ldots\ldots [35]$$

and this latter has to be considered as a constant. The shear is given as before by $\gamma = r\vartheta$. With these expressions the variables ϵ and ϵ' can be found from [15] as

$$\left.\begin{aligned} \epsilon &= \epsilon_z + \epsilon_t - 2\epsilon_r = \frac{3\epsilon_z}{2} \\ \epsilon' &= \epsilon_z - \epsilon_t = \frac{3\epsilon_z}{2} \end{aligned}\right\} \quad \ldots\ldots [36]$$

and the quantity δ as equal to:

$$\delta = 3\epsilon_z \sqrt{1 + \frac{r^2\vartheta^2}{3\epsilon_z^2}} \quad \ldots\ldots [37]$$

As it is not essential the double sign $\pm$ can be cancelled, if only tension in axial direction is to be considered. (cf. [31], etc.). The ratio s'/s_z, taken from Equation [29] is now equal to

$$\frac{s'}{s_z} = \frac{\epsilon'}{\gamma} = \frac{3\epsilon_z}{2\vartheta r} \quad \ldots\ldots [38]$$

Using the expression just found for δ in [37] and [38], the three unknown quantities s, s', s_r are given:

$$s = s' = \frac{s_0}{2} \frac{1}{\sqrt{1 + \frac{\vartheta^2 r^2}{3\epsilon_z^2}}} \quad \ldots\ldots [39]$$

$$s_r = \frac{s_0 \vartheta r}{3\epsilon_z} \frac{1}{\sqrt{1 + \frac{\vartheta^2 r^2}{3\epsilon_z^2}}} \quad \ldots\ldots [40]$$

These expressions can be also written in the following very simple form:

$$\left.\begin{aligned} s = s' &= \frac{s_0}{2} \cos\alpha \\ s_z &= \frac{s_0}{\sqrt{3}} \sin\alpha \end{aligned}\right\} \quad \ldots\ldots [41]$$

or also

$$\left.\begin{aligned} s = s' &= \frac{s_0}{2} \frac{1}{\sqrt{1+u^2}} \\ s_z &= \frac{s_0}{\sqrt{3}} \frac{u}{\sqrt{1+u^2}} \end{aligned}\right\} \quad \ldots\ldots [42]$$

[17a] Dr. W. Lode in Elberfeld, with whom the author has worked during several years, has contributed much to the analysis of this case.

by writing

$$\frac{\vartheta r}{\sqrt{3}\cdot\epsilon_z} = \tan\alpha = u \quad \ldots\ldots [43]$$

As can be seen from [32] and [33], since $s = s'$, both the radial and the tangential stresses s_r, s_t vanish in this case. Hence the distribution of stress in a cylindrical bar subjected to the combined action of an axial load and a twisting moment is given by the formulas:

$$\left.\begin{aligned} &\text{Shearing stress:} \quad s_s = \frac{s_0}{\sqrt{3}} \sin\alpha = \frac{s_0}{\sqrt{3}} \frac{u}{\sqrt{1+u^2}} \\ &\text{Axial normal stress:} \quad s_z = s_0 \cos\alpha = s_0 \frac{1}{\sqrt{1+u^2}} \end{aligned}\right\} \quad [44]$$

These stresses are acting in a bar, in which the material yields from the center to the surface. Here s_0 is the yield stress, ϑ the angle of twist per unit of length, ϵ_z the unit elongation of

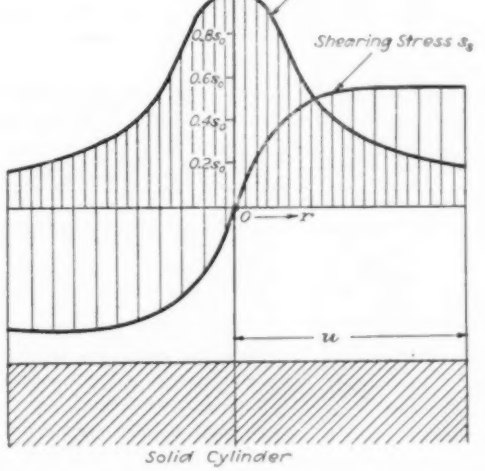

Fig. 10 Stress Distribution Under Plastic Flow in Cylindrical Bar Subjected to the Combined Action of an Axial Pull and a Twisting Moment

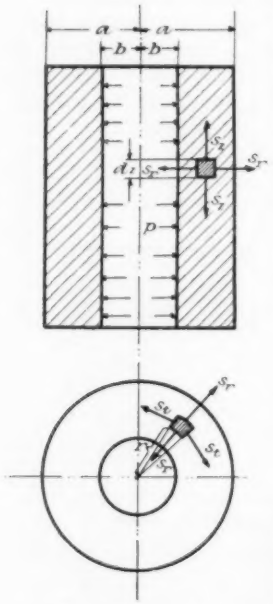
the bar in the axial direction, r the distance of a point from the axis of the cylinder, and α and u are given by $\frac{\vartheta r}{\sqrt{3}\epsilon_z} = \tan\alpha = u$. Using a for the radius of the bar and for

$$\frac{\vartheta a}{\sqrt{3}\,\epsilon_z} = \tan\alpha_a = u_a \quad \ldots\ldots [45]$$



the axial force or the axial load P and the twisting moment M are given as

$$P = 2\pi \int_0^a s_z r dr = 2\pi s_0 a^2 \left(\frac{\sqrt{1+u_a^2} - 1}{u_a^2} \right) \quad \ldots\ldots [46]$$

$$M = 2\pi \int_0^a s_s r^2 dr = \frac{2\pi s_0 a^3}{3\sqrt{3}} \frac{(u_a^2 - 2)\sqrt{1+u_a^2} + 2}{u_a^3} \quad \ldots\ldots [47]$$

In Fig. 10 an example of a stress distribution is given for the value $u_a = 5.25$. As can be seen in the figure, the normal stress becomes a maximum at the center of the cylinder. As at this point the shearing stress vanishes, the normal stress becomes equal to the yield stress in pure tension. To verify

our formulas for P and M, we may derive from them the special cases of pure tension and of pure torsion. In the first case u becomes small, hence the axial stress $s_z = \frac{s_0}{\sqrt{1+u^2}} \sim = s_0$ = const. and $P = \pi a^2 s_0$, and $M = 0$. (The value of P becomes indeterminate for $u_a = 0$: $P = 2\pi a^2 s_0 \frac{\sqrt{1+u_a^2}-1}{u_a^2} = \frac{0}{0}$, but the true value of this fraction is $1/2$, and therefore $P = \pi a^2 s_0$ = yield stress times the area of the cross-section of the cylinder.) In the case of pure torsion, on the contrary, u becomes infinite, hence $s_z = 0$, $s_t = \frac{s_0}{\sqrt{3}}$ and the twisting moment $M = \frac{2\pi s_0 a^3}{3\sqrt{3}} = \frac{2\pi s_t a^3}{3}$. The same moment would have been found by taking the shearing stress s_t as a constant $= s_0/\sqrt{3}$ through the circular cross-section of the bar.

FIGS. 11 AND 12

The formulas derived above for the resultant force P of the axial stresses s_z and for the moment of twist M may be also expressed by using the parameter α_a given in [45] instead of using u_a as

$$P = 2\pi a^2 s_0 \tan \frac{\alpha_a}{2} \quad [48]$$

$$M = \frac{Pa}{3\sqrt{3}} \cot \alpha_a \tan \frac{\alpha_a}{2} \quad [49]$$

V—Thick Hollow Cylinder Subjected to Internal Pressure and Axial Load

If a hollow cylinder with thick walls is submitted to the combined action of high internal pressure and axial load, no shearing stresses s_z will be produced in the planes z = const. In the following case the whole tube will be considered to yield under the forces acting. Let $r = a$ be the outer radius, $r = b$ the inner one, and p the pressure on the cylinder of radius $r = b$ (Figs. 11 and 12).

As the unit elongations ϵ_r and ϵ_t taken from Equation [21] will be

$$\left.\begin{aligned} \epsilon_r &= -\frac{\epsilon_z}{2} - \frac{c_1}{r^2} \\ \epsilon_t &= -\frac{\epsilon_z}{2} + \frac{c_1}{r^2} \end{aligned}\right\} \quad [50]$$

and the unit shear γ is now zero, the quantities ϵ and ϵ' defined in [15] will now equal

$$\epsilon = \frac{3\epsilon_z}{2} + \frac{3c_1}{r^2} \quad \epsilon' = \frac{3\epsilon_z}{2} - \frac{c_1}{r^2} \quad [51]$$

In order to simplify the following expressions, a new independent variable will be used, defined by

$$u = \frac{2c_1}{\epsilon_z r^2 \sqrt{3}} \quad [52]$$

Let the tangential unit elongation ϵ_t at the outer surface of the cylinder $r = a$ be

$$\epsilon_t = \epsilon_a = -\frac{\epsilon_z}{2} + \frac{c_1}{a^2} \quad [53]$$

then

$$u = \frac{1}{\sqrt{3}} \left(1 + \frac{2\epsilon_a}{\epsilon_z}\right) \frac{a^2}{r^2} \quad [54]$$

$$\epsilon = \frac{3\epsilon_z}{2}\left(1 + u\sqrt{3}\right) \qquad \epsilon' = \frac{3\epsilon_z}{2}\left(1 - \frac{u}{\sqrt{3}}\right) \quad [55]$$

The stress variables s and s' in [27] and [29] must satisfy the equations:

$$\frac{s'}{s} = \frac{\epsilon'}{\epsilon} = \frac{\sqrt{3}-u}{\sqrt{3}+3u} \quad [56]$$

$$s^2 + 3s'^2 = s_0^2 \quad [57]$$

From these equations s and s' are found:

$$s = \frac{s_0}{2\sqrt{3}} \frac{\sqrt{3}+3u}{\sqrt{1+u^2}}, \quad s' = \frac{s_0}{2\sqrt{3}} \frac{\sqrt{3}-u}{\sqrt{1+u^2}} \quad [58]$$

Replacing now s and s' by their expressions given in [9], the three components of stress are found:

$$\left.\begin{aligned} &\text{Axial stress:} && s_z = s + s' + s_r \\ &\text{Tangential stress:} && s_t = s - s' + s_r \\ &\text{Radial stress:} && s_r = \int \frac{(s-s')}{r}\, dr + c_2 \\ & && = \pm \frac{s_0}{\sqrt{3}} \int \frac{du}{\sqrt{1+u^2}} + c_2 \end{aligned}\right\} \quad [59]$$

Integrating the last expression and taking, for $r = a$,

$$u = u_a = \frac{1}{\sqrt{3}} \left(1 + \frac{2\epsilon_a}{\epsilon_z}\right) \quad [60]$$

and for $r = a$ the stress $s_r = 0$, it is seen that the radial stress is

$$s_r = \frac{s_0}{\sqrt{3}} \log_e \frac{u_a + \sqrt{1+u_a^2}}{u + \sqrt{1+u^2}} \quad [61]$$

This equation now permits us to find an expression for the pressure p under which the whole thick tube will yield. At the inner surface of the tube, for $r = b$, $s = -p_r$. If $r = b$, the variable u becomes

$$u = u_b = \frac{a^2}{b^2} u_a \quad [62]$$

Hence the pressure p is

$$p = \frac{s_0}{\sqrt{3}} \log_e \frac{u_b + \sqrt{1+u_b^2}}{u_a + \sqrt{1+u_a^2}} \quad [63]$$

As u varies inversely as the square of r, if $b < r < a$ the variable u is $u_a < u < u_b$. Both u_a and u_b depend on the ratio ϵ_a/ϵ_z. The meaning of the integration constant u_a has already been explained by Equation [60]. The distribution of stress depends mainly on two parameters: the ratio of the outer to the inner radius a/b, and the ratio of the tangential unit elongation ϵ_a at the outer surface $r = a$ to the axial unit elongation ϵ_z. In a tube with a given ratio a/b, different stress distributions will be obtained for different ratios ϵ_a/ϵ_z. The pressure p necessary to produce yield in the whole tube will also depend on ϵ_a/ϵ_z.

One special case which must be included in Equation [59] is that of the yielding of a hollow cylinder under axial pull. We know that for the simple case of pure tension, the lateral plastic contraction of the tube must be half of the longitudinal expansion if the volume of the material is not to be changed. Hence $\epsilon_a = -\epsilon_z/2$, and in this case, u and u_a must vanish. Equations [59] show that for pure tension the stresses $s_r = s_t = 0$, and the axial normal stress s_z becomes

$$s_z = \frac{\sqrt{3}}{\sqrt{3}} s_0 = s_0 = \text{const.}$$

An interesting special case is that of a thick tube under high internal pressure p which is not allowed to expand or contract in axial direction. In this case the unit elongation parallel to the axis of the tube must be $\epsilon_z = 0$ and the integration constants u_a and u_b become both infinite, but their ratio $u_b/u_a = a^2/b^2$ remains finite. Here a and b designate the outer and the

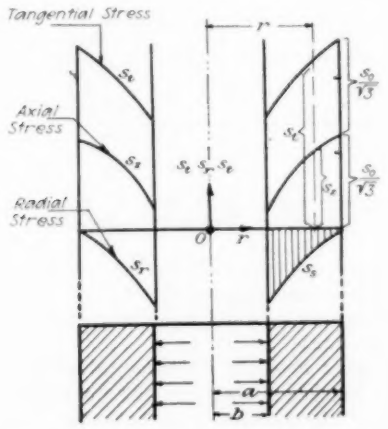


FIG. 13 PLASTIC FLOW IN THICK HOLLOW CYLINDER: STRESS DISTRIBUTION WHEN AXIAL ELONGATION $\epsilon = 0$

inner radius of the hollow cylinder. Equation [63] for the internal pressure p simplifies in this case and leads to the formula

$$p = \frac{2s_0}{\sqrt{3}} \log_e \frac{a}{b} \quad \text{[64]}$$

Equations [59] and [61] now take the simpler and symmetrical forms:

$$\left.\begin{aligned} &\text{Radial stress:} && s_r = -\frac{2s_0}{\sqrt{3}} \log_e \frac{a}{r} \\ &\text{Tangential stress:} && s_t = \frac{2s_0}{\sqrt{3}}\left(1 - \log_e \frac{a}{r}\right) \\ &\text{Axial stress:} && s_z = \frac{s_0}{\sqrt{3}}\left(1 - 2\log_e \frac{a}{r}\right) \end{aligned}\right\} \quad \text{[65]}$$

The resultant of the axial stresses s_z can now be easily calculated and is

$$P = \frac{\pi s_0}{\sqrt{3}}\left[\frac{3(a^2 - b^2)}{2} - b^2 \log_e \frac{a}{b}\right] \quad \text{[66]}$$

As the expression can never vanish for any tube with a *finite* thickness $a - b$, we see that if a thick tube exposed to an internal pressure p is not allowed to expand or to contract in the axial direction during the plastic flow, normal stresses s_z in the axial direction of considerable amount must act, and these will prevent axial contraction. The axial normal stress is at every point of the tube equal to the average value of the radial and the tangential normal stresses. The three normal stresses are given by three equidistant logarithmic curves. The curves for the axial and the tangential stress s_z and s_t are obtained from the curve of the radial stress s_r by shifting the latter in the vertical direction (see Fig. 13) by the amounts $\frac{s_0}{\sqrt{3}}$ and $\frac{2s_0}{\sqrt{3}}$.

VI—ROTATING CYLINDER

In this case, it is necessary to modify the equilibrium condition. Let ω be the angular speed of the cylinder, λ the specific gravity of the material, g the acceleration of gravity, and a the radius of the cylinder. In the condition of equilibrium [33] an additional term must be introduced with regard to the action of the centrifugal forces:

$$\frac{ds_r}{dr} = \frac{s_t - s_r}{r} - \frac{\lambda\omega^2}{g} \cdot r \quad \text{[67]}$$

In a solid cylinder again the constant c_1 in Equation [50] must be taken equal to zero; hence the radial and the tangential unit elongations in the cylinder will become again equal to

$$\epsilon_r = \epsilon_t = -\frac{\epsilon_z}{2} \quad \text{[68]}$$

A consequence of this fact will be that in an infinitely long, solid rotating cylinder, both the radial and the tangential stresses become equal, or

$$s_r = s_t \quad \text{[69]}$$

Hence the equation of equilibrium takes the form

$$\frac{ds_r}{dr} = -\frac{\lambda\omega^2}{g} \cdot r$$

whence by integration

$$s_r = \frac{\lambda\omega^2}{2g}(a^2 - r^2) \quad \text{[70]}$$

The condition of plasticity [7] is now

$$s_t - s_z = \pm s_0 \quad \text{[71]}$$

where s_0 designates the yield stress for pure tension. Two distinct cases are obtained, depending on whether the upper or the lower sign is taken. Taking the upper sign, the axial stress is given by

$$s_z = s_t - s_0 \quad \text{[72]}$$

From the condition that the resultant of the axial stresses

$$2\pi \int_0^a s_z r dr = 0 \quad \text{[73]}$$

should become zero, the peripheral speed $a\omega$ is found under which the entire cylinder will yield, or

$$a\omega = 2\sqrt{\frac{s_0 g}{\lambda}} \quad \text{[74]}$$

It may be of interest to compare this speed with the velocity at which first yield occurs in a rotating cylinder. As shown in the theory of elasticity, in a rotating solid cylinder of radius a, yield starts at the center if the peripheral velocity is equal to

$$u\omega' = 2\sqrt{\frac{2(1-\nu)\, s_0 g}{(3-4\nu)\lambda}} \quad \text{[75]}$$

where ν is Poisson's ratio. In this formula it is assumed that the resultant of the axial stresses $s_z = 0$. Assuming that $\nu = 1/3$, this velocity is found to be

$$a\omega' = 1.764\sqrt{\frac{s_0 g}{\lambda}} \quad [76]$$

Comparing [74] with [76] it is seen that with an increase of speed above the velocity given in [76] of about 13 per cent, the entire cylinder will be brought into the plastic state. The distribution of stress under which the whole cylinder becomes plastic is as follows:

$$\left.\begin{aligned} &\text{Radial and tangential stresses: } s_r = s_t = 2s_0\left(1 - \frac{r^2}{a^2}\right) \\ &\text{Axial stress: } \qquad s_z = s_0\left(1 - 2\frac{r^2}{a^2}\right) \end{aligned}\right\} \quad [77]$$

where s_0 is the yield stress in pure tension.

The central part of the cylinder receives tensile, and the peripheral parts compressive stresses in the axial direction, but the action of the tensile stresses balances that of the compressive, so that no resultant axial force is acting.

VII—Pure Bending of Bars With Arbitrary Law of Deformation

In this and the following sections some applications of the theory will be shown for plastic or inelastic materials which do not follow the simple rules for deformation as stated and applied in the preceding sections. The theory of bending of a slender cylinder or prismatic bar, or of torsion of a cylindrical bar when the deformation does not obey Hooke's law, may be taken as examples. The calculation is based on certain assumptions with regard to the deformation, which are also made in the ordinary theory of elastic bending or torsion. The validity of these assumptions for bending in the case of non-elastic materials such as cast iron or plastic materials such as steel has been carefully studied, especially by C. v. Bach,[18] E. Meyer,[19] and Herbert,[20] who have proved by their tests that the assumptions are well founded.

The theory of bending of a narrow bar with an arbitrary form of the cross-section when the deformation obeys a general law as stated under (*c*), Section II, may be worked out in a different, but relatively simple manner.[21]

In the following, only the case of pure bending of a bar with rectangular cross-section will be treated, as this is the simplest case to which these calculations may be applied. It is assumed that the bar is bent by the action of two equal bending moments M acting at the ends of the bar in opposite directions and in one of the principal planes of inertia of the cross-section.

Two problems, the direct and the inverse problem, are here of interest. In the former, given the stress-strain diagram of the material for pure tension and compression, the stress s may be taken as a known function $f(\epsilon)$ of the unit elongation ϵ, or,

$$s = f(\epsilon) \quad [78]$$

The problem then is to determine how the bending moment M of the bar will increase with the deformation of the bar, or how it will depend on the deflection y or on the slope β of the tangent to the elastic line of the bar for a certain given gage length l.

The relation which gives the bending moment M as a function of the slope β of the tangent to the elastic line will be denoted by $M = F(\beta)$.

In the inverse problem, the bending moment M in a bar of rectangular cross-section of a given material is to be considered as a given function:

$$M = F(\beta) \quad [79]$$

as it depends on the deformation of the bar. This function is found by observation. The problem here is to find or construct the stress-strain diagram

$$s = f(\epsilon)$$

in pure tension and compression for this material. As will be seen, the direct problem involves an integration and the inverse problem a differentiation, both of which may be effected by graphic methods.

The assumptions on which the calculation of the bending

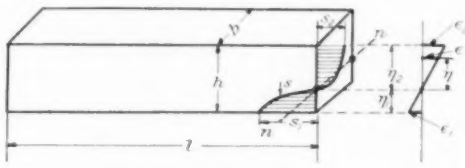

Fig. 14 Bending Stresses in Bar of Inelastic or Plastic Material Under Pure Bending

stresses is based are the same as those made in the ordinary theory of bending, namely, that the cross-sections remain plane during bending and that the unit elongations ϵ remain small compared with unity.

(*a*) *The Direct Problem.* In order to determine the distribution of the bending stress s over the cross-section, the stress-strain curve of the material must be known from tests. We can assume that it is given by an analytical expression or graphically by the function

$$s = f(\epsilon)$$

of the unit elongation ϵ.

Referring to Fig. 14, let us take $n - n$ as the position of the neutral axis in the cross-section in which the bending stress s vanishes and η as the distance of a point in the cross-section from the neutral axis where the bending stress is s. An element dx at the distance η from the neutral axis undergoes an extension and the unit strain ϵ at this distance will be

$$\epsilon = \frac{\eta}{\rho} \quad [80]$$

In this ρ is the radius of curvature of the bent bar. If h is the height and b the width of the cross-section, and if η_1 and η_2 are the distances of the lower and upper fibers of the bar, where the greatest tensile and compression stresses s_1 and s_2 may act, then

$$\eta_1 + \eta_2 = h \quad [81]$$

and

$$\epsilon_1 + \epsilon_2 = \frac{h}{\rho} \quad [82]$$

If ρ and ϵ_1 are given, then ϵ_2 is determined by Equation [82].

The equilibrium of the forces acting in a cross-section is expressed by the two equations:

$$\int s\,d\eta = 0 \quad [83]$$

[18] C. v. Bach und R. Baumann: "Elastizität und Festigkeit, Berlin, 1924. 9th ed., p. 259.

[19] *Zeitschrift des Vereines deutscher Ingenieure*, vol. 52 (1908), p. 167.

[20] Mitteilungen Forschungsarbeiten V.D.I., Heft 89, 1910.

[21] A. Nadai: "Der bildsame Zustand der Werkstoffe," Berlin, 1927, p. 111.

$$M = b \int s\eta d\eta \quad \ldots\ldots [84]$$

where the integrals must be taken between the limits $\eta = -\eta_1$ and $\eta = \eta_2$. Taking s from [78] and replacing the variable η by ϵ Equation [83] leads to the condition

$$\int_{-\epsilon_1}^{\epsilon_2} f(\epsilon) d\epsilon = 0 \quad \ldots\ldots [85]$$

Let A_1 and A_2 be the absolute values of the area in the stress-strain diagram of Fig. 15.

$$A_1 = -\int_{-\epsilon}^{0} f(\epsilon) d\epsilon; \quad A_2 = \int_{0}^{\epsilon_2} f(\epsilon) d\epsilon \quad \ldots\ldots [86]$$

Then condition [85], which may also be expressed as

$$A_1 = A_2 \quad \ldots\ldots [87]$$

determines for any given stress-strain curve $s = f(\epsilon)$ to any arbitrarily chosen value of ϵ_1 a certain value $\epsilon_2 = \varphi(\epsilon_1)$. Equation [82] then determines the corresponding value of the radius of curvature ρ of the bent bar, and from Equation [84] the bending moment M is found:

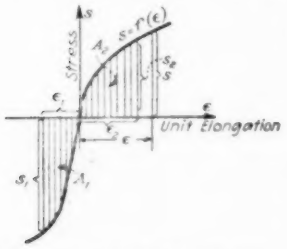

FIG. 15 STRESS-STRAIN DIAGRAM IN TENSION AND COMPRESSION

$$M = b\rho^2 \int_{-\epsilon_1}^{\epsilon_2} f(\epsilon)\, \epsilon d\epsilon \quad [88]$$

The slope β of the tangent to the elastic line of the bent bar is, for the gage length l,

$$\beta = \frac{l}{2\rho} = \frac{l(\epsilon_1 + \epsilon_2)}{2\rho} \quad \ldots [89]$$

The deflection y of the bar for the length l is (Fig. 16).

$$y = \rho \frac{\beta^2}{2} = \frac{l^2}{8\rho} \quad \ldots\ldots [90]$$

Equations [88] and [89] determine the unknown relation

$$M = F(\beta) \quad \ldots\ldots [91]$$

This provides a convenient experimental proof of the assumptions made in the calculations, as the bending moment M and the slope β can be determined on the one hand by [91] and on the other hand by observation from a bending test.

(*b*) *The Inverse Problem.* In order to obtain the stress-strain diagram $s = f(\epsilon)$ in pure tension and compression *from a bending test*, it must be assumed that in a bending test with a straight bar with rectangular cross-section it has been observed how the bending moment M increases with the slope at the ends of the gage length l of the bent middle line of the bar. Then M is known as a function of β, or

$$M = F(\beta) \quad \ldots\ldots [92]$$

In order to obtain the stress-strain diagram

$$s = f(\epsilon) \quad \ldots\ldots [93]$$

from the bending test, a start is made with Equation [88], in which ρ is replaced by the angle β using [89], where $\rho = l/2\beta$. Multiplying both sides of [88] by β^2 we obtain:

$$M\beta^2 = \frac{bl^2}{4} \int_{-\epsilon_1}^{\epsilon_2} f(\epsilon)\, \epsilon d\epsilon \quad \ldots\ldots [94]$$

The left-hand member of [94] has now to be considered as a known function of β since the moment is known to be $M = F(\beta)$. Hence the right-hand member must be a function of β. Differentiating [94] with respect to the variable β,

$$\frac{d}{d\beta}(M\beta^2) = \frac{bl^2}{4}\left[f(\epsilon_2)\epsilon_2 \frac{d\epsilon_2}{d\beta} - f(-\epsilon_1)(-\epsilon_1)\frac{d(-\epsilon_1)}{d\beta}\right] \quad [95]$$

Now

$$f(\epsilon_2) = s_2; \quad f(-\epsilon_1) = -s_1 \quad \ldots\ldots [96]$$

are the tensile and compression stresses at the extreme fibers $\eta = \eta_2$ and $\eta = -\eta_1$ of the bar, and from the equilibrium conditions [86] or [87] it is seen that the small increments of the area A_1 and A_2, that is

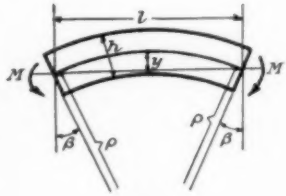

FIG. 16

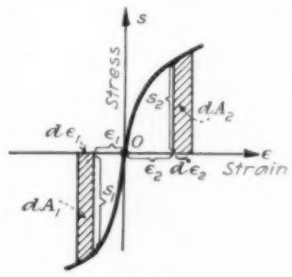

FIG. 17

$$dA_1 = dA_2 \quad \text{or} \quad s_1 d\epsilon_1 = s_2 d\epsilon_2 \quad \ldots\ldots [97]$$

must always be equal. (Fig. 17.) Differentiating [82],

$$d\epsilon_1 + d\epsilon_2 = \frac{2h}{l} d\beta \quad \ldots\ldots [98]$$

From [97] and [98],

$$\left.\begin{aligned} d\epsilon_1 &= \frac{2hs_1}{l(s_1 + s_2)} d\beta \\ d\epsilon_2 &= \frac{2hs_2}{l(s_1 + s_2)} d\beta \end{aligned}\right\} \quad \ldots\ldots [99]$$

Using [96]–[99] it is found that [95] can also be written as

$$d(M\beta^2) = \frac{bl^2}{4}(s_2\epsilon_2 d\epsilon_2 + s_1\epsilon_1 d\epsilon_1) \quad \ldots\ldots [100]$$

$$\frac{1}{\beta}\frac{d}{d\beta}(M\beta^2) = bhl \cdot \frac{s_1 s_2}{s_1 + s_2} \quad \ldots\ldots [101]$$

The left-hand side of this last equation is a known function of β. Equation [101] and the condition [97] that

$$\frac{d\epsilon_1}{d\epsilon_2} = \frac{s_2}{s_1} \quad \ldots\ldots [102]$$

permit us to calculate the unknown stresses s_1 and s_2 at the extreme fibers of the bar for different values of the unit elongations ϵ_1 and ϵ_2; that is, to construct from the bending test the stress-strain diagram $s = f(\epsilon)$ of the material for pure tension and compression.

VIII—TORSION OF BAR OF CIRCULAR CROSS-SECTION AND HAVING AN ARBITRARY LAW OF DEFORMATION

In a similar way as for bending, the theory of torsion can be extended to the case of a cylindrical bar and having a general

law of deformation.[22] If a solid or hollow cylinder is submitted to the action of two pure twisting moments, it will twist uniformly. If the material is stressed beyond the limit of plasticity, the angle of twist per unit of length may become permanent. But as the cross-sections after twist will remain plane and will simply turn around the axis of the cylinder (we assume that there is no perceptible change in the volume of the coaxial cylindrical shells with plastic deformation), coaxial cylindrical shells are deformed with the increasing twisting moment in proportion to their radii. As they do not exert stresses in a radial direction on one another, we can assume that the unit shear γ at a distance r from the center of the circular cross-sections is proportional to the radius r, or

$$\gamma = \vartheta r \ldots\ldots\ldots\ldots\ldots\ldots [103]$$

The constant of proportionality ϑ is the angle of twist per unit of length.

A consequence of the manner in which the small elements of a cylinder are deformed by pure shear is that the internal

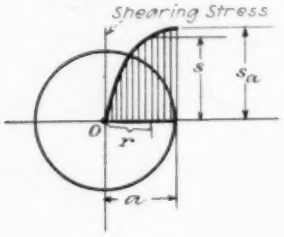

FIG. 18

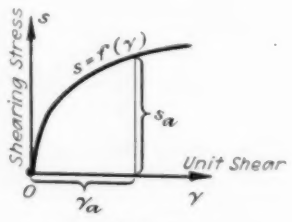

FIG. 19

stresses acting in the plane cross-sections of the bar are only shearing stresses which are perpendicular to the radii r. In general, the shearing stress s will depend on the amount of deformation, that is, it will be a function of the unit shear γ

$$s = f(\gamma) \ldots\ldots\ldots\ldots\ldots\ldots [104]$$

This relation may be called the "stress-strain diagram of the material in pure shear," and can be considered as given analytically or graphically (see Fig. 19).

(*a*) *Direct Problem.* If the stress-strain diagram of the material in pure shear is given it is easy to find the magnitude of the twisting moment M which corresponds to a given angle of twist ϑ. The moment M for a solid cylinder is

$$M = 2\pi \int_0^a sr^2 dr \ldots\ldots\ldots\ldots\ldots [105]$$

The integration variable r being, for a given angle of twist ϑ, proportional to the unit shear γ, can be replaced by γ/ϑ and s by $f(\gamma)$. Hence:

$$M = \frac{2\pi}{\vartheta^3} \int_0^{\gamma_a} f(\gamma)\gamma^2 d\gamma \ldots\ldots\ldots\ldots\ldots [106]$$

The upper limit of this integral is $\gamma_a = \vartheta a$, where a is the radius of the cylinder. Expressed in words:

> For a given unit angular twist the corresponding twisting moment M of a solid cylinder subjected to torsion beyond the plastic limit is equal to the moment of inertia of the area under the stress-strain diagram $s = f(\gamma)$ taken about the s-axis (see Fig. 19) and extending to the unit shear $\gamma_a = \vartheta a$, this being multiplied by $2\pi/\vartheta^3$.

(*b*) *The Inverse Problem.* Conversely, if the moment twist curve $M = F(\vartheta)$ is known from an ordinary torsion test, it is possible to determine from it the stress-strain diagram of the material in pure shear. Multiply [106] by ϑ^3. Then the left-hand member side of [106] is a known function of the variable ϑ. Hence the right-hand member of [107] must be a function of ϑ. The upper limit γ_a contains the angle ϑ, as

$$\gamma_a = \vartheta a \ldots\ldots\ldots\ldots\ldots\ldots [107]$$

Differentiating both sides of [106],

$$\frac{d}{d\vartheta}(M\vartheta^3) = 2\pi f(\gamma_a)\,\gamma_a^2 \frac{d\gamma_a}{d\vartheta} \ldots\ldots\ldots [108]$$

Here we can replace γ_a by ϑa. $f(\gamma_a)$ is the shearing stress s_a at

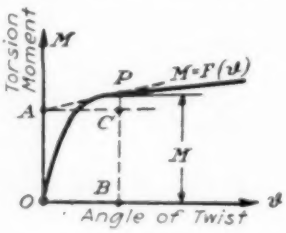

FIG. 20

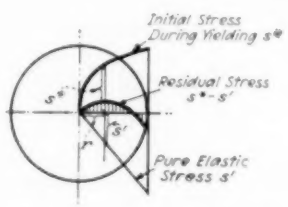

FIG. 21 RESIDUAL STRESSES IN TWISTED CYLINDRICAL BAR AFTER YIELDING

the extreme fiber $r = a$. Thus, solving [108] for s_a we find the shearing stress for $r = a$ in the twisted bar equal to

$$s_a = \frac{1}{2\pi a^3 \vartheta^2} \frac{d}{d\vartheta}(M\vartheta^3) = \frac{1}{2\pi a^3}\left[\vartheta \frac{dM}{d\vartheta} + 3M\right] \ldots [109]$$

The shearing stress s_a corresponding to a unit shear $\gamma_a = a\vartheta$ can be obtained by a geometrical construction from the moment-twist diagram $M = F(\vartheta)$ taken from a torsion test as follows: Referring to Fig. 20, project on the ordinate PB the tangent AP to the moment-twist curve $M = F(\vartheta)$. Add to this length PC three times the value of the moment M and divide this sum by $2\pi a^3$. The form of the stress-strain diagram for pure shear and the stress distribution in cylindrical bars under the combined action of an axial load and a twisting moment have been studied carefully for ductile metals by P. Ludwik[23] and Seigle.[24]

IX—PLASTIC FLOW IN A THICK-WALLED TUBE UNDER THE ACTION OF INTERNAL PRESSURE FOR AN ARBITRARY LAW OF DEFORMATION

The case of a thick-walled tube can also be treated in a similar manner as the preceding two cases by assuming a general law of deformation if the cylinder expands only in a radial direction, that is, if the tube does not change in dimension parallel to its axis. Assuming that the axial unit elongation $\epsilon_z = 0$, the other two unit elongations ϵ_r and ϵ_t must be equal and have opposite signs, or

$$\epsilon_r = -\epsilon_t \ldots\ldots\ldots\ldots\ldots\ldots [110]$$

Let a be the outer and b the inner radius of the tube and ρ the

[22] The theory seems to have been established the first time by C. Duguet in his book, previously referred to, which appeared in 1883. P. Ludwik ("Elemente der technologischen Mechanik," Berlin, 1909) and L. Prandtl (lectures) have independently derived essentially the same rules. Tests in torsion with plastic metals which support the assumptions have been made by W. Bader (Dissertation, University of Göttingen, 1927).

[23] "Elemente der technische Mechanik," Berlin 1909. See also Ludwik and Scheu, *Stahl und Eisen*, vol. 45 (1925), p. 373.

[24] Comptes rendus, Paris, 1925. Page 98, also Genie Civil, Paris, years 1925, 1926, also Revue de metallurgie, 1925, p. 374.

radial displacement of a point at a distance r from the axis of the tube. As $\epsilon_r = \frac{d\rho}{dr}$ and $\epsilon_t = \frac{\rho}{r}$, the radial displacement ρ must satisfy the condition that

$$\frac{d\rho}{dr} = -\frac{\rho}{r} \quad \text{[111]}$$

and

$$\rho = \rho_a \frac{a}{r} \quad \text{[111}a\text{]}$$

Obviously the integration constant ρ_a is one-half of the total expansion of the external diameter $2a$ of the tube. As $\epsilon_t = 0$ and $\epsilon_r = -\epsilon_t$, the rule of plastic flow requires that the axial normal stress shall become equal to the average value of the radial and tangential stresses:

$$s_z = \frac{s_r + s_t}{2} \quad \text{[112]}$$

(otherwise the figure of the three principal circles in Mohr's stress-diagram would not be similar to the figure of the three principal circles of strain). In both diagrams the two smaller circles must have equal diameters. Under these circumstances the state of strain in every element of the tube is a pure shear. At a distance r from the axis of the tube this unit shear must be

$$\gamma = \epsilon_t - \epsilon_r = 2\epsilon_t = 2\rho_a \frac{a}{r^2} \quad \text{[113]}$$

Evidently all the small elements of the tube are deformed in a similar manner as are the elements in a solid cylinder under the action of a twisting moment as described in Section VIII. The only difference is that the shear in the tube under internal pressure has now a different direction from that in the cylinder under torsion. It is easy now to see that the stresses in the tube can be determined if the stress-strain diagram of the material in pure shear is known. This latter could, for example, be determined by an ordinary torsion test with a bar of circular cross-section as shown in Section VIII. Let the law of plastic deformation in pure shear be given by

$$s = f(\gamma) \quad \text{[114]}$$

where s is the maximum shearing stress and γ the unit shear. For a hollow cylinder stressed by an internal pressure p, the maximum shearing stress is given by

$$s = \frac{s_t - s_r}{2} \quad \text{[115]}$$

and the unit shear γ given by

$$\gamma = \epsilon_t - \epsilon_r = 2\rho_a \frac{a}{r^2} \quad \text{[116]}$$

These two expressions have then to be combined with the condition of equilibrium of the stresses, or

$$\frac{ds_r}{dr} = \frac{s_t - s_r}{r} \quad \text{[117]}$$

Integrating this expression between the limits r and a and taking into consideration that the radial stress s_r must vanish for $r = a$, the radial stress is found to be

$$s_r = \int_r^a \frac{(s_t - s_r)}{r}\, dr \quad \text{[118]}$$

Replacing here the variable r by the variable γ, using [116],

$$\frac{dr}{r} = -\frac{d\gamma}{2\gamma}; \quad s_t - s_r = 2s = 2f(\gamma)$$

the radial and the tangential stresses are found to be

$$\left.\begin{aligned} s_r &= -\int_{\gamma_a}^{\gamma} f(\gamma)\,\frac{d\gamma}{\gamma} \\ s_t &= 2s + s_r = 2f(\gamma) - \int_{\gamma_a}^{\gamma} f(\gamma)\,\frac{d\gamma}{\gamma} \end{aligned}\right\} \quad \text{[119]}$$

Since for $r = b$ the radial stress $s_r = -p$ from the last equation for s_r, the pressure p can be calculated under which the whole tube will yield. It is given by the integral:

$$p = \int_{\gamma_b}^{\gamma_a} f(\gamma)\,\frac{d\gamma}{\gamma} \quad \text{[120]}$$

The limits of this integral are

$$\gamma_a = \frac{2\rho_a}{a}, \qquad \gamma_b = \frac{2\rho_a a}{b^2} = \gamma_a \frac{a^2}{b^2} \quad \text{[121]}$$

So far none of the above expressions contain any assumptions with regard to the special form of the stress-strain diagram $s = f(\gamma)$ in pure shear, and they can therefore be used for any material. We can, however, try to employ some analytical expression for this function and to calculate the corresponding stresses. Taking, for example, as the law of deformation a power function

$$s = s_0 \left(\frac{\gamma}{\gamma_0}\right)^{\frac{m}{2}} \quad \text{[122]}$$

the components of stress will be given by functions containing $(a/r)^m$. In [122] the constants s_0 and γ_0 are two arbitrarily chosen, corresponding values of stress and unit shear in the stress-strain diagram for pure shear.[23] The exponent m must be taken $0 < m < 2$. Using the above relation for the stress diagram, the radial and tangential stresses can be calculated from [119]. They are:

$$\text{Radial stress:} \quad s_r = -\frac{pb^m}{a^m - b^m}\left(\frac{a^m}{r^m} - 1\right)$$

$$\text{Tangential stress:} \quad s_t = \frac{d}{dr}(rs_r) = \frac{pb^m}{a^m - b^m}\left[(m-1)\frac{a^m}{r^m} + 1\right] \quad \text{[123]}$$

They determine the distribution of stress in a thick-walled tube yielding under an internal pressure p if (1) the tube does not expand or contract in the axial direction and if (2) the stress-strain relation can be expressed by a power function.

The limiting case, that the exponent $m = 2$, may be mentioned here as in this case

$$\left.\begin{aligned} s_r &= -p\,\frac{b^2}{a^2 - b^2}\left(\frac{a^2}{r^2} - 1\right) \\ s_t &= \frac{pb^2}{a^2 - b^2}\left(\frac{a^2}{r^2} + 1\right) \end{aligned}\right\} \quad \text{[124]}$$

[23] It should be noted that a power function cannot express quite accurately the behavior of the stresses for low values of stresses for such plastic materials as the ductile metals. If $m < 2$ the angle of the tangent of the stress-strain curve at the origin $s = 0$ would become equal $\pi/2$, while all diagrams for ductile metals have a slope smaller than 90 deg. An exception is the case where $m = 2$, in which case the diagram is correct also for $s = 0$.

These are exactly the same expressions for the radial stress s_r and the tangential stress s_t which would have been found by assuming Hooke's law or a linear function for the stress-strain diagram. Thus we see that the deformation of a perfectly elastic tube is included as a special case in [119].

The stresses are given at the inner surface (for $r = b$):

$$s_r = -p; \qquad s_t = p \cdot \frac{(m-1)a^m + b^m}{a^m - b^m}$$

and at the outer surface (for $r = a$):

$$s_r = 0; \qquad s_t = \frac{mb^m p}{a^m - b^m}$$

X—Residual Stresses

As is well known, in an isotropic elastic material internal stresses can be produced without having an external load acting on the surface of the stressed piece of material. In a ring of elastic material, for example, spring steel, internal stresses will be set up if the ring is slotted radially and then the ends are brought together and welded or fastened with a bolt. In an elastic material, internal stresses of considerable amount may result also from non-uniform heating. In such cases one speaks of "thermal stresses." These will result, for instance, in the case of a thick-walled tube cooled on the outside and conducting a hot fluid. On the other hand, if in a severely stressed material one portion is permanently strained and the external forces are removed, in general, in the neighborhood of the permanently strained region, stresses will remain. With suitable means or methods these permanent or "residual stresses" can be demonstrated, as was proved by the late E. Heyn in cold-rolled or drawn bars of ductile metals. If, for example, a hardened steel ball is pressed into a piece of mild steel, the material in the neighborhood of the indentation after removal of the load cannot remain unstressed. While the ball was sinking into the soft metal and the material was yielding under the ball, very considerable compressive stresses must have acted not only in a direction parallel to the load but also in a direction perpendicular to it. The portion plastically distorted under the ball behaves like a wedge driven into a soft mass, and the neighboring parts must be stressed like a tree trunk into which a wedge has been driven. Thus after the removal of the external pressure the lateral stresses will not disappear and will form a system of residual stresses. Such internal stresses and severe residual stresses present after plastic deformation are familar to steel men and engineers on account of their deleterious action and destructive consequences in the case of pressed, forged, or rolled bars. Sometimes fractures are caused by the action of these stresses if the forged or rolled pieces are not annealed before they are further deformed. Methods of estimating these residual stresses may therefore have several practical applications.

The theory of residual stresses can be based on assumptions analogous to those on which is based the theory of plastic deformations, which are the causes of the existence of these stresses. As in the case of the fundamental assumptions with regard to the mechanical conditions of plastic flow, also for the residual stresses, several cases may be distinguished, according to the magnitude of the deformations during the removal of the load or to the character of the stress-strain relation during unloading. In the following, only two cases will be discussed.[26]

[26] For methods relative to the calculation of internal stresses, there may be mentioned papers of E. Heyn: (Martens-Heyn: Materialkunde, 2d ed., p. 280 (1912). Festschrft Kaiser Wilhelm Ges., p. 121, 1921, and *Stahl und Eisen*, 1917.) G. Masing: (several papers in Veröffentlichungen des Siemenskonzerns, Berlin 1923–1926). Ch. Duguet (loc. cit.), and A. u. L. Föppl "Drang u. Zwang," vol. 2, p. 297, 1920, Munich.

(*a*) *Linear Law for Unloading.* In metals having a definite yield point, the residual stresses after unloading may as a first approximation be obtained by assuming that after plastic deformation and subsequent removal of the load the metal behaves like a perfectly elastic material. If a bar of soft steel, previously stressed somewhat above the yield point in tension, be unloaded and then loaded again in *tension*, it will be observed that as long as the stresses remain below a certain value, it behaves as an elastic body. Thus the elastic modulus will be found of practically the same value as that observed before permanent elongation. Therefore, to obtain in some degree

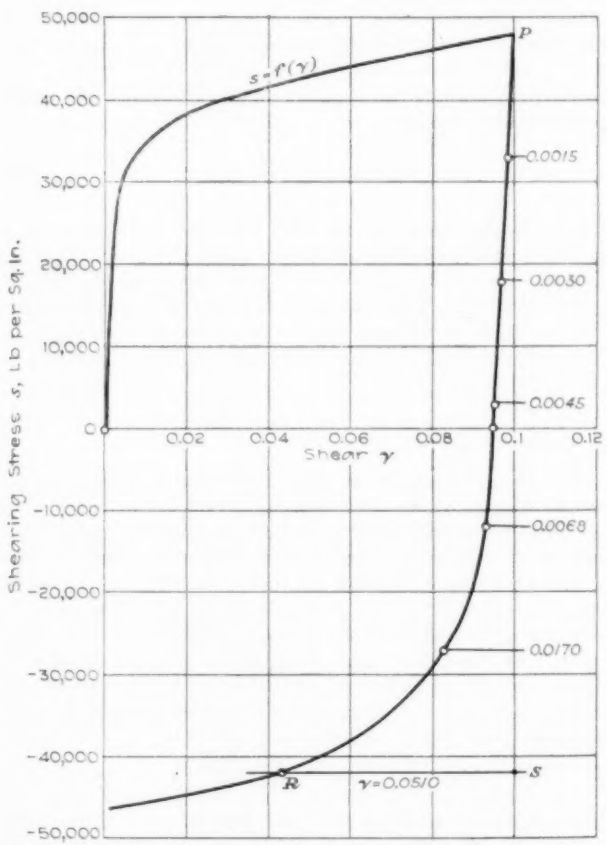

Fig. 22 Stress-Strain Diagram for Pure Shear for Direct and Reversed Sense of Shear

a picture of the residual stresses in soft iron after plastic deformation, it will be necessary only to subtract from the stresses s_x^*, s_y^*, ... occurring when the external forces and moments begin to diminish, a certain ideal system of internal stresses s_x', s_y', ..., assuming purely elastic deformations. The latter are so chosen that after unloading the original values of the resultant forces and external moments will disappear. Hence this second system of stresses s_x', s_y', ... possible in a perfectly elastic body must lead to the same *resultant* forces and resultant moments as the first system, but must balance the action thereof. In using this method, of course, such effects on residual stress as that of "after flow," the after effects of previous stresses, and the phenomenon known as the "Bauschinger effect" (decreasing of the stress at which the stress-strain curves leaves Hooke's straight line when the stresses change sign) are naturally not considered.

(*b*) *General Law for Deformation for Unloading.* From tests with subsequent change of sign in stress, for example, from a

test in torsion with thin-walled tubes with subsequent twisting of the test piece in both directions to the plastic limit, it is known that the shape of the curve for pure shear tends to have a more or less curved portion where the stresses change their sign. The shape of a stress-strain diagram in pure shear containing also the portion of the curve for the decreasing of the torsion moment and reverse twisting is shown in Fig. 22 for mild steel.[27] The shape of the curve for twisting in a reversed sense seems to change with the increasing amounts of plastic deformation (of cold work); the first section of the curves, *PQ* (Fig. 22), however, seems to differ but little from a straight line.

With these considerations it is possible to improve the first method [as mentioned under (*a*)] to find the residual stresses by using now a curved stress-strain diagram also for the unloading (obtained from tests), such as the line *PQR* in Fig. 22. If the shape of the curve *PQR* for the unloading does not change with the amount of cold work preceding the unloading, this curve can be used at all distances r from the center of the bar.

As an example, the case of the twisting and untwisting of a solid, cylindrical bar should be taken. Let the shape of the stress-strain diagram in pure shear for direct twist be represented by the curve *OP* in Fig. 22. With the help of the curve $s = f(\gamma)$ the true distribution of shearing stress s in the cross-section of the bar can be obtained in the manner described under Section VIII. Let this distribution be called s^*. Then s^* are the shearing stresses, acting at the distance r from the center of the bar at the moment when untwisting begins, and γ_a^* is the corresponding unit shear at the extreme fiber $r = a$ of the bar. If now the torsion moment is decreased and the bar begins to untwist, the shearing stresses will begin to decrease. Let the amount of untwist be given by the unit shear γ_a' at the extreme fiber $r = a$. This amount γ_a' may be represented in the diagram (Fig. 22) by the horizontal distance *RS*. To find the distribution of stress in the cross-section of the bar corresponding to a unit shear $\gamma_a^* - \gamma_a'$, we have to subtract at every point in the distance r from s^* a certain stress distribution s'. This latter is obtained by distributing a system of shearing stresses s' as given in the portion *PR* of the curve *PQR* in Fig. 22, over the radii r of the circular cross-section, and by plotting the differences $s^* - s'$ over the radii r. In this manner the different stress curves in Fig. 23 have been obtained for a cylindrical bar of mild steel with a diameter of 2 in. ($a = 1$ in.). These curves show the distribution of shearing stress over the radial distances r for different amounts of untwisting. The latter is indicated by the figures giving the final angle of twist per unit of length, and these are written above the corresponding stress curves. Thus, for example, in Fig. 23 the lowest curve shows the distribution of shearing stress in the bar for a total angle of twist per unit of length $\vartheta = -4.30$ deg. The highest curve shows the original distribution of stress corresponding to an angle of twist of $\vartheta = 5.7$ deg. For intermediate angles of twist several other curves have been constructed in Fig. 23 which show the corresponding stress distributions during the unloading of the bar and the subsequent twisting in the opposite direction. Under these intermediate curves might be drawn one to which a torsion moment equal to zero would correspond. This curve would give the residual stresses which must remain after the complete removal of the torsion moment. (This curve is not shown in Fig. 23.)

In a similar manner the residual stresses in a thick-walled tube after plastic flow could be obtained. If, for example, the stress-strain curve of the material could be expressed by a power function as assumed in Section IX, the radial and the tangential stresses at the moment when the plastic flow is interrupted would be given by the expressions:

[27] Relative to such tests see dissertation of W. Bader (Univ. of Göttingen, 1927).

$$s_r^* = -p\,\frac{br^m}{a^m - b^m}\left(\frac{a^m}{r^m} - 1\right)$$

$$s_t^* = p\,\frac{b^m}{a^m - b^m}\left[(m-1)\,\frac{a^m}{r^m} + 1\right]$$

Here a and b are the outer and inner radii of the tube, and p is the internal pressure. It is assumed that the tube does not change its dimensions in the axial direction.

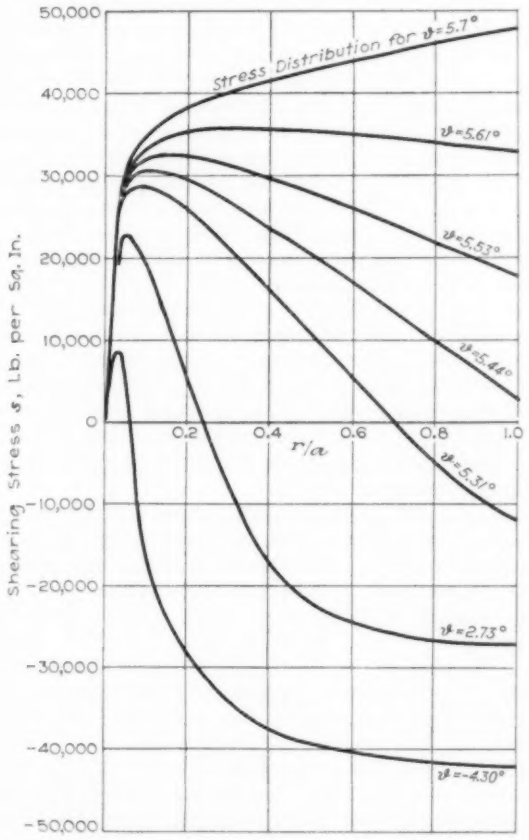

FIG. 23 RESIDUAL STRESSES IN TWISTED CYLINDRICAL BAR FOR DIFFERENT ANGLES OF TWIST

($2a$ = diam. = 2 in.; ϑ = angle of twist per inch; r = distance of point from axis of cylinder.)

Assuming that during the subsequent decreasing of the pressure p a linear stress-strain law would hold, the second stress system (denoted by the prime mark) would be given by

$$s_r' = -p\,\frac{b^2}{a^2 - b^2}\left(\frac{a^2}{r^2} - 1\right)$$

$$s_t' = p\,\frac{b^2}{a^2 - b^2}\left(\frac{a^2}{r^2} + 1\right)$$

Hence the residual stresses acting in the tube after the internal pressure p has been removed will be given by the stress differences

$$s_r = s_r^* - s_r'; \quad s_t = s_t^* - s_t'$$

It should be remembered, however, that these expressions will only hold when at no place within the tube is the limit of plasticity reached during the removal of the pressure a second time.

Discussion

ARTHUR MCCUTCHAN.[28] The paper is a highly interesting excursion into the land where stress is no longer directly proportional to strain and where deformation depends on time and temperature as well as on stress. The paper should help to clarify present rather obscure conceptions of just how one should distribute materials advantageously in equipment operating at temperatures which place the metal in the plastic condition.

It is noted in the analysis of a thick hollow cylinder, on the eighth page and Fig. 13, that the maximum tangential stress occurs at the outer surface of the tube. As this is exactly contrary to the result obtained from elastic consideration,[29] it is pertinent to inquire if the effect of heat flow from the outside to the inside of a tube in the plastic state would tend to reduce the stress rather than augment it as is found from the elastic theory. This effect of heat flow on the stress in a tube wall is an important factor in present-day design of heat-absorption equipment. Hence, if it can be shown that heat flowing through a tube wall from the outside does not increase the stress in the tube wall, one of the restrictions on the design of such apparatus for high-temperature service will be removed.

It is to be hoped that the author will indicate how to coordinate the findings of this paper with available test data on the behavior of materials at high temperature. Stress-strain curves in the plastic region are seldom reported, attention being directed toward creep phenomena. It would appear that the majority of investigators are more concerned with the behavior of metals in the temperature range in which rate of change of shape is a dominating factor.

In designing equipment in which the stress set up by thermal expansion is a determining factor, the lack of a satisfactory equivalent for Young's modulus for materials operating at or near the plastic condition is evident. It is not clear just how such problems can be handled by the methods outlined in this paper.

J. J. KANTER.[30] During recent years, use of metals under severe stresses at elevated temperatures has given impetus to the study of plastic flow under such conditions. As the author has intimated in introducing his theories, tests have shown that steels and other metals at temperatures of 750 deg. fahr. possess stress-strain diagrams of the type shown in his Fig. 2. Furthermore, the creep or continuous deformation under load becomes a considerable factor in many service applications.

While it is not the intention in any manner to deprecate the excellent and scholarly analysis that the paper presents, it appears that the theories advanced could well be extended to embrace creep conditions. From the standpoint of testing materials, plastic flow of metals at temperatures permitting stress-strain diagrams as shown in the author's Fig. 1 is of great importance and may be applied to the interpretation of cold plastic deformation. When creep is a factor, however, as is the case in most high-temperature applications, the variable of time must be taken into account in the stress-elongation and stress-shear functions.

It would appear that in the theories developed by the author where he uses

$$s = f(\epsilon) \quad \ldots\ldots [2]$$

$$s = f(\gamma) \quad \ldots\ldots [114]$$

to represent equilibrium conditions of axial deformation and shear, respectively, inverse experimental functions also containing the variable of time could be applied to include the more general case, as

$$\epsilon = f(s, t)$$

or

$$\gamma = f(s, t)$$

where t is time under stress.

Many technical data on the creep of various materials are being accumulated from a number of laboratories. The author's theories, particularly in the case of tubes under internal pressure, should be of value in applying this information if revised to take account of deformation as a function of both stress and time. Inasmuch as an arbitrary law is resorted to for the tube case, it would seem that the formulation could just as well be altered to include plastic-flow conditions at elevated temperatures.

FRANKLIN L. EVERETT.[31] An investigation of the behavior in the plastic region of ductile materials subjected to twist is being conducted at the University of Michigan. This is in the nature of an academic experimental problem and is related to the character of the analytical work presented in the paper. The validity of the maximum-shear theory is to be studied at elevated temperatures. The work until the present time has been at normal temperatures. Annealed medium-carbon-steel tubing with thin walls is used.

Tests commonly described as "creep" will be made in torsion to produce pure shear, and the results compared with tension tests performed under similar conditions of loading and temperature. A special apparatus has been constructed with the desired features. Angular deformation is accurately measured by projecting beams of light on a distant scale.

The present interest is in discovering a suitable design of specimen to provide a pure shear fracture. Buckling offers some complexities which are being overcome.

Some of the earlier experiments were concerned with obtaining a general knowledge of the characteristics of the material. In several cases specimens were carefully loaded to cause yielding, and allowed to remain in this stressed condition for twelve hours. Upon further loading without having removed the load, an elastic region was again observed, followed by a second yielding. The inference is that during the period of rest there occurred some internal readjustment (possibly an "aging" effect) which restored the elastic properties. The second elastic range was of the order of 4 per cent of the former.

EARLE B. NORRIS.[32] The last few years have seen a great development in the use of cold-worked steel, in which material in sheet or bar form is permanently shaped by the application of stresses beyond the elastic limit of the material. It is known that such cold-working produces an increasing resistance of the material to further deformation. In many cases it is necessary to anneal the material between the various steps of cold-working, in order to restore its ductility.

It is known in a general way that deforming a piece of metal beyond its elastic limit produces a new elastic limit equal to the stress which has been applied and reduces the ductility by the amount of unit deformation which has taken place. And it is known that annealing will restore the metal practically to its initial physical properties. For many applications of cold-working such general information is sufficient. In other cases, however, direct use is made of the altered properties. In the design of a machine part which is to be made by cold-working, one may,

[28] Engineering Division, The Detroit Edison Company, Detroit, Mich.

[32] Dean of Engineering, Virginia Polytechnic Institute, Blacksburg, Va. Mem. A.S.M.E.

and should, make use of the higher elastic limit produced in the process of shaping. Even where the altered physical properties are not used in design, one may be concerned with the amount of energy required to perform the operations of cold-forming against a progressively increasing resistance. In wire mills cold-drawing produces an increase in elastic limit and ultimate strength of the wire, and dependence is placed on these higher physical properties in use of the wire; as, for example, in the cables of suspension bridges. The wire mills have certain rule-of-thumb equations which are used as an indication of the physical properties to be expected by any given amount of wire drawing.

Referring to Fig. 24, it is known that when an ordinary tensile specimen has been stretched to the point A on a stress-strain curve, if the load is removed the recovery will be elastic, and that when the load is again applied the material will be elastic until the point A is again reached, when the original curve of the material will be followed if the load is continued to rupture. There never has been, however, any equation that represented accurately the stress-strain curve, and, due to the irregularities of shape, it is doubtful if any equation could be derived of general application. The French use a parabolic curve starting with the

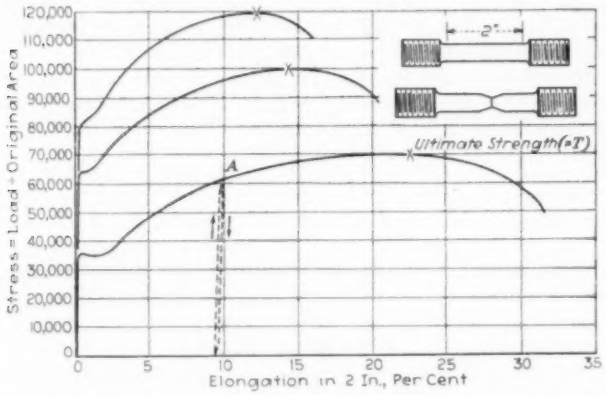

Fig. 24 Conventional Stress-Strain Curves, Elongations in 2 In. as Abscissas, Stresses on Original Area as Ordinates

original elastic limit and increasing the elastic limit according to the square root of the elongation. This is only a rough approximation and certainly could not apply beyond the ultimate strength of the material, where the actual curves begin to curve downward to rupture. Furthermore, it is an open question whether the shape of the curve between the elastic limit and the ultimate strength is a function of the elastic limit or of the ultimate strength, or possibly of both.

It is known that in these ordinary stress-strain curves there are used as abscissas the mean elongation of the specimen in a standard gage length. Actually, one part of the specimen is receiving more elongation than the rest, and is being gradually drawn to a small diameter until rupture finally occurs at this minimum section. Obviously the resistance of the material as shown by the ordinate of the curve is the resistance of this minimum section, while the elongation which is plotted is not the elongation of this section, but is the average for the entire gage length of the specimen. The curves are therefore not a true indication of the relationship of resistance to flow.

In looking for a possible method of plotting physical test data which might give a better indication of a reliable law, the writer used first a practice adopted from the English of plotting "true stress." By "true stress" they mean the load upon the specimen divided by the actual area at the minimum section corresponding to each load. This gives a constantly rising curve instead of one which begins to fall off at the time the ultimate strength is reached. This use of "the true stress" seems more logical, because in the design of any cold-worked article one is concerned with the finished dimensions and not with the original dimensions of the piece from which it is made.

As a measure of true deformation there are a number of terms which might be used. One might plot as abscissas the reduction in area at the minimum section. He might plot the reduction of diameter, which, of course, is merely a function of reduction of area; or he might plot the true elongation, meaning the elonga-

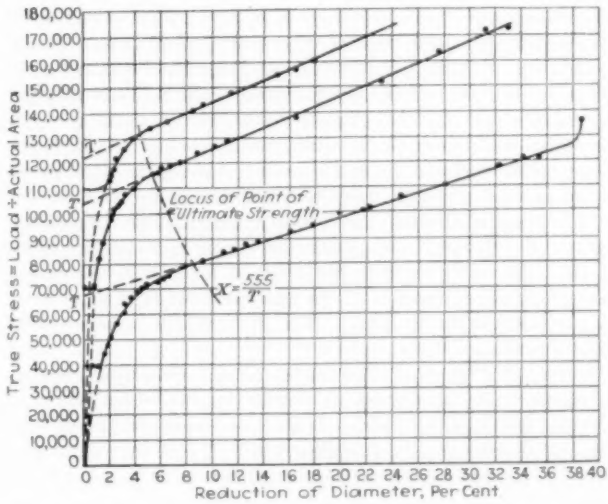

Fig. 25 Curves Obtained by Plotting Reductions of Diameter as Abscissas and True Stresses as Ordinates

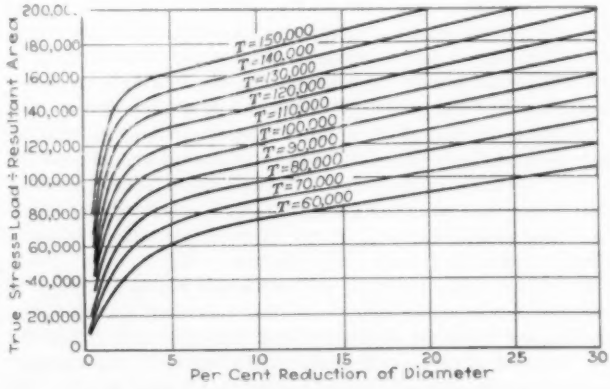

Fig. 26 Stress-Strain Curves From Formula

tion which takes place right at the minimum section and which would represent the elongation of the specimen if it had all been drawn down to the minimum diameter. Whichever one of these is used seems immaterial, because any of them may be computed from any of the others. After trial of these three possibilities for abscissas the writer finds the most promising at present to be to plot reduction of diameter as abscissas and true stress as ordinates. Fig. 25 shows a series of curves obtained in this way from which many interesting deductions may be made. To get these curves from the ordinary tensile test requires only the addition to the equipment of a micrometer with ball points. As each load is observed, the corresponding diameter is determined with the micrometer, from which the per cent reduction of the diameter may be calculated. Each load is divided by the actual area supporting it, as determined by the micrometer readings,

thus giving the ordinates of "true stress," or load per unit of actual area.

Fig. 25 shows such curves for three specimens of radically different physical properties. One is immediately struck by the straight-line characteristic of the greater part of these curves. This discovery was not original with the writer, but so far as he knows was first made by Mr. John Stead, an English metallurgist, and was presented in a paper given before the Iron and Steel Institute in about 1924. Mr. Stead tested 39 steel specimens of widely varying physical properties, and all of them showed this characteristic. He overlooked, however, what seems to be the most significant feature of this method of plotting. If the straight-line section of the curve is prolonged to its intersection with the y-axis, this intersection proves to be the ordinary ultimate tensile strength based on original area. The ultimate strength therefore becomes one of the constants of the equation which can be set up to represent the entire curve. In fact, the equation as the writer has deduced it contains no other constant than the ordinary tensile strength, and therefore indicates that the elastic limit of the material once passed, the elastic limit has no effect on the behavior of the material afterward, but that the plastic flow is entirely a function of the ultimate strength and of some measure of true deformation. This deduction is believed to be great significance.

The point of tangency on these curves corresponds to the point at which the ultimate strength is reached on the ordinary curve of a tensile test, but the ordinate is the true stress at this point instead of the stress on the original area. Up to that point this new curve proves to be logarithmic and beyond that is a straight line.

To deduce an equation representing this combination of a curve with a straight line is not as complicated as it might appear. The straight line, of course, is the ordinary equation $Y = a + mx$, in which a is the y-intercept ($= T$) and m is the slope of the line. From this equation there must be subtracted a third term on the right which has a maximum value equal to a when x is 0, and which vanishes at the point of tangency. This term therefore takes the form $-T^{(1-bx)}$, in which the value of b is such that bx is equal to 1 at the point of tangency. This subtractive term therefore has a value of T when x is 0 and has a value of T^0 or 1 at the point of tangency. In comparison with stresses of several thousand pounds a value of unity is practically infinitesimal. For greater values of x, the value of this term becomes a fraction, less than 1, and also negligible.

The writer finds that the stronger steels reach the point of tangency much earlier than the softer and more ductile steels. The locus of this point appears to be a function of x such that the x at the point of tangency is equal to 555 divided by the ultimate strength of the steel in thousands of pounds. The term b in the writer's equation therefore becomes $0.0018T$.

In examining a great many of these curves, both Mr. Stead's and his own, the writer finds that in general the slope of the straight line increases for the stronger steels. This slope may be approximated as $^2/_{10}$ of the square root of T, where T is the ultimate strength in thousands of pounds. This study thus gives a general equation for the true stress upon a specimen at a reduction of diameter of x per cent:

$$S = T + 0.2\sqrt{T}\,x - T^{(1\,-\,0.0018\,Tx)}$$

As it stands, this equation is clearly an equation made up of two sections, one of which is exponential or logarithmic in general form, and the other of which is a straight line.

In plotting his curves the writer finds that austenitic steels, such as very high-tungsten or nickel steels, give radically different slopes to the line from all other varieties. Probably this is due to a different crystalline structure. It is a question whether alloys of 15 to 30 per cent tungsten or nickel should be classed as steels or as alloys. In any event, their behavior requires different constants from those in the equations proposed. These equations are, however, applicable to the ordinary carbon steels, to nickel steels, and chrome-nickel steels up to 4 per cent nickel and 1.6 per cent chromium, and to a manganese content up to 0.75 per cent. Whether these limits may be extended cannot be said, but in all probability the limits established will cover the full range of steels which are likely to be cold-worked under any methods known at present. The austenitic steels display merely a change of slope of the line and require changing the slope coefficient from $0.2\sqrt{T}$ to some other value. Otherwise the curves are the same.

It will further be noticed that these curves, if prolonged in a logical direction, seem to converge at the intersection of the two axes. This would indicate that there are two laws of behavior of steel, one of which is Hooke's law, which prevails up to the proportional limit. The other law, which the writer will call the "law of plastic flow," apparently also starts at zero load, but is not apparent until Hooke's law has been broken down, when it comes into action and controls the plastic behavior of the metal.

A rather complicated mathematical study of this equation for plastic flow indicates that the curved section is purely logarithmic in form, which is the form that might be rationally expected for a progressive building-up of specific resistance.

If each successive increment of deformation dx produced an increment $K\,S\,dx$ in the specific resistance of the metal, there would be the relation $dS = K\,S\,dx$, whence by integration one would have

$$\log_e S = K\,x + C$$

or

$$S = e^C\,e^{Kx}$$

In comparison with this, the logarithmic part of the equation may be written

$$S = e^C\left(1 - \frac{1}{e^{Kx}}\right)$$

There is an interesting similarity here, but the writer so far has been unable to evolve a rational explanation of the difference between the two forms.

The straight-line section corresponds to a fundamental assumption that $ds/dx = m$, whence $S = a + mx$.

The physical significance of this is that for this part of the flow curve the rate of true stress increment with respect to reduction of diameter is a constant.

In Fig. 26 the equation has been plotted for steels of different tensile strengths. The value of S from these curves, for a steel of any given tensile strength, represents the resistance per unit of final area which the steel will exert at the end of cold working to a given reduction of diameter of x per cent. From the ordinary tensile tests it is known that a specimen which has been stressed to a value S beyond its original yield point becomes elastic up to this same stress S when load is reapplied; in other words, S becomes the new yield point. Consequently, Fig. 26 should indicate the approximate yield point of steel which has been cold-worked. In the case of drawn wire, these values could be used only where the diameter has been reduced without intermediate annealing, since the anneal removes much of the effect of previous wiredrawing.

It would seem, however, that the necking of a specimen after the ultimate strength has been reached has a tendency to produce stresses which are not uniform over the section, and that therefore the simple tensile test cannot be used to determine the effect of cold-working beyond that point. This discussion is therefore offered merely to indicate the direction in which the writer has been working and to indicate the value of and the need

for further research in this field if full use is to be made of the changes in physical properties of metals produced by plastic working.

THOMAS MCLEAN JASPER.[33] This paper is exceedingly timely and is on a subject which is of great interest to all designers of heavy equipment. The writer has been particularly aware in the past two years of the different action of cylinders of thin section as compared to cylinders of thick section. In the thin cylinder, adjustment to shape may occur which allows it to a greater degree to carry the full load represented by the strength of the metal, while in the thick cylinder a slight out-of-roundness is not adjusted for at the yield-point stress of the metal, with the result that the load carried at failure is less than that anticipated. An endeavor to calculate for this, using the stress-strain diagram of the metal, has not answered all of the questions involved. The development of plastic mechanics which can be superimposed upon the elastic mechanics will be of great benefit, and it is anticipated will materially help the designer of thick sections to appreciate the problems involved.

In thick cylinders where there is a slight out-of-roundness, it is believed that the plane section at no stress does not remain plane under stress. The action of forming the cylinder walls by rolling does not allow it to act under stress according to the stress-strain diagram obtained on a tensile- or compression-test specimen, and therefore there are introduced considerable difficulties in the application of strains to thick-walled sections.

In the forming of all thick cylinders, no matter by what method made, the general principle just suggested will apply to a greater or lesser degree. It is not believed that a heating of the cylinder will adjust this difficulty completely. It will, it is believed, materially help the situation.

What applies to the problem of thick cylinders also applies to all heavy sections carrying load.

The value of this paper lies in the attempt to outline a rational system of plastic mechanics. Its need first attracted the attention of the writer when the effects of a hole in ductile steel under fatigue indicated that the stress was really twice the average instead of around three times as indicated by elastic mechanics.

To have a man of Dr. Nadai's qualifications attempt to rationalize this problem means that it will get much farther than if attempted by one of less experience or with a less appreciation of the use of mathematical tools.

G. M. EATON.[34] The writer has comparatively recently come to the clear realization that internal or residual stress is the direct result of plastic flow. If one permits himself to imagine a piece of steel in which residual stress is absolutely non-existent and puts this piece of steel through any heat cycle with the sole limitation that no plastic flow occurs at any stage of this heat cycle, then at the end of the cycle, after the metal has returned to the original temperature, residual stress will still be non-existent.

It is on account of the fact that plastic flow plants the seeds for the future building up of residual stress that one recognizes the vital importance of learning all that he can about plastic flow. The type of plastic-flow phenomena in which the writer is now most vitally interested is that plastic flow which occurs when steel is quenched. The conditions surrounding the passage of the steel through the recalescence point make a problem of rare complication. The major variable is the volumetric change occurring in the steel during this cycle, and the local distress in weak spots of the steel is, among other things, a function of the rate at which this volumetric change takes place. A great deal of work has been done purporting to evaluate this change of volume, but logical criticism can be directed at every attempt which has come to attention to give even a close approximation of this rate. The writer is convinced that the rate of change of volume is more rapid, and he believes far more rapid, than any of the tests referred to would appear to indicate.

It is hoped that eventually the work of the Division in connection with plasticity will shed some light on this difficult subject.

S. TIMOSHENKO.[35] This paper contains not only the original work of Dr. Nadai, but also an introduction describing the general theory of plastic flow. Such an introduction is necessary because the paper is the first work on plastic flow published in this country. Having this in mind, the writer feels that it is desirable to have some portions of the general theory discussed more in detail. For instance, he would like to have a more detailed discussion of the *rule of plastic flow*, especially its physical side, and the experimental evidence supporting the theory.

The problems of plastic flow with rotational symmetry are of more theoretical than practical interest, but they are necessary for illustrating the general theory. It seems to the writer that the discussion of the first example can be simplified. Since shear does not produce change in volume, it can be concluded that S_r and S_t are zero. Hence the problem is reduced to pure shear combined with tension. The problem on plastic flow in bending is of practical importance. Here the author discusses not only the *direct problem*, but also the *inverse problem*, and shows that having the relation between the bending moment and the deflection, it is possible to obtain the strain-stress curve of the material. There are no indications regarding the accuracy of this method, and some experimental development in this direction would be of practical interest.

The theory of plastic flow in a twisted circular shaft is discussed very completely. Solutions are given for both the direct and the inverse problem. The assumption taken as the basis is that, during twist beyond the elastic limit, the radii of cross-sections remain straight; hence the shearing strain is proportional to the distance from the axis of the shaft. This assumption is quite natural, and it would be very important to have it proved by direct tests.

The last portion of the paper contains a discussion of *residual stresses*. This subject is of utmost practical importance. In many practical cases there are residual stresses due to plastic flow. Sometimes this plastic flow is produced intentionally, so as to raise the yield point of the material and to develop residual stresses, which, combined with stresses produced by external loads, give a more favorable stress distribution. It is common practice, for instance, to submit the chains of hoisting machines to a certain amount of overstrain to eliminate undesirable stretching of these parts in service. The cylinders of hydraulic presses are sometimes submitted to an initial internal pressure sufficient to produce a permanent deformation in the walls. The strain hardening and the residual stresses produced by this method prevent any permanent set in service. The overstraining of metal is sometimes used in the manufacture of guns.[36] By stretching the metal in the wall of a gun beyond the initial yield point and afterward submitting it to a mild heat treatment, the elastic properties of the material are improved; at the same time initial stresses are produced, which combined with the stresses produced by the explosion, give a more favorable stress distribution. Tur-

bine disks and rotors are sometimes given an analogous treatment. By running these parts at *overspeed*, a permanent set is obtained around the central hole, which raises the yield point of the material and produces initial stresses, which are in a favorable direction. This problem has been discussed in detail by A. Nadai and L. H. Donnell.[37] Die-cast aluminum fans are sometimes submitted to overstrain at the bore to prevent any possibility of their loosening on the shaft in service.

In using overstrain in this manner, it is necessary to keep in mind (1) that the hardening disappears if the structure is submitted to annealing temperatures, and (2) that the stretching of metal in a certain direction, while making it stronger with respect to tension in this direction, does not proportionately improve the mechanical properties with respect to compression in the same direction.

Considerable residual stresses are produced in the process of drawing or rolling metals. In drawing a bar through a die, for

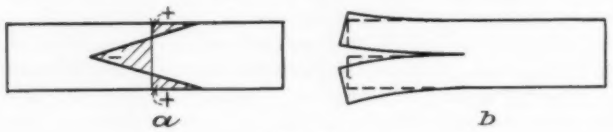

FIG. 27

instance, the metal at the outside is stretched more than the metal at the middle. Hence, drawn bars have considerable residual stresses in tension at the surface and compression at the middle. In drawn copper bars of narrow rectangular cross-section, the distribution of these stresses at a distance from the ends is as shown in Fig. 27-*a*. If the bar is cut lengthwise, there will be bending such as shown in Fig. 27-*b*. Measurement of this bending shows that the maximum residual stresses produced in drawing the copper bars are of the same order as the yield point of the material. These kinds of stresses are of great practical importance. They cause undesirable warping in the process of machining, and to them must be attributed also *season cracking* in various copper alloys which have been cold-worked and not properly annealed afterward.

C. A. NORMAN.[38] It is very much to be appreciated that the author now has developed methods for at least approximately estimating the stress and strain conditions arising in machine parts when the elastic limit has been passed, at least locally.

It has been well known for a long time that such situations might exist, for instance, at the edges of holes in highly stressed parts, at sharp reentrant corners, etc., but just how serious and how widespread these situations were could not be quantitatively stated, except perhaps on the basis of rather complicated tests with polarized light or other roundabout methods.

It is to be hoped that the paper will form the first step toward a great number of mathematical investigations of this character, and particularly it is to be hoped that men carrying out such investigations will be able to use methods as clear and comparatively simple as those introduced by Dr. Nadai.

As for the formation of a committee to coordinate research along these lines, there are perhaps arguments both for and against. It is certain that no serious progress can be made unless certain individuals of outstanding ability are willing to sink themselves more or less wholeheartedly for a while into these problems. Persons capable of such work are often irritated or paralyzed rather than helped by being made wheels of an organization, and they can usually be depended upon to have a fair knowledge of work that has been done in the same field before.

Nevertheless, if a committee can secure financial support for individual workers, give them either leisure or experimental equipment; or if the committee can secure the help of routine workers to produce a bibliography, etc., it may be of considerable assistance to the men on whom real progress must depend. Also, such a committee may of course act as a source of information to persons not very familiar with the field and yet in need of information.

W. TRINKS.[39] This excellent paper refers, it is believed, to the plastic state of metals at infinitely low velocity of deformation. From a statement in the paper it appears that the author is of the opinion that internal friction of the metal plays a part in plastic deformation only at elevated temperatures of the metal and not at room temperature. As far as the writer knows, the viscosity or internal friction does play an important part even at room temperature. The diagram (Fig. 28) was copied from original data furnished by the Ellwood City works of the National Tube Company. In that particular plant it was desired to speed up the cold-drawing of tubes. The drawing force was furnished by hydraulic pressure acting upon a piston. Higher speed required higher pressure in the cylinder. The cylinder area multiplied by the pressure gives the straight line shown in the diagram. It is quite remarkable how well all the data furnished by the National Tube Company plot on a straight line.

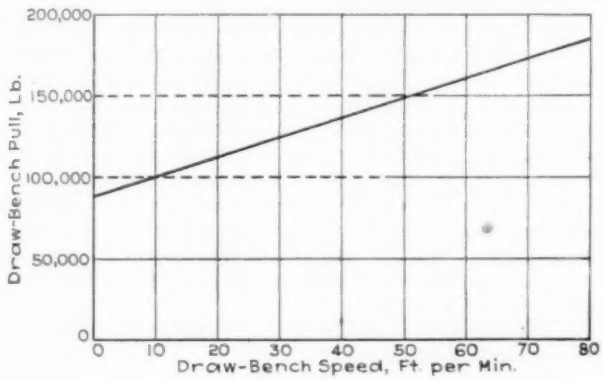

FIG. 28

Since the tubes have a chance to cool down to room temperature, it is quite evident that the increase of resisting force is a function of speed of deformation even at room temperature, because it cannot be assumed that the material would be heated to a red heat in the die. Neither can it be assumed that friction in the operating mechanism grows with the speed, because the friction of the hydraulic cylinder does not vary perceptibly with the speed.

AUTHOR'S CLOSURE

In reviewing the different discussions, the author first wishes to recapitulate briefly one or two points mentioned in the introductory part of his paper which were perhaps not worked out with sufficient clearness. It appears from all that is known about the laws under which plastic deformations in ductile metals in general start to develop, that these deformations seem not to follow as general rules, as do, for example, the elastic deformations of isotropic and perfectly elastic bodies. While it seems necessary—and is inevitable if any mechanical methods of com-

parative simplicity shall be applied to analyze distributions of stress or of strain in the plastic state—to restrict the considerations to some few assumptions and to describe plastic flow under certain idealized conditions, it should be remembered that the results of computations should not be generalized beyond the limitations under which they were obtained. The author endeavored, however, to show in some few examples that the methods appear to be flexible enough to allow more general assumptions to be considered also in cases of plastic flow in which more complicated stress-strain relations may be assumed or to include other experimentally known facts or effects, such as work-hardening, elasticity, a non-linear stress-strain relation for loading different from that for unloading, or other observable facts.

In the paper, cases were considered where the entire body was assumed to be in the plastic state. In many cases in the practical applications, however, it is important to study how plastic flow gradually spreads through a given body under an increasing load. If the material has a well-defined yield point, in such cases in general an elastic portion of the stressed body can be distinguished from a plastic part. In the first, the stresses do not reach the limit of plasticity and all the strains remain purely elastic. In the second, the stresses will satisfy the condition of plasticity.

As an example, the case of a thick-walled tube under internal pressure and without axial extension may be mentioned, consisting of a material having a well-defined yield point. Using the same notation as before for the thick-walled cylinder, (see Figs. 11 and 12) there will be a plastic part $b \leqq r \leqq c$, and an elastic part $c \leqq r \leqq a$ in the tube. In the first, the stresses can be expressed by formulas similar to Equation [65]. Taking in account that for $b < r < c$ the condition of equilibrium is:

$$\frac{d(rs_r)}{dr} - s_t = 0$$

and the condition of plasticity:

$$s_t - s_r = \frac{2s_0}{\sqrt{3}} = \text{const}$$

the stresses s_r and s_t are already given, whence

$$s_r = -\frac{2s_0}{\sqrt{3}} \log_e \frac{c}{r}$$

$$s_t = \frac{2s_0}{\sqrt{3}}\left(1 - \log_e \frac{c}{r}\right)$$

$$s_z = \frac{s_0}{\sqrt{3}}\left(1 - 2\log_e \frac{c}{r}\right)$$

where c is a constant of integration.

In the elastic portion $c < r < a$ of the tube, the stresses satisfy the conditions of an elastic material and are given by the well-known formulas

$$s_r' = c_1 + \frac{c_2}{r_2}$$

$$s_t' = c_1 - \frac{c_2}{r^2}$$

$$s_z' = \nu(s_r + s_t) = 2\nu c_1$$

where ν is Poisson's ratio. To determine the three constants c, c_1, and c_2 we have the conditions:

$$r = a_1,\ s_r' = 0$$

$$r = c_1,\ s_r' = s_r$$

$$r = c_1,\ s_t' = s_t$$

The pressure p under which the plastic part of the tube will reach to a radius $r = c$ is given by

$$p = \frac{2s_0}{\sqrt{3}}\left[\log_e \frac{c}{b} + \frac{1}{2}\left(1 - \frac{c^2}{a^2}\right)\right]$$

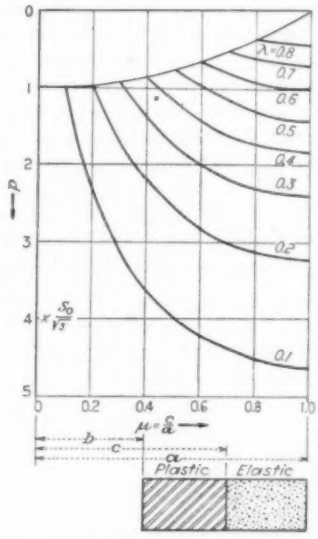

FIG. 29 PRESSURE P PRODUCING YIELDING PLOTTED AGAINST RATIO $\mu = c/\alpha$
(c = radius of surface to which plastic region extends.)

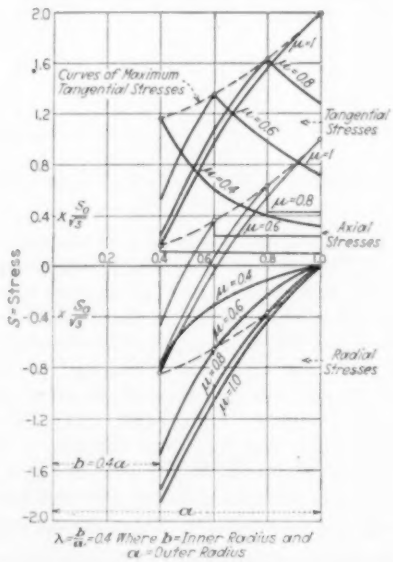

FIG. 30 CURVES SHOWING STRESSES IN THICK-WALLED TUBES

where s_0 is the yield stress in pure tension or compression, and a and b are the outer and inner radius of the tube. Denoting by

$$\rho = \frac{r}{a}, \qquad \lambda = \frac{b}{a}, \qquad \mu = \frac{c}{a}$$

in Fig. 29, the pressures p for a thick-walled tube are plotted against the ratio $\mu = c/\alpha$, thus indicating how the pressure p will increase in a tube which yields to a distance $r = c$ in the radial direction. In Fig. 29, ten curves are shown, each for a given

value of $\lambda = b/a$ of the ratio of inner to outer radius of the tube.[40]

An example showing the stress distribution is given in Fig. 28 for a tube with $\lambda = b/a = 0.4$ and $\mu = c/a = 0.4, 0.6, 0.8,$ and 1.0.

It is perhaps instructive to compare now the shape of the curves showing the distribution of the radial, tangential, and axial stress in a thick-walled tube subjected to high internal pressure p and yielding partially or completely under the assumption of *an idealized stress-strain diagram*, such as Fig. 1 and as used in the preceding formulas or in Figs. 29 and 30 with results obtained by *assuming a general curve for stress-strain diagram* such as Fig. 2. Such a comparison is given in that which follows, by using a stress-strain diagram which was actually obtained in a tensile test with a die-cast aluminum. The stress-strain curve for this die-cast aluminum is shown in Fig. 31 for a unit elongation not exceeding $\epsilon = 0.02$ or 2 per cent. It may be remarked that this diagram shows a case where the material does not exhibit a yield point: the stresses increase quite gradually and there

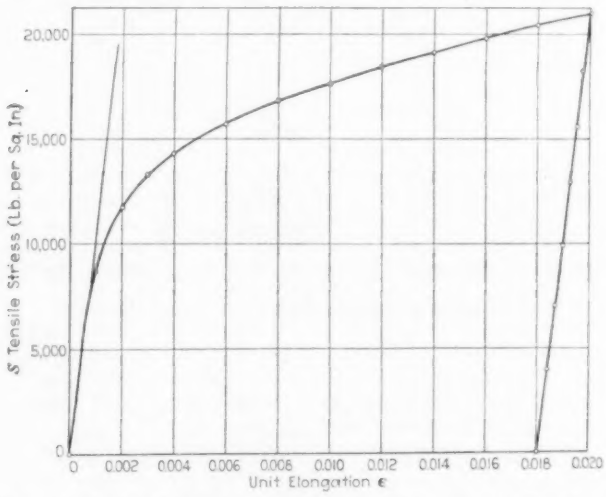

FIG. 31 STRESS-STRAIN CURVE IN PURE TENSION FOR DIE-CAST ALUMINUM

is no "elastic range" which could be first distinguished from a "plastic region." To obtain from the tensile diagram the "stress-strain curve for pure shear" which is necessary to compute the stresses according to what was said in the paper under section IX, it was assumed that the elastic parts of the strains could be first neglected if compared with their permanent or plastic parts. Under these assumptions, the stress-strain curve *in pure shear* for the die-cast aluminum $s = f(\gamma)$ (Eq. [114]) can be obtained in first approximation from the tensile curve $s_0 = \varphi(\epsilon)$ as given by Fig. 31 by multiplying all the abscissas of Fig. 31 by $^3/_2$ and by plotting against the thus obtained new abscissas γ the new ordinates s which are equal to $s_0/\sqrt{3}$ at the corresponding points. By means of this transformation: $\gamma = 3\epsilon/2$ and $s = s_0/\sqrt{3}$, the shear diagram Fig. 32 was constructed. In this figure, an "idealized diagram," with thin lines also, consisting of two straight lines was plotted and the stresses were computed according to what was said above and according to section IX, by using these two stress-strain curves. The tube was assumed to have a ratio of inner to outer radius equal to $\lambda = b/a = 0.4$. In Fig. 33, the distribution of the radial, tangential, and axial stresses is shown as obtained by using the actual curved stress-strain diagram as well as the idealized straight-line diagram. A comparison of the two sets of stress curves shows that a greater difference between the actual and the ideal stresses can only be observed at the tangential stresses s_t. The tangential stresses s_t in the outermost parts of the tube are smaller according to the actual stress-strain curve than those derived by the ideal diagram. The values of the two other stresses s_r and s_z are, however, not considerably different.

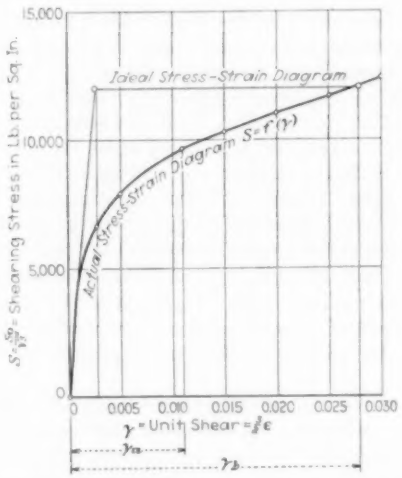

FIG. 32 STRESS-STRAIN DIAGRAM IN PURE SHEAR FOR DIE-CAST ALUMINUM

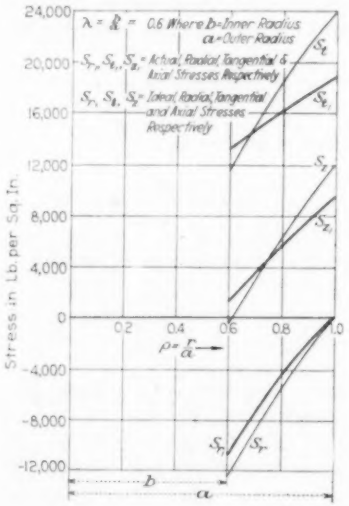

FIG. 33 COMPARISON OF ACTUAL STRESS WITH IDEAL STRESS IN A THICK-WALLED TUBE OF DIE-CAST ALUMINUM

Regarding the possible extension of these methods to the case of creep, that is, where the plastic deformation of metals at elevated temperature must be considered, the author feels that such an extension of the methods would be of practical value. In this paper, however, he restricted himself first to the simplest case of a slow plastic flow, such as occurs during a tensile, compression, or torsion test with a ductile metal and at a comparatively low temperature, and what was perhaps not clearly enough said, also assuming comparatively *small velocities* of deformation. If the temperature is raised to temperatures where recrystallization or creep begins, the laws become different and it will be necessary to introduce in addition to the one independent variable which was the unit extension in a tensile test, a second independent variable, namely, the rate of flow or the unit elongation

[40] The author is much indebted to Mr. H. Friedman for having constructed the diagrams shown in Figs. 29–32, including those for the die-cast aluminum tube.

per unit of time. Thus the velocity of deformation has to be considered, which was not necessary at slow deformations and under ordinary temperatures.

In this connection, the remarks of Professor Trinks might be answered by referring to some old results of tests made by P. Ludwik with tin wires and by Cassebaum with mild steel. The latter showed that a metal such as mild steel even at room temperature exhibits an effect of the velocity of deformation on the stress-strain diagram. It is a well-known fact to steel producers that the stress-strain diagram can be altered slightly by the speed with which, for example, a tensile-test bar is stretched while it yields. The higher the speed, the higher the tensile-stress curve proceeds. But it was shown by both Ludwik and Cassebaum that the law appears to be a logarithmic one, i.e., that if the ordinates of the stress-strain diagram are increased by equally small amounts, the corresponding velocities must be increased by much more and they follow in first approximation a geometric progression. This means that under low velocities applied in ordinary testing, stress may practically be considered as independent o velocity of deformation and the whole effect can be considered as a secondary one. Under the high velocities of an impact test, during quick cold rolling, or the drawing manipulation of a metal, the velocities are of a different order of magnitude and their effect of speed might become appreciable, as appears to be the case in Professor Trinks' tests. This effect also has been observed, for example, in impact tests.

Referring to the remarks of Professor Norris, the author thinks that here again a case of plastic flow is mentioned, which appears to be more complicated than the cases to which he wished to call attention. In the paper, only small deformations were considered, while the diagrams to which Professor Norris refers include comparatively large deformations, which in general involve a more complicated analysis. The diagrams (Figs. 25 and 26) extend to 30 and 40 per cent reduction of diameter, respectively. Denoting by l the length and by a the diameter of a tensile bar at the instant it carries a stress s and by the subscript zero the initial values of these lengths, the unit elongation ϵ and the reduction of diameter designated hereafter are given by

$$\epsilon = \frac{l - l_0}{l_0}, \qquad \delta = \frac{a_0 - a}{a_0}$$

Considering now that the volume of the bar remains practically unchanged until necking starts, we have

$$\pi a^2 l = \pi a_0^2 l_0$$

which equation permits us to express ϵ by means of the variable δ:

$$1 + \epsilon = \frac{1}{(1 - \delta)^2}$$

and this relation might be used as a first approximation also to express the mean axial extension in the smallest cross-section of the neck of a tensile-test piece. From this it is seen that an axial unit elongation ϵ corresponds to a reduction of diameter of 30 per cent or $\delta = 0.3$, which is nearly equal to unity or $\epsilon = 100$ per cent.

The stress-strain curve of a tensile test ordinarily expressed by

$$s = f(\epsilon)$$

may, according to Professor Norris, be transformed into a function

$$s = F(\delta)$$

using δ as the independent variable, where δ and ϵ satisfy the equation

$$(1 + \epsilon)(1 - \delta)^2 = 1$$

In the former form $s = f(\epsilon)$, the point on the stress-strain curve which corresponds to "the ultimate strength" (denoted hereafter by S_0 if based on the original cross-section A_0) is found in taking the load P or

$$P = A_0 s_0 = A \frac{s}{1 + \epsilon}$$

a maximum, where A designates the area of cross-section of the bar. The condition that P shall become a maximum leads here to the equivalent condition that

$$\frac{ds}{d\epsilon} = \frac{s}{1 + \epsilon}$$

which equation suggests a very simple geometrical construction of the tangent of the tensile stress-strain curve $s = f(\epsilon)$ at the point where the stress s_0 computed by the original cross-section A_0 is just equal to the ultimate strength S_0. This contruction, according to Rejtö, consists of drawing the tangent to the true stress-strain diagram $s = f(\epsilon)$ from a point situated at a distance = unity from the origin of the $s_1\epsilon$-axis system on the negative ϵ-axis. If one wishes, the same condition can be expressed by using the variable δ of Professor Norris as

$$\frac{ds}{d\delta} = \frac{2s}{1 - \delta}$$

and by means of this last equation it is now possible to compute the length of the ordinate on the stress axis s comprised between the origin and the intersection of the tangent to the stress-strain curve $s = F(\delta)$ at the point which corresponds to the ultimate strength S_0 on it. This length, which should, according to Professor Norris, be equal to the ultimate strength S_0, is found equal to

$$\frac{1 - 3\delta'}{(1 - \delta')^3} \cdot S_0$$

where δ' designates the reduction of diameter at the moment the necking starts. From the last formula it is seen that the rule Professor Norris mentions is not exactly verified. Only when δ' is a small quantity (compared to unity) does the fraction which precedes the term S_0 in the last equation equal unity.

Regarding the formula proposed by Professor Norris to express the curve $s = F(\delta)$ by an analytic law, the author would prefer an expression for the stress-strain curve which would not depend on the dimensions of the quantities entering in it, and which would not contain two distinct analytical laws in the two respective intervals of the independent variable quoted. There is no physical reason apparent which would make it necessary to assume that in the point where the ultimate strength is reached in a tensile bar, a new law of deformation comes into action. All that actually occurs is that a certain resultant of the stresses taken over the cross-section of the bar, namely, the tensile load P, becomes an analytical maximum. A consequence of this fact is that the deformation ceases to spread uniformly over the length of the bar and is further localized, this causing the well-known effect of necking, and finally rupture.

With respect to the question of residual stresses, which has been referred to by Professor Timoshenko as one of practical interest and which has only been touched in the paper, the author feels that much more has to be done to discuss the conditions under which these stresses are formed after partial plastic flow or in connection with temperature stresses as in the case of quenched-steel specimens mentioned by Mr. Eaton, where also an essential part of the question seems to be the sudden change in volume occurring during quenching. Referring to the question of Mr.

McCutchan, it seems to the author that the cases of a plastic flow in a thick-walled tube might be treated first independently of the question of temperature stresses, and that perhaps temperature stresses might be superimposed later on the first distribution, if plastic flow had ceased to spread and provided that by the addition of the new stresses the plastic limit was not reached again.

The author agrees with Professor Timoshenko that it would have been possible to treat the case of the pure combination of an axial tensile stress with a twisting couple by assuming at once that the stresses s_t and s_r are zero. It was, however, the intention to derive all the simpler cases, which are included in the case of rotational symmetry, as special cases from the more general case treated in the paper. The question whether these cases have more theoretical than practical interest seems to the author not so clear, because it could be conceived perhaps that one might analyze with similar methods the equilibrium of plastic bodies pressed between rigid plates or during such manipulations as the production of a seamless tube (combined tension and twist) or in other cases of pressing hollow or solid cylinders. It is true that in these cases of practical interest the conditions have probably been more complicated than could be treated until now, and as was already pointed out during the discussion by Messrs. McCutchan, Kanter, and Trinks, but the author is nevertheless of the opinion that in attempting to learn more regarding the distributions of stress in the plastic state, it will be perhaps also useful to discuss first some of the simpler cases under restricting or idealizing assumptions.

APM-52-18

Further Research on Helical Springs of Round and Square Wire

By A. M. WAHL,[1] EAST PITTSBURGH, PA.

A method of calculating the stress in helical springs of square or rectangular wire is proposed. The method is to use an approximate formula, based on St. Venant's results for torsion of rectangular wire, and multiply by a correction factor based on the spring index. The method is quantitatively checked by strain measurements both on semi-coils of actual square-wire springs and on complete springs loaded in compression. It is suggested that this new formula replace those commonly given in handbooks, which may lead to considerable error in certain cases.

Deflection measurements between coils of helical round-wire tension springs made from the same bar but having spring indices varying from 2.7 to 9.5 indicate that the ordinary helical-spring formula for round wire gives results quite close to the actual deflection.

A simple approximate formula, based on St. Venant's results, for deflection of rectangular-bar springs is proposed to replace those ordinarily used and commonly given in handbooks. These ordinary deflection formulas may also lead to considerable error in certain cases.

THE fact that helical springs of round wire may be stressed much higher than ordinary spring tables or formulas indicate has been shown both analytically and experimentally in a previous paper.[2] This paper showed that where the spring index—i.e., the ratio of the mean coil diameter to the wire diameter—was 3, the maximum stress was approximately 60 per cent greater than that computed by the use of ordinary spring formulas or tables. Furthermore, it was shown that the stress at the inside of the coil at *a* (Fig. 1) was around $2^1/_2$ times that on the outside of the coil at *b*.

In the discussion of this paper it was asked whether or not this effect would exist in springs made from square wire, which because of the coiling operation assume the trapezoidal form shown in Fig. 2. Because of the increase in width at the inside edge at *a* (Fig. 2), it was suggested that the stress might even be reduced. The experiments described in this paper, however, do not indicate any such reduction, but on the other hand indicate quite clearly that the same thing happens in the case of square wire as in the case of round wire, i.e., there is a stress at the inside of the coil about 2 or $2^1/_2$ times greater than that at the outside of the coil and around 40 to 60 per cent greater than that calculated by St. Venant's torsion theory.

In this discussion it was also suggested that the deflections of helical springs having small indices might deviate somewhat from the results calculated by the ordinary spring-deflection formulas or tables. The experiments described in this paper indicate that this deviation is quite small and of the order of a few per cent only, the experimental results checking those calculated by the ordinary deflection formula with a considerable degree of accuracy.

I—THE STRESS IN HELICAL SPRINGS OF SQUARE OR RECTANGULAR WIRE

In order to calculate the stress in helical springs of square wire, it is proposed to use the following method. From St. Venant's results for the torsion of a square bar,[3] the maximum shearing stress is given by

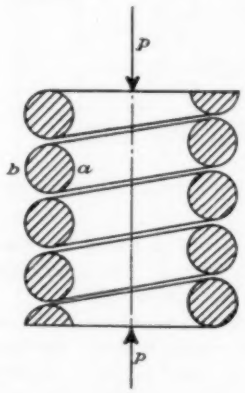

FIG. 1 HELICAL SPRING OF ROUND WIRE, AXIALLY LOADED

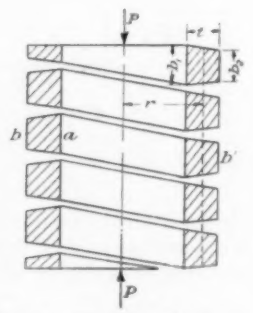

FIG. 2 HELICAL SPRING OF SQUARE WIRE, AXIALLY LOADED

(Note that the wire becomes somewhat trapezoidal due to the coiling operation.)

$$S = \frac{M}{0.208\, b^3} \qquad [1]$$

where S = maximum shearing stress, lb. per sq. in.
b = side of square cross-section, in.
M = applied torsional moment, in-lb.

For a helical spring of fairly small index, the fibers along the inside of the coil are shorter than those along the outside; this fact causes an increase in stress on the inside. To take into account this increase, it is proposed to use the same stress multiplication factor K as that given in the author's previous paper[2] (see Equation [2] of that paper), namely,

$$K = \frac{4c-1}{4c-4} + \frac{0.615}{c} \qquad [2]$$

where c = spring index. For a spring of square wire we take

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] St. Venant's results for square and rectangular bars are given in "A History of the Theory of Elasticity," by Todhunter and Pearson, vol. II, part 1. See also "Applied Elasticity," by Timoshenko and Lessells; and Edgerton, Trans. A.S.M.E., vol. 47, p. 717.

$c = 2r/t$ (see Fig. 2). The value of K may be obtained graphically from the curve of Fig. 3.

To get the true maximum stress in a spring of square wire, it is therefore proposed to use Equation [1] and multiply by K as taken from Fig. 3, thus obtaining

$$S = K \frac{Pr}{0.208\, b^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where P = axial load on spring, lb. (Fig. 2), and
r = mean radius of coil, in.

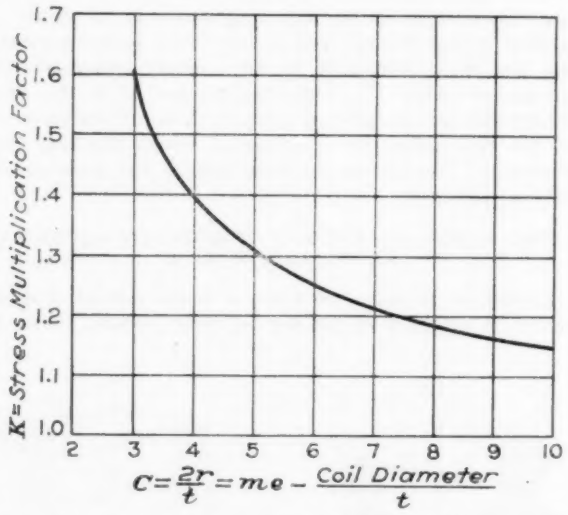

FIG. 3 CURVE FOR DETERMINING THE STRESS MULTIPLICATION FACTOR K

In determining b, an approximation will be had if b is taken as the average side of the trapezoid (Fig. 2). In determining the spring index c, however, the ratio $2r/t$ is to be taken.

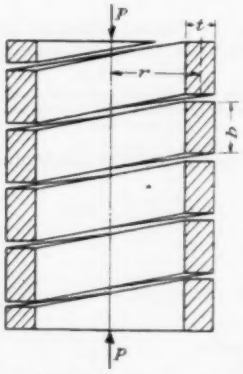

FIG. 4 HELICAL SPRING OF RECTANGULAR WIRE, AXIALLY LOADED

In calculating the stress on the outside of the coil we multiply the value of stress as given by [1] by a factor K', where K' is given by Equation [3] of the above-mentioned paper:

$$K' = \frac{4c + 1}{4c + 4} - \frac{0.615}{c} \quad \ldots [4]$$

We thus obtain the stress on the outside of the coil $S_{min.}$ equal to

$$S_{min.} = K' \frac{Pr}{0.208\, b^3} \quad \ldots [5]$$

where K' is given by [4].

Tests made as described below indicate that this method of calculation will give fairly accurate results.

STRESS CALCULATION IN HELICAL SPRINGS OF RECTANGULAR WIRE, AXIALLY LOADED

For calculating the stress in a helical spring of rectangular wire, axially loaded, and having the longer side of the rectangle parallel to the spring axis (Fig. 4), the following formula is proposed:[4]

$$S = K \frac{Pr(3b + 1.8t)}{b^2 t^2} \quad \ldots [6]$$

where S = maximum shearing stress, lb. per sq. in.
b = length of side of rectangular cross-section (Fig. 4)
t = width of rectangular cross-section, in.
r = mean radius of coil, in.
K = stress multiplication factor (to be computed from Equation [2] or taken from the curve of Fig. 3).

The approximate formula as given by Equation [6] will, if K is unity, give the stress in a bar of rectangular cross-section acted on[5] by a twisting moment Pr. The results calculated by this formula for $K = 1$ agree with those calculated by St. Venant's more exact theory within about 4 per cent in all cases from $b/t = 1$ to $b/t = \infty$. Since authorities on the theory of elasticity generally agree that St. Venant's torsion theory is correct, it

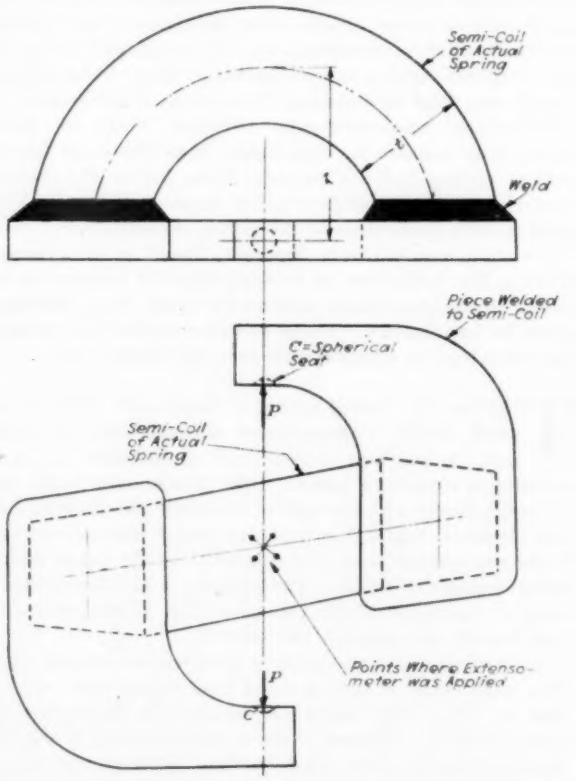

FIG. 5 SQUARE-WIRE SEMI-COIL, TEST ARRANGEMENT

seems to the author that any formula for rectangular-bar springs should be based on this theory. Some of the approximate formulas given in handbooks for springs of rectangular wire may deviate considerably from St. Venant's results when the ratio b/t is 2 or more. It appears that some simple formula such as Equation [6], which is approximately correct throughout the whole range from $b/t = 1$ to $b/t = \infty$, should be used in spring tables and handbooks rather than the formulas which are ordinarily given. These latter are in error for two reasons: first, because they do not agree with St. Venant's results, and, second, because they take no account of the effect of change in fiber length as the spring index is decreased.

Where $b < t$ in Fig. 4, i.e., where the longer side of the rectangle is perpendicular to the spring axis, the author does not believe that the above method of calculation will be accurate. In the author's opinion, further research will probably be necessary on this point.

[4] It should be noted that this formula holds only where the longer side of the rectangle is parallel to the spring axis as in Fig. 4.

[5] See "Applied Elasticity," p. 33.

Experiments to Check Proposed Method of Calculation

In order to confirm the above-described method of calculation, strain measurements were made on helical springs of square

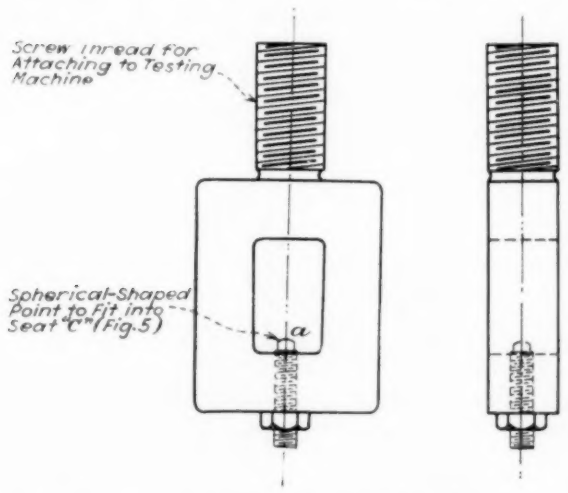

Fig. 6 Eyebolt for Applying Load to Semi-Coil of Spring

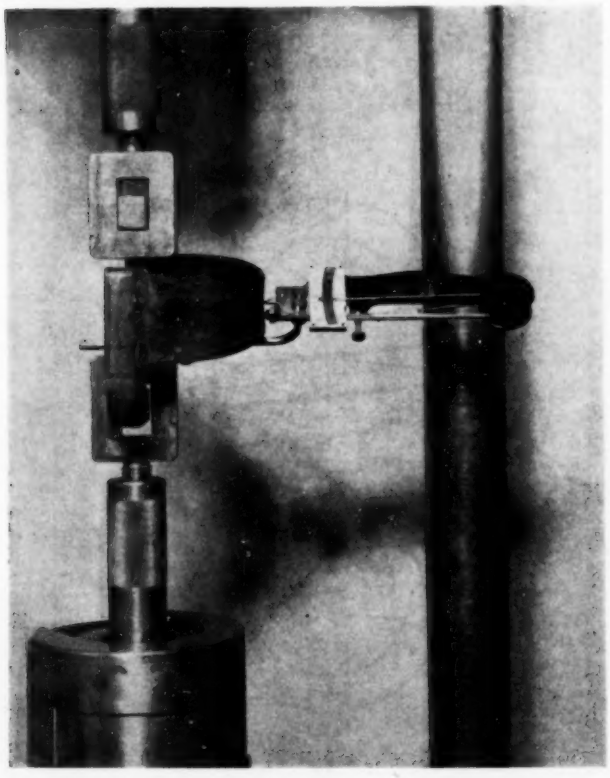

Fig. 7 Test With Extensometer on Outside of Coil

wire which, because of the forming operation, became somewhat trapezoidal in cross-section (see Fig. 2). The method of doing this was exactly the same as that described in the author's previous paper,[2] except that in this case all springs tested were made of square wire. In brief, the method was as follows: Semi-coils were cut from actual helical springs made of ordinary carbon spring steel, heat treated. Two arms were welded on to each semi-coil to form the arrangement shown in Fig. 5. The points of a special extensometer were placed as shown in Fig. 5 so that the strains at 45 deg. to the axis of the spring could be measured. The load was applied to the spherical seat by means of a testing machine, using the eyebolt shown in Fig. 6. By means of this arrangement it was possible to measure the maximum stress at the inside of the coil while the spring was subjected to an axial load as in the complete spring. A photograph of the test arrangement in the testing machine with the extensometer on the outside of the coil is shown in Fig. 7, while in Fig. 8 is

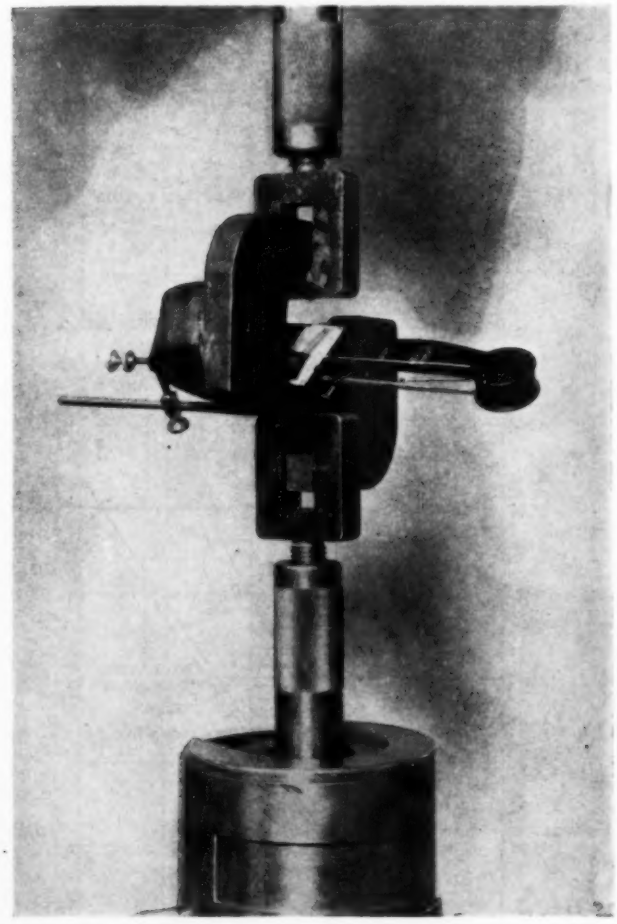

Fig. 8 Test With Extensometer on Inside of Coil

shown the test arrangement with the extensometer on the inside of the coil. The method of loading the semi-coil and of measuring the stress are clearly shown in the photographs.

The method of determining the stresses from the measured strains is fully described in the paper mentioned above[2] and will not be discussed here, since it merely makes use of the fundamental equations of elasticity. In working up the test results, a modulus of elasticity in tension $E = 30 \times 10^6$ lb. per sq.in. and a value of Poisson's ratio equal to 0.3 were used. The equivalent value of the shear modulus is 11.5×10^6 lb. per sq. in. Tests on the spring material (about 1 per cent carbon steel) indicate values very close to these.

Two semi-coils were made and tested, one having an index $c = 2r/t = 3.07$ and the other an index $c = 4.14$. The test results for semi-coil A are shown by the full lines on Fig. 9, one full line representing the stress on the inside of the coil, and

the other that on the outside of the coil. The broken line midway between the two test curves gives the result calculated by St. Venant's torsion formula (Equation [1]). The broken line representing the stress on the outside of the coil was calculated from Equation [5] while that representing the stress on the inside of the coil was calculated from Equation [3], the method of

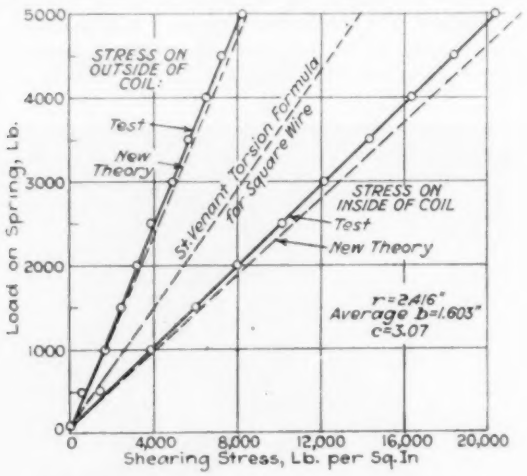

FIG. 9 LOAD-STRESS CURVES FOR SEMI-COIL A

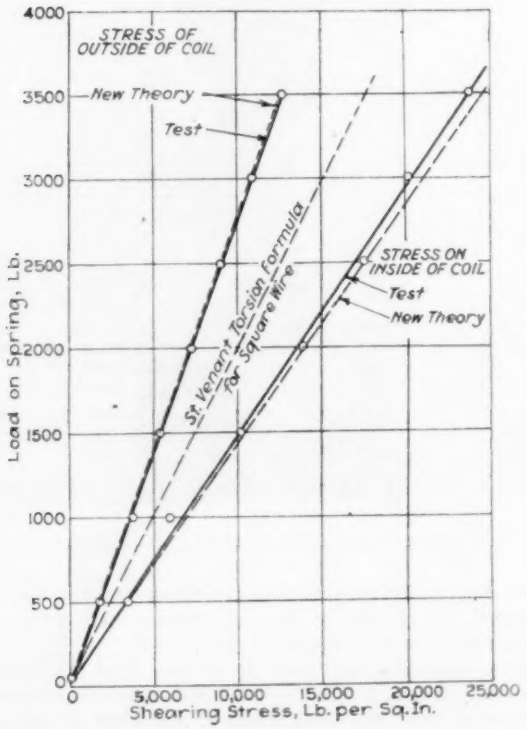

FIG. 10 LOAD-STRESS CURVES FOR SEMI-COIL B

calculation as outlined above being used. It may be seen that while the new method gives fairly accurate results, St. Venant's torsion theory is considerably in error in such cases. The stress on the inside of the coil is seen to be around $2^1/_2$ times that on the outside of the coil, and around 50 per cent greater than that figured by St. Venant's theory. These general results are about the same as those previously obtained by the author for springs of circular wire.

The test results on semi-coil B which had an index of 4.14 are shown in Fig. 10. The method of calculating the theoretical curves is exactly the same as that used for semi-coil A. In this case, however, since the spring index was not as small as was the case for semi-coil A, the stress on the inside of the coil was only about 1.9 times that on the outside and about 35 per cent greater

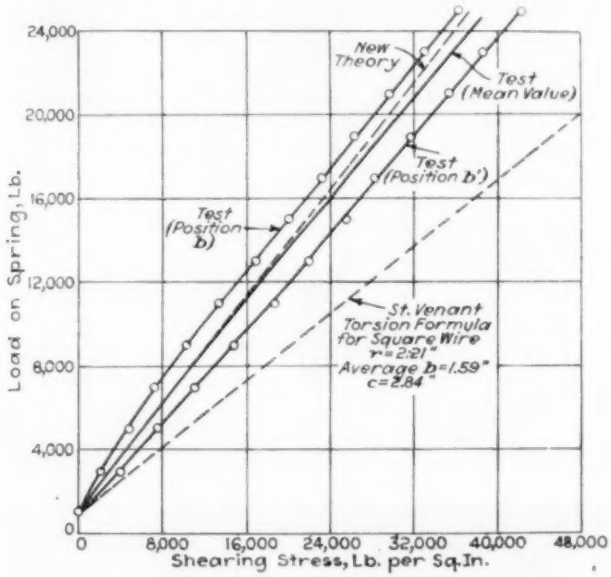

FIG. 11 LOAD-STRESS CURVES FOR COMPLETE SPRING

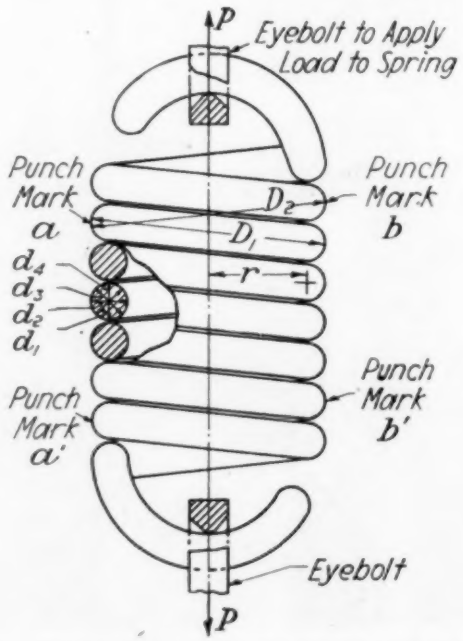

FIG. 12 METHOD OF TESTING SPRING FOR DEFLECTION

than that figured from St. Venant's theory. It is seen that, in this case, very good agreement with the new method of calculation is obtained.

In order to show that these test results were representative of complete springs axially loaded, a test was made on a helical spring of square wire loaded in compression as shown in Fig. 2. Stresses were measured by applying the extensometer at positions

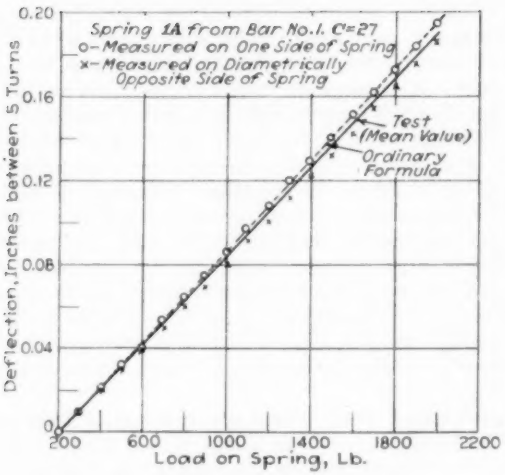

FIG. 13 DEFLECTION TEST OF SPRING 1 A

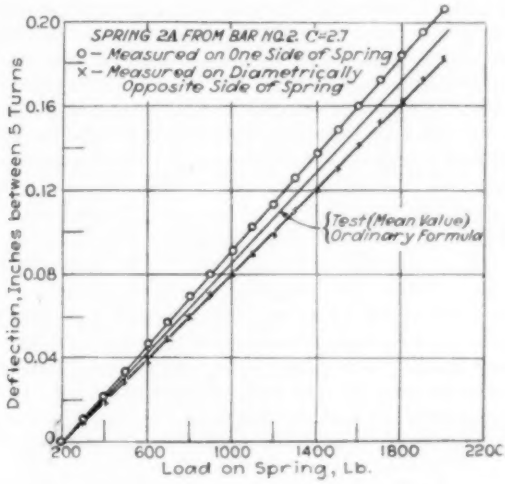

FIG. 16 DEFLECTION TEST OF SPRING 2 A

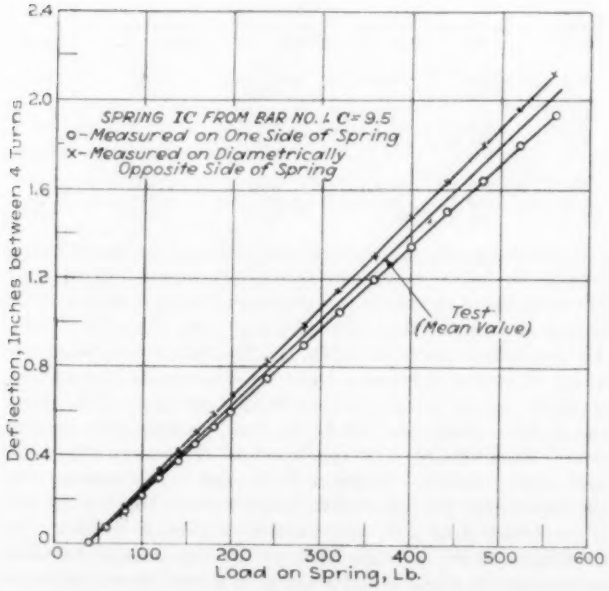

FIG. 15 DEFLECTION TEST OF SPRING 1 C

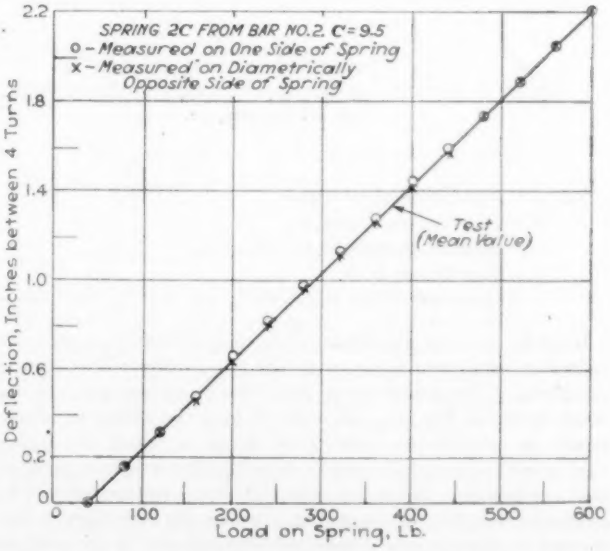

FIG. 18 DEFLECTION TEST OF SPRING 2 C

b and b' on diametrically opposite points of the spring on the outside of the coil. This was done to eliminate the effect of eccentricity of load. The results of this test are shown in Fig. 11. It will be noticed that the stress at position b' (Fig. 2) is somewhat greater than that at position b because of the eccentricity of the load. To get the stress due only to the axial load we take a mean value as shown by the full line midway between the experimental curves. The theoretical curve, computed from Equation [5], is shown as a broken line. This curve agrees very well with the mean experimental value. For comparison, the curve computed by St. Venant's theory (Equation [1]) is also given. Moreover, the mean experimental curve of Fig. 11 agrees very well with that representing the stress on the outside of semi-coil A (Fig. 9), which had about the same index. This indicates that the semi-coil test arrangement does simulate the axial loading of helical spring. Therefore the results indicate that the above-described method of calculation gives sufficiently accurate results for practical work.

II—DEFLECTION OF HELICAL SPRINGS WHEN AXIALLY LOADED

Experiments to Check Ordinary Deflection Formula for Round-Wire Springs

The commonly used formula for the deflection of helical springs of circular wire, axially loaded, is:

$$\delta = \frac{64\ Pr^3n}{Gd^4} \qquad [7]$$

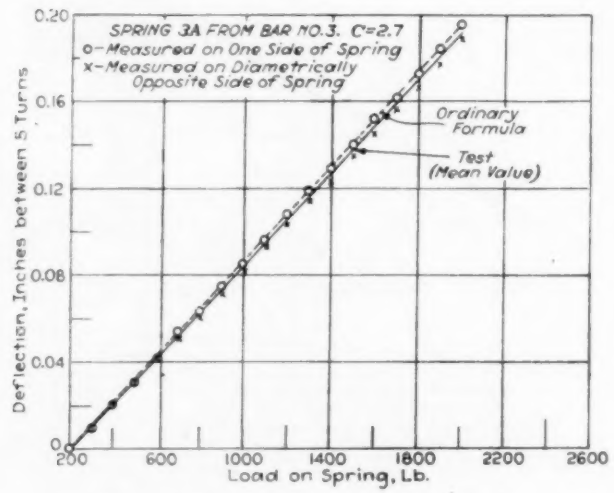

Fig. 19 Deflection Test of Spring 3 A

where n = number of active turns
P = axial load on spring, lb.
G = modulus of rigidity, lb. per sq. in.
d = wire diameter, in.
r = mean coil radius, in.

In order to check up the accuracy of this formula, a series of deflection tests were made on actual round-wire helical springs as follows. The springs tested were tension springs made to the shape shown in Fig. 12. In order to load the spring as nearly axially as possible the eyebolts by means of which the spring was loaded had rounded edges as shown, giving a definite point of load application. Since the object of this investigation was to determine the effect of the spring index on the deflection, it was decided to measure only deflections between coils in the body of the spring in order to eliminate the disturbing effect of the end coils. Therefore deflections were measured between the punch marks a and a' and b and b' which were a given whole number of turns apart as shown on Fig. 12. The reason for putting these marks on diametrically opposite sides of the spring was to eliminate the effect of the almost unavoidable eccentricity of the load. For the smallest springs ($2^1/_4$ in. O.D.) a cathetometer was used to measure the deflections, which were rather small; for the larger springs having larger deflections, a steel scale was used with dividers, this giving sufficient accuracy. Since an eccentric load may be resolved into an axial load plus a pure couple, and since the pure couple does not produce axial extension of the spring but only an increase in length on one side of the spring and a corresponding decrease in length on the other, the deflection due only to the axial load will therefore be obtained by taking the average deflection on diametrically opposite sides of the spring.

A total of nine springs were made from three different bars of $^5/_8$-in. diameter wire by the Union Spring & Manufacturing Company. The material for these springs was ordinary carbon spring steel of about 1 per cent carbon, heat treated. The bars were labeled No. 1, No. 2, and No. 3. From each bar, one spring of $2^1/_4$ in. O. D., one of about $3^1/_2$ in. O. D., and one of about $6^1/_2$ in. O. D., were made, giving a total of 9 springs. The reason for making springs of widely different indices from each bar was that presumably the modulus of rigidity would be the same in all springs cut from the same bar. The springs were then tested for deflection in the manner described above. After the test, the dimensions of the springs were measured to determine accurately the mean coil diameter and wire diameter for computation purposes. For each spring the diameters D_1 and D_2 were measured with a micrometer caliper at two points on each coil between the punch marks as shown in Fig. 12. Then the spring was cut along a plane through its axis by means of a cutting torch and the diameters of the wire d_1, d_2, d_3, and d_4 in the axial, transverse, and oblique directions measured as shown on each coil between the punch marks. Using the average values of d_1, d_2, d_3, and d_4 and the average value of d for the coils between the punch marks, the mean diameter $2r$ could be determined. The average dimensions for each spring, together with other information, are given in Table 1.

TABLE 1 DIMENSIONS OF SPRINGS TESTED

Spring no.	Cut from no.	Nominal O.D., in.	Measured avg. wire diam., in.	Measured avg. mean coil diam., in.	Approximate index
1 A	Bar 1	$2^1/_4$	0.6192	1.657	2.7
1 B	Bar 1	$3^1/_2$	0.6201	2.906	4.7
1 C	Bar 1	$6^1/_2$	0.6208	5.923	9.5
2 A	Bar 2	$2^1/_4$	0.6190	1.654	2.7
2 B	Bar 2	$3^1/_2$	0.6160	2.902	4.7
2 C	Bar 2	$6^1/_2$	0.6202	5.931	9.5
3 A	Bar 3	$2^1/_4$	0.6200	1.664	2.7
3 B	Bar 3	$3^1/_2$	0.6179	2.910	4.7
3 C	Bar 3	$6^1/_2$	0.6207	5.900	9.5

In working up the results the ordinary spring-deflection formula for helical round-wire springs (Equation [7]) was used. The modulus of rigidity G was determined from the tests on the springs of largest index from each bar using Equation [7] and the dimensions given in Table 1. The reason for taking the spring of largest index as a basis for determining the modulus of rigidity is that in this case the effects of curvature of the spring and of direct shear load will be the least; consequently we may expect the ordinary deflection formula (Equation [7]) to be most nearly correct. Values of G obtained in this manner from the slope of the mean load-deflection curves of Figs. 15, 18, and 21 on springs 1 C, 2 C, and 3 C are as given in Table 2. As mentioned before, it is necessary to use the average deflection between points a and a' and b and b' as a basis, to eliminate the effect of eccentricity of load.

TABLE 2 VALUES OF MODULUS OF RIGIDITY FOR BARS NOS. 1, 2, AND 3

Bar No.	1	2	3
G, lb. per sq. in.	11.45×10^6	11.46×10^6	11.50×10^6

This table indicates that the modulus of rigidity was practically the same for all three bars, which fact indicates a uniform material.

The test results on the springs of smaller index are given on the curves of Figs. 13, 14, 16, 17, 19, and 20. In these curves the ordinates represent deflections measured between the punch marks a, a' and b, b' while the abscissas represent load on the spring. The circles represent experimental points obtained on one side of the spring, and the crosses experimental points obtained on a diametrically opposite side of the spring. In most of the springs a small but definite eccentricity of the load is evident. Where possible, full lines were drawn through these points to represent deflection on opposite sides of the springs; in all cases a full line representing the average deflection between the two sides was drawn. The broken lines marked "Ordinary Formula" represent the load-deflection curve as calculated from the ordinary helical-spring deflection formula (Equation [7]). In this computation, a modulus G was used for each spring corresponding to the bar from which the spring was made (Table 2), while the dimensions given in Table 1 were also used. It may be seen that the theoretical curves as represented by the broken lines in all cases come very close to the mean experimental curve, in some cases actually coinciding with it. This indicates that the ordinary spring deflection formula gives results quite close to the truth.

Discussion of Results

For the present let us assume that the ordinary helical-spring formula is correct for determining the deflection due only to torsion of the wire section, and let us add to this deflection the deflection due to direct shear caused by the axial load. Assuming the shearing stress due to the direct axial load as uniformly distributed over the cross-section, we obtain the shearing deflection due only to the direct axial load:

$$\delta_s = \frac{\text{shearing stress} \times \text{length of wire}}{G}$$

$$\delta_s = \frac{P}{(\pi/4)d^2} \times \frac{2\pi nr}{G} = \frac{8\,Pnr}{Gd^2} \quad \ldots\ldots\ldots\ldots [8]$$

Actually the shearing stress is not uniform, and the value given by [8] must therefore be multiplied by a factor usually slightly greater than unity; however, this factor may be taken equal to unity for our present purpose.

Adding δ_s as given by [8] to δ as given by [7] we obtain an approximate solution which takes into account the additional deflection due to direct shear.

This may be written as the ordinary deflection formula [7] multiplied by a factor K_f, thus:

$$\delta_s = K_f \frac{64\,Pr^3n}{Gd^4} \quad \ldots\ldots\ldots\ldots\ldots [10]$$

where

$$K_f = 1 + \frac{0.5}{c^2} \quad \ldots\ldots\ldots\ldots\ldots [10a]$$

It may be seen that for most practical springs having indices greater than 3, K_f differs but little from unity. Thus for $c = 3$, $Kf = 1.055$, i.e., according to this formula the deflection is about $5^1/_2$ per cent greater than that figured by the ordinary formula.

Since the smallest springs tested had indices of about 2.7, the factor K_f from Equation [10a] would be about 1.07, i.e., the deflections as measured should have been about 7 per cent greater than those calculated by the ordinary formula on the basis of this equation. In the case of the largest springs 1 C, 2 C, and 3 C having indices of 9.5, the error as given by [10a] was only about $^1/_2$ per cent, and hence it seems justifiable to use the values obtained from these springs for use in determining G.

J. K. Wood, in his discussion of the author's previous paper,[6] has also derived an expression for K_f, namely,

$$K_f = \frac{2c^2 + c - 1}{2c^2} \quad \ldots\ldots\ldots\ldots\ldots [11]$$

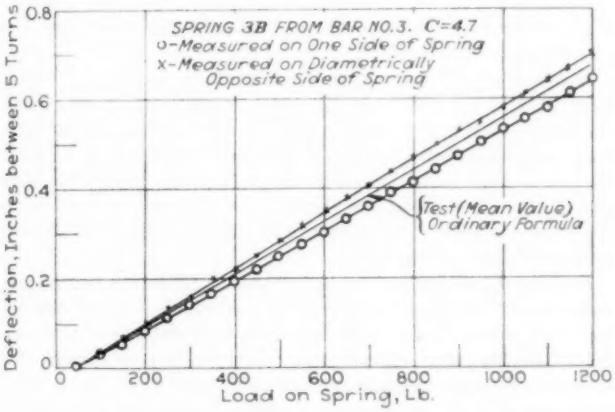

FIG. 20 DEFLECTION TEST OF SPRING 3 B

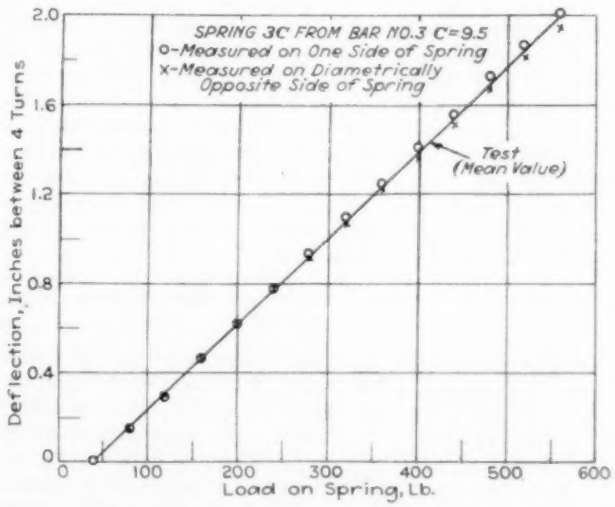

FIG. 21 DEFLECTION TEST OF SPRING 3 C

For an index of 9.5, this gives $K_f = 1.047$ and for an index of 2.7 it gives $K_f = 1.116$. Since the author assumed $K_f = 1$ in determining the modulus G for the largest springs having an index of 9.5, the deflection as measured on the smallest springs having indices 2.7 should on the basis of this formula be about $1.116/1.047 = 1.068$ times the value computed by the author's method. This gives a value of the discrepancy about the same as that estimated by the author using Equation [10a], i.e., about 7 per cent.

As may be seen by referring to the test curves (Figs. 13 to 21),

[6] Trans. A.S.M.E. (1929), APM-51-17, p. 197.

in no case was the test deflection greater than that computed from the ordinary formula, and much less was it 7 per cent greater. In some cases the mean test and the theoretical curve determined from the ordinary formula coincide; in others the mean test deflection is actually slightly less than that computed by the ordinary formula, the difference in no case being more than about 3 per cent. A cumulative error of 1 per cent in measuring the wire diameter, combined with one of 1 per cent in measuring the coil diameter, might account for a 7 per cent difference between test and theory, but it is difficult to see how such a large error could be made in the measurements using a micrometer reading to thousandths of an inch. Furthermore, it is difficult to see how such an error could be made on the three springs of small index simultaneously. The testing machine was calibrated by means of dead weights after the test and was found to be within 1 per cent in accuracy at all loads over one quarter the scale deflection.

It is not certain that the material of the spring made from a given bar of material and having a small index would have the same modulus of rigidity as that of the spring having a large index and made from the same bar. However, in view of the uniformity of the modulus obtained from the three bars (see Table 2), it seems very probable that springs made from the same bar should have practically the same modulus, as was assumed in the calculations.

Another possibility is the error arising from measuring the deflections. For the small springs, the accuracy of the cathetometer was within about 0.001 in. for a total deflection of about 0.2 in., or less than 0.5 per cent. For the largest springs the error in steel-scale measurement was around 0.01 in. for a total deflection of 2 in., or an error of about $^1/_2$ per cent. None of these errors appear to be large enough to make a 7 per cent difference in results. For the present, it may be said that the tests checked the ordinary deflection formula within 3 per cent in all cases, while they did not show an additional deflection as predicted from the above formulas (Equations [10] and [11]), but if anything, a slightly less deflection. It is therefore the author's opinion that the ordinary deflection formula will give results sufficiently accurate for most practical purposes in calculating the deflections in the body of the spring, provided the actual dimensions of the spring and the modulus of rigidity of the material are both accurately known. The effect of the end coils is, however, not considered here.

Deflection of Helical Springs of Rectangular Wire, Axially Loaded

Various formulas are given in handbooks for the calculation of the deflection of helical springs of rectangular wire, axially loaded. None of these formulas give results which agree closely with those obtained by St. Venant, while some of them are in error by as much as 30 per cent for certain ratios of b/t (Fig. 4). For these reasons the author recommends the following approximate formula[7] which will give results agreeing within 4 per cent with St. Venant's for all cases from the ratio $b/t = 1$ to $b/c = \infty$. The formula is accurate within about 1 per cent in the practical range from $b/t = 1$ to $b/t = 3$. The formula is

$$\delta = \frac{19.6\ Pr^3n}{Gt^3(b - 0.56t)} \qquad [12]$$

where P = axial load on spring, lb.
r = mean coil radius, in.
G = modulus of rigidity, lb. per sq. in.
t = thickness of rectangular section (Fig. 4)
b = width of rectangular section (Fig. 4)
n = number of coils.

[7] This formula only applies where the longer side of the rectangle is parallel to the spring axis as in Fig. 4. Where $b < t$, an approximation will be had by interchanging b and t in Equation [12].

Conclusions

The strain measurements which have been described indicate that the stress in square- or rectangular-wire springs may be calculated with sufficient accuracy by the method proposed in this paper. In this connection, the author believes that the formulas for rectangular wire commonly given in handbooks should be replaced by more exact formulas, both for stress and deflection, such as those given in this paper.

The deflection tests on helical springs of round wire, having different indices but made from the same bar of material, indicate that the ordinary helical-spring deflection formula is very close to the truth.

Acknowledgments

For assisting in the work covered by this paper, acknowledgment should be made to C. E. Crang and K. R. Waugh of the Research Laboratories for carrying out the deflection tests on the round-wire springs, to C. McGregor for making most of the measurements of the spring dimensions, to T. C. Rathbone of the Turbine Engineering Department for suggesting the research on square-wire springs, and to Drs. A. Nadai and S. Timoshenko for various suggestions. Credit is also due the Union Spring & Manufacturing Company for furnishing the springs used in the deflection tests.

Discussion

W. M. Austin.[8] The first part of the author's present paper is a companion to his previous paper describing experiments with springs of round wire, and we should expect similar conclusions. His experiments that show a slightly less deflection than that given by the formulas agree with an analytical investigation made by the writer on round-wire springs which showed a correction factor of 0.974 for a spring with an index 3 and of 0.994 for an index of 6.

The writer's analysis of the deflection eliminates the direct shear entirely from the problem, by considering the moment of the load about the torsional axis as resisted by equal moment (not a couple), due to the stresses in the wire, in the opposite direction.

The usual formula for deflection for round-wire springs assumes that the wire is twisted about the center of the section and stressed uniformly in every direction from this center. It also assumes that the lever arms of the load is the mean radius of the spring. Neither of these assumptions is true. The center about which the wire is twisted is distant from the axis of the spring approximately $r + {}^1/_4a^2/r$ where r is the mean radius of the helix and a the radius of the wire. This has the effect of increasing the effective diameter of the spring by $^1/_2a^2/r$. This would tend to make the deflection larger than that given by the formula. It is more than offset, however, by the increased torsional moment of resistance, for a given deflection, about the eccentric torsional axis of the wire.

One would expect, therefore, that with wires of prismatic or composite shape similar conditions would be found; although analytical proof is much more difficult.

In the writer's analytical determination of the deflection he found the correction factor for an index of 9.5 to be between 0.997 and 0.998, so if we neglect errors in observation the author's determination of G from the spring of largest diameter should be correct to $^1/_4$ per cent.

[8] Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

The writer believes that the modulus of rigidity G should be considered as a property of the material of the spring and independent of the relative spring dimensions. He also thinks that the proper way to ascertain G for helical springs is to take torque and angular-deflection measurements on relatively long straight cylindrical bars that have the same heat treatments that the springs are to receive.

The method of fastening the arms to the semi-coil shown in the paper and also in the author's previous paper on round-wire springs is easy and convenient. The writer remembers that in the previous paper it was stated that the stresses were not carried anywhere near the elastic limit for fear of the weld's yielding. Would not it have been possible for a good blacksmith to have forged the ends from the same piece of steel as the semi-coil? If this could have been done, extensometer readings nearly twice as great as those taken could have been secured and the degree of accuracy increased.

As pointed out by Edgerton in the paper mentioned by the author, relatively few helical springs of square or rectangular wire are made as compared to round wire. One reason is that springs of square or rectangular wire are not as economical in the use of material or space as are springs of round wire. The primary function of a spring is to store energy, and more energy can be stored in the annular cylinder occupied by a spring of round wire than by a square-wire spring of the same material occupying the same space when solid and subjected to the same maximum stress.

To show this, let us calculate two springs, one made from round wire of diameter d and mean radius r, and the other from square wire of short diameter d and mean radius r.

For round wire

$$P = \frac{\pi d^3 S}{16rK} \text{ and } F = \frac{64Pr^2}{Gd^4} = \frac{4\pi r^2 S}{GdK} \text{ and the energy stored per turn} = \frac{1}{2}PF = \frac{\pi^2 S^2 r d^3}{8GK^2} = 1.234\frac{S^2 r d^3}{GK^2} \text{ in inch-pounds.}$$

For square wire

$$P^1 = \frac{0.208\, d^3 S}{Kr} \text{ and } F^1 = \frac{44.5\, Pr^2}{Gd^4} = \frac{9.256\, r^2 S}{GdK} \text{ and the energy stored per turn equals } \frac{1}{2}PF = \frac{0.996\, rd^3 S}{GK^2} \text{ in inch-pounds. The ratio of energies} = \frac{1.234}{0.996} = 1.24.$$

The ratio of weights of material is $\frac{1.24}{0.7854} = 1.57$.

The above figures hold for springs having a square-sectioned wire in the finished spring. If the wire is square before winding the length occupied by one turn will be greater than for round wire. This will cause the space factor 1.24 to be increased a little for springs of large index and much more for springs of small index.

The space ratio of 1.24 and the material-weight ratio of 1.57 in favor of the round-wire spring hold only for springs that are free from stress when unloaded. If, as is often the case, the springs are surged to a lower free height after tempering, these ratios may be somewhat reduced.

If we compare the energies that can be stored by round- and square-wire springs according to the annular cylindrical spaces occupied by the springs in their free state, the ratio 1.24 in favor of the round-wire spring for the solid loaded condition will be found to be much reduced for the free condition and may even be changed to a ratio in favor of the square-wire spring if the springs have a very large index.

One argument in favor of the use of helical compression springs of square wire is that they are somewhat less liable to buckle than springs of round wire having the same outside and inside dimensions. Another is that they can be compressed solid and thereafter act as a column with much less danger of damaging the springs than if the springs were made of round wire. In order to fully realize this last advantage it is necessary in springs of small index to wind them from trapezoidal-shaped wire having dimensions such that the wire is square after the spring is wound.

Successful attempts have been made to make springs having some of the characteristics of both round- and square-wire springs. A notable case is the recoil springs in the 14-in. U. S. Naval gun carriage. These springs are wound from a cylindrical wire that is flattened on opposite sides, the elements of these flat sides becoming perpendicular to the axis of the finished spring (see Fig. 22). In accordance with St. Venant's theory, there

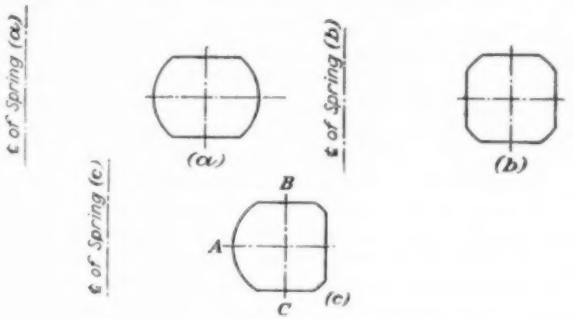

FIG. 22

is a stress maximum in the middle of the flat side. But if the proper amount of flattening is done the stress in the middle of the flat side can be made the same as the stress on the inside diameter of the spring. It is evident that economy in space occupied over round-wire springs is secured by this design.

The writer once had the idea of making a spring the wire of which was to be of circular section except to be flattened on four sides, or it might be described as a square wire with the corners cut off by circular arcs having the same center as the square—see Fig. 22 (*b*). He now believes that a spring made from a wire of circular section flattened on three sides and wound with the unflattened side on the inside of the spring is preferable. It appears that the greatest economy would be had if the wire were flattened more on the outside of the spring than on the sides at right angles to the outside. This follows from the fact that in the flat-sided straight wire the greatest stress is found in the middle of the widest flat side, and from the further condition that in the wound spring having the four sides flattened equally the greatest stress is in the middle of the inside flat. There is a somewhat lower stress in the middle of the radial flat side and a lower stress yet in the middle of the outside flat. Thus by proper proportioning the stresses at *A*, *B*, and *C*, Fig. 22 (*c*), can be made the same.

A little greater economy might still be had if the curvature on the inside of the springs were made elliptical with the focus of the ellipse in the axis of torsion and the directrix of the ellipse were the axis of the spring.

One serious objection to the use of these composite sections is that we have no accurate method of calculating the stress. Unquestionably there is tensile stress at the corners and a maximum shear at or near the middle of the flat sides, which causes a plane section when the spring is free to be curved when the spring is loaded. It is very probable that even in springs of round wire a plane section when the spring is free is not a plane when the spring is loaded, and that the distortion of the plane is greater

the smaller the index of the spring. The distortion of the plane section in the case of circular-wire springs is very small compared to that in the case of flat-sided wires, and, the writer believes, has only a very small influence on the stress.

W. G. Brombacher.[9] Although the formulas of Röver were published in 1913, until the author's work their significance has been but little appreciated by the practical spring designer. The author has made a distinct contribution in calling attention to the fact that the ordinarily accepted and used formulas for the maximum stresses in helical springs are in many cases seriously in error. He has brought this out vividly in his two papers, in which each case has been carefully considered both experimentally and theoretically.

In the past the error in using the commonly given formulas for the maximum fiber stress of helical springs has been compensated by the experience of the spring maker. The breaking load of the springs of various sizes was determined by tests. These test data were used to determine the maximum stress in terms of the common formula, which finally gave rise to tables of permissible stresses for springs of typical design. The author's results now permit a better coordination of the data available on the strength of spring materials, and the performance which may be expected of springs of such materials.

The paper shows that the formulas commonly given for the deflection of a helical spring in tension or compression are independent of the spring index in all cases with but small error. It should be pointed out that the experimental verification was carried out on springs of only one diameter of wire, and further, that the modulus of rigidity was determined by means of data obtained on the helical springs. It is common experience that the value of the modulus of rigidity must be modified when used in designing helical springs by an amount which depends on the diameter of the spring wire and perhaps on the spring index, although the author's data apparently indicate that the value does not depend on this index. It would appear worth while to extend the experimental data to include some on springs of two or three additional wire diameters in order to eliminate definitely all doubts as to the value of the modulus. The discrepancy in the modulus of rigidity of the material and of that used in the deflection formula of helical springs is real and its theoretical explanation is still lacking. This further experimental work may lead well to a deflection formula which is on a logical basis.

The policy of the Westinghouse Electric and Manufacturing Company in releasing the author's paper should be commended. It is to be hoped that other manufacturers who are carrying on research on springs and spring materials will follow their example.

T. McLean Jasper.[10] The question of evaluating spring formulas is a difficult one. The writer would like to see the tests on springs sufficiently extended so that the calculated stress at the elastic limit of the spring would be compared with tests on the elastic limit of the steel from which the spring is made. This involves a very careful set-up with reference to the heat treatment of the finished test bars to bring them to the same general elastic limit.

The writer is in complete agreement with the author that springs in general are not used to a sufficiently high stress, and that for this reason springs do not have the real cushioning effect which they could be designed to give.

There is no question but that the spring problem is closely associated with that of fatigue, and this question also should be considered in determining the maximum allowable stress values to use.

Most problems involving the use of springs can be solved so as to avoid overstressing the springs when unusual conditions are imposed upon the equipment.

The author's work is very much appreciated by the writer.

Jos. B. Reynolds.[11] In discussing the degree of accuracy to be expected from the method of this paper, it seems to the writer that in deducing Equation [13] of the author's previous paper [APM-51-17] from Equation [12], instead of putting $M = Pr$ as was there done, we should set $M = P(r - \gamma)$, giving

$$S''_{a'} = \frac{16P}{\pi d^3}(r - \gamma)\frac{4c - 1}{4c - 4}$$

Now by Equation [7] of the same paper, $\gamma = d^2/16r = r/4c^2$, since $c = 2r/d$ hence

$$S''_{a'} = \frac{16Pr}{\pi d^3}(1 - 1/4c^2)\frac{4c - 1}{4c - 4}$$

If c is as low as 3, this is seen to make a difference of about 3 per cent.

Again, since the moment M is about a horizontal line tangent to the cylinder of the helix, its component about the tangent to the helix is $M \cos \alpha$, where α is the angle of the helical spring. For a closely wound spring $\tan \alpha = d/2\pi r = 1/\pi c$; hence $\cos \alpha = (1 - 1/\pi^2 c^2)^{1/2} = 1 - 1/2\pi^2 c^2$; neglecting powers of $1/c$ higher than the squares. This would give

$$S''_{a'} = \frac{16Pr}{\pi d^3}(1 - 1/4c^2 - 1/2\pi^2 c^2)\frac{4c - 1}{4c - 4}$$

This second correction does not amount to 1 per cent for $c = 3$, but its value increases as the spring deflects.

If this reasoning is correct, it would seem that a theoretical formula containing the coefficient 0.615 gives an appearance of accuracy that the theory does not substantiate.

The composite sections proposed by Mr. Austin are interesting, but, as he mentions, it is difficult to evaluate the worth of these sections because the lack of accurate methods for calculating the stresses set up in such complicated shapes.

Author's Closure

Mr. Austin remarks that the value of G as found from the tests on the springs of largest index should be correct to within about $1/4$ per cent. This coincides with the author's opinion also that the values of G found experimentally are quite near the truth. Tensile tests on this spring material in the heat-treated condition showed values of modulus of elasticity in tension E varying from 39.6×10^6 to 31.1×10^6 lb. per sq. in. the average being $E = 29.9 \times 10^6$ lb. per sq. in. Taking Poisson's ratio equal to 0.3 (the commonly accepted value for steel), this would be equivalent to a modulus of rigidity $G = 29.9 \times 10^6/(2 \times 1.3) = 11.5 \times 10^6$ lb. per sq. in., using the fundamental formula of elasticity connecting E and G. It will be noted that this value is very close to the values found from the tests on the springs of largest index and given in Table 2 of the paper. Frequently, however, spring manufacturers recommend values of the modulus G as low as 10×10^6 lb. per sq. in. for use in design. It is the author's opinion that this low modulus is possibly used to compensate for the fact the wire of the spring may be slightly undersize, or perhaps to compensate for inaccuracy in estimating the effect of the end turns. A modulus of rigidity of 10×10^6 lb. per sq. in. would (taking Poisson's ratio = 0.3) correspond to a modulus of elasticity in tension of

[9] Bureau of Standards, Washington, D. C.

[10] Director of Research, A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

[11] Lehigh University, Bethlehem, Pa.

only 26×10^6 lb. per sq. in., which seems to be an abnormally low value for spring steel. However, the author agrees with Mr. Brombacher that further tests on springs of several different wire sizes would be very desirable. No doubt the most nearly correct way to ascertain G would be to take torque and angular-deflection measurements on a heat-treated straight cylindrical bar, as Mr. Austin suggests, but the author does not believe that a great difference would be found between this method and that of measuring the deflections inside the coils of a spring of large index, as described in the paper.

The author also believes that additional tests as suggested by Mr. Jasper would be desirable. Fatigue tests on actual springs loaded as in service would also be of value. By comparing the results of such fatigue tests with those obtained in ordinary torsion fatigue tests, the effect of surface imperfections in the springs would be clearly brought out.

Regarding Professor Reynolds' discussion, the author cannot agree that more accuracy would be gained by putting $M = P(r - \gamma)$ instead of Pr. It is well known that a force acting at a distance from the center of the wire may be replaced by a couple M equal to the load P times the distance of the resultant shearing force from the axis, plus an additional shearing force P. Professor Reynolds' suggestion is equivalent to placing this shearing force P at a distance γ from the center of the wire section. Since the shearing force is placed eccentrically with respect to the wire section, it will *itself* produce an *additional* twisting moment acting on the section. This additional twisting moment would be equal to $P\gamma$ and when added to the couple $P(r - \gamma)$ would give a couple Pr, as the author used in his derivation. However, the author agrees with Professor Reynolds that the method of derivation given in his previous paper [APM-51-17] is, as mentioned therein, not exact. Nevertheless he believes that the formula thus derived is sufficiently accurate for most practical purposes. It should also be noted that this formula agrees within less than 1 per cent with a more exact value derived by Röver, using the equations of the theory of elasticity for the case of a spring with an index of 4. For this reason, it is the author's opinion that this formula, although derived by approximate methods, is quite close to the truth, particularly since it agrees well with test results.

The forging of a semi-coil from spring steel and heat-treating it to simulate the condition in an actual spring, as suggested by Mr. Austin, appear to be very difficult, although if this could be done more accuracy would be obtained. From a practical standpoint, however, the author believes that the method described in his papers gives sufficiently good results.

The author takes this opportunity to express his indebtedness to those who have contributed to the discussion.

Progress in Fuel Utilization in 1929

Contributed by the Fuels Division

Executive Committee: Victor J. Azbe, *Chairman*, A. D. Blake, *Secretary*, John Van Brunt, C. P. Tolman, S. B. Ely, and W. J. Wohlenberg

ALTHOUGH during the past year there have been no revolutionary developments in the field of fuel utilization, there has been a slow but consistent progression in the direction of greater efficiency and lower operating, maintenance, and capital charges. Of particular importance is the gradual adoption of the more advanced methods by those industries which have until recently shown only a slight amount of interest in fuel economy.

However gratifying may be the progress which has been made, there is still ample room for improvement, particularly in the more general application of existing knowledge and methods. It has been demonstrated, for example, that steam may be produced consistently at efficiencies of 90 per cent and above, but the average efficiency of all steam-generating stations is far below this figure. It is believed that the greatest strides in the future will be made not so much in the improvement of the present best methods, but in the adoption of these methods by a larger portion of the fuel-using industries.

It is obviously impossible in a report of this length to refer to all the detailed improvements which have been made. It is the intention merely to summarize the more important advances which have occurred during the past year.

Solid Fuels

Production of bituminous coal during the year 1928 and the first nine months of 1929 was only slightly below the average for the five-year period 1924–1928. It is highly probable that the output for the year 1929 will be above that for 1928, owing to the general increase in industrial consumption and notwithstanding

TABLE 1 PRODUCTION OF BITUMINOUS COAL, 1918–1929

		Annual Production 1918 to 1928		
		Average no.	Average tons per man	
Year	Net tons	days worked	Per day	Per year
1918	579,386,000	249	3.78	942
1919	465,860,000	195	3.84	749
1920	568,667,000	220	4.00	881
1921	415,922,000	149	4.20	627
1922	422,268,000	142	4.28	609
1923	564,565,000	179	4.47	801
1924	483,686,538	171	4.56	781
1925	520,052,741	195	4.52	884
1926	573,366,985	215	4.50	966
1927	517,763,352	191	4.55	872
1928	500,744,790	203	4.73	...

First 224 Days of Each Year

Year	Net tons
1925	351,405,000
1926	388,336,000
1927	379,015,000
1928	340,118,000
1929	368,797,000

economies in use. In spite of the increased output, the amount of coal held in storage has shown a practically uniform decrease. On July 1 the commercial stocks of bituminous coal in the hands of commercial consumers amounted to about 33,100,000 net tons, the lowest amount reported since 1922.

Table 1 gives the annual production, 1918 to 1928, inclusive, and for the first 224 days, 1922 to 1929, inclusive.

Owing largely to low price levels (averaging the lowest in thirteen years) the past year has witnessed increased and effective efforts to reduce production costs and bring about a greater percentage of recovery. These efforts have been largely centered in the more extended use of mechanical loaders and conveyers of various types, the adoption of improved mining methods and systems, and more careful supervision. Improvements have been made in ventilation and timbering, and there has been a continued increase in the attention given to safety measures.

Particular care has been given to the cleaning and sizing of bituminous coal. Many new installations of mechanical cleaning equipment have been completed during the year, and more have been contracted for. There has been a progressive and important movement toward standardization of the "prepared sizes," with a reduction in their number. Standard sizes have been adopted during the year by two important producing and marketing organizations.

Production of anthracite during the year 1928 showed a slight decrease as compared with that in 1927, and the 1929 production has about kept pace with the 1928 output. In 1929 the output up to September 21 amounted to 52,193,000 net tons as compared with 52,388,000 tons in the corresponding period of 1928.

The anthracite operators and producing companies are continuing to give more concentrated and effective attention to improvements in mining methods and equipment. Preparation, cleaning, and sizing are being given greater attention than ever before, and have resulted in a marked improvement in the quality of coal as shipped.

Owing principally to conditions in the iron and steel trade, the past year has been one of unprecedented activity in the coke-making industry. The total coke produced during the period Jan. 1–Aug. 1, 1929, with that produced in the corresponding period of 1928, is as follows:

	1928	1929
By-product coke, net tons	31,577,542	35,950,237
Beehive coke, net tons	2,829,500	4,282,300
Total, net tons	34,407,042	40,232,537

On January 1, 1929, there were 12,544 by-product and 41,288 beehive ovens in existence; 8300 of the latter type were dismantled during the year. The 86 by-products plants in operation in August were producing about 93 per cent of their capacity.

Liquid Fuels

In spite of efforts to curtail production of petroleum, the first seven months of 1929 showed an increase in production of 12.8 per cent as compared with the corresponding period for 1928. For example, the total domestic production for July-August, 1929, was 576,581,331 bbl. as compared with 511,323,929 bbl. for the same months in 1928.

For several years past and continuing during 1929, improvements have been made in petroleum production methods resulting in appreciably greater recoveries. Repressuring, gas lifts, extraction of gasoline from casinghead gas, and gastight storage tanks are being more generally adopted. Particular attention has been paid to the problem of crooked holes. Improved methods of fractionating casinghead gasoline have placed on the market liquid propane and butane, which products are being adopted for the enrichment of water gas and also as fuel in industrial furnaces.

Refining methods have been improved to give better products, greater yields, and lower costs. The old type of inefficient batch shell stills are rapidly being replaced with continuous tube stills

equipped with heat exchangers, air preheaters, and furnaces designed for high efficiencies and for high rates of radiant-heat transfer. Continuously operating units producing only distillates and coke have come in largely as a result of the fuel-oil market. The use of stills operating at high vacua for handling lubricating stocks has been quite widely extended. Refinery boiler plants have been the subject of increased attention which has resulted in marked economies. The rotary clay burners used for many years are being replaced with shelf-type burners which use less fuel and give a better product. The volatility and anti-knock value of gasolines have generally increased. The end point of motor fuels marketed has shown a constant tendency to be lowered. This period has also been characterized by the development of several commercial processes for producing motor fuels of high anti-knock value and a more widespread use of such fuels by motorists. There seems also to have resulted an increased yield of gasoline as a percentage of the crude.

Perhaps the most interesting development in petroleum refining during the past year is the construction of a 5000-bbl-per-day hydrogenation plant which is now under way and the projected building of two others of equal size. The hydrogenation of coal has been carried out in Germany for several years, and in 1928 300,000 bbl. of gasoline were produced by this process. The plant being constructed in this country, while similar in principle to the German plant, will be used for the hydrogenation of fuel oils and heavy refinery residues to produce high-quality distillates. This process will be watched with a great deal of interest.

Natural Gas

There has been an enormous increase in the utilization of natural gas during the past year which has been brought about by the construction of long mains from the gas fields to various industrial centers. Certain of these lines are from 400 to 600 miles long, and a contemplated line from the Louisiana fields to Chicago will be even longer. The line construction has in almost all cases been steel pipe, using welded joints in the smaller sizes and Dresser couplings in the larger sizes. There has been some difficulty in changing over from manufactured to natural gas due to the fact that natural gas is essentially dry and therefore has a deleterious effect on the joints and meters of the typical system handling artificial gas. The difficulties have been overcome in several instances by supersaturating the gas with gas oil prior to its distribution through the city mains. The conservation of natural-gas resources has been the subject of much interest. Legal means have been taken to require the economic use of gas for repressuring oil fields. The biggest step in this direction has taken place in California during the past year, and is a distinct advance in the economic development of both gas and oil, with a minimum wastage of both.

Manufactured Gas

During the past year there has again been a decided increase in coke-oven-gas production and a decrease in water-gas production. Data given by 96 typical gas companies indicate that for the first five months of this year there was a 6 per cent decrease in water gas produced, a 12 per cent decrease in coal gas produced, a 39 per cent increase in coke-oven gas produced, and a 22 per cent increase in coke-oven gas purchased from coke and steel companies as compared with the corresponding five months of 1928. The total gas sold during these five months was 9.4 per cent higher in 1929 than in 1928, due largely to the increased use of gas for house-heating and industrial purposes.

There have been no outstanding new developments in the manufacturing field. The matter of dry quenching of coke and the dehydration of gas mentioned in last year's report are still very much in the limelight and are both apparently being received with increased favor. The Fort Wayne dehydration plant has now been in operation sufficiently long so that data are available, and the possibility of thereby producing non-corrosive, clean gas has awakened increased interest. A new dry-quenching plant is soon to be placed in operation at Flint, Michigan, which will be the second installation in this country. The original installation at Rochester has been in service three full years, and the results there have been very favorable. Considerable progress has been made this past year in the method of disposing of phenol from the coke-plant ammonia-still waste, and it is now possible to eliminate this source of stream pollution which has in the past been a very troublesome problem.

There has been a continual increase in the number of waterless holders for the storage of gas at relatively low pressures. The largest holder in the world, having a capacity of 20,000,000 cu. ft., which was recently placed in service in Chicago, is of the waterless type. Experience throughout the country in the use of these holders has been generally satisfactory. The use of high-pressure holders has met with increased popularity during the past year. Strategic location of these holders at points along the transmission line and at local distributing points has resulted in improved load factors on the transmission equipment.

Low Temperature Carbonization

In recent months a 600-ton-per-day K.S.G. low-temperature-carbonization plant has been placed in operation near New Brunswick, New Jersey, by the International Coal Carbonization Co. The semi-coke produced is being marketed locally as a domestic fuel, and the coal gas, mixed with blue gas, is sold to the Public Service Gas and Electric Corporation of New Jersey. Since this plant is the first of its type erected in this country and is moreover the largest of any type in the United States, much interest is being displayed in the results obtained. A similar plant of 50 tons per day capacity is under construction at Coatesville, Pennsylvania.

A "Lurgi" process plant having a capacity of 100 tons of briquets per day has been in operation at Lehigh, North Dakota, since December, 1928. It is adapted to North Dakota lignite and produces a carbonized-coal residue which is briquetted with pitch obtained from the process. So far it has given the results promised by the Lurgi Corporation.

Several experimental plants of other processes have been in operation during the year and have been more or less successful. It is reported that test work on the Carbocite plant at Philo, Ohio, has been completed, and that a commercial plant is to be designed. Plans are also under way for the erection of a Hayes process plant with a capacity of 400 tons per day.

Boilers

The outstanding point of interest in boiler development has been the radical increase in size as illustrated by the new units, each having a capacity of 800,000 lb. of steam per hour, which are to be placed in service at Hell Gate Station. These will supply steam for a 160,000-kw. turbo-generator, which is the largest single-shaft, single-unit generating machine in the world.

There has been an increase in the number of installations generating steam at pressures of 1200 to 1400 lb. per sq. in. Until recently high pressures have been used only for base-load conditions, but at least two high-pressure installations are now being erected which will operate at variable loads. In Europe pressures have gone much higher than 1400 lb. The Benson boiler, which generates steam at a pressure of 3200 lb. per sq. in., has been thoroughly tested experimentally, and large-size plants are being erected in England and Belgium.

The possibilities of using higher steam temperatures are attracting much attention. Practice in this country has not yet gone above 750 deg. fahr., but there are several experimental and

semi-commercial plants in Europe which are operating at maximum temperatures of 900 to 950 deg. fahr. A plant in Belgium is operating commercially with a steam temperature of 800–825 deg. fahr. The Detroit Edison Company will shortly have in operation a 10,000-kw. turbine designed for an initial steam temperature of 1000 deg. fahr. The success of this experiment will be watched with interest.

There are said to be a number of boiler plants in Europe operating on the Löffler principle. A plant of this type at the Vienna Locomotive Works which generates steam at 1700 lb. per sq. in. and at 900 deg. fahr., has been in operation for about a year and has given satisfactory service. Improvements have been made in the Atmos boiler (described in MECHANICAL ENGINEERING, vol. 45, p. 253, April, 1923), and a unit having a capacity of 26,000 lb. of steam per hour at 1400 lb. per sq. in. and 840 deg. fahr. is being erected.

Some experimental work on the development of drumless boilers has been carried out in this country, and it is possible that high-pressure boilers in future years will be of this type.

An interesting European development is the use of steam accumulators for handling peak loads in central power stations. An order has been placed for the installation of 16 accumulators at the Charlottenburg Station of the greater Berlin system. Each accumulator will be 14 ft. 9 in. in diameter and 69 ft. high, with a capacity of 11,000 cu. ft. The combined steam-storage capacity will be sufficient to generate 67,000 kw-hr.

Boiler Furnaces

The outstanding feature of the great majority of recent boiler installations is the almost universal use of furnace-wall cooling by means of air or water, with the trend apparently in favor of the latter. The reduction of refractory maintenance costs has been so marked that even the very expensive types of furnace-wall construction have proved to be good investments. At the same time the increased steaming capacity given by the extended radiant surface has reduced the fixed charges per unit of steam generated. In some cases, in which the furnace is entirely enclosed with water walls, as much as 40 to 65 per cent of the total heat in the steam is being absorbed by the water walls. Whether bare tubes or refractory-faced tubes are preferable is still a controversial question. Both types seem to be giving good service. In some cases both are used in the same furnace. In the latest pulverized-coal furnaces with bare tubes, blocks are being used for local protection against the effect of dripping slag. Facings of materials such as carborundum continue to attract attention because of their apparent ability to stand up under intense firing conditions.

The earlier expressed fears of incomplete combustion due to cooling of the reacting products have not been realized. The selection of the proper amount of water cooling to use in any particular installation has proved to be a question of economics rather than of combustion. Many stoker-fired furnaces are being equipped with local water-cooled-block-covered surfaces along the rear and side walls of the stoker. In the arched furnaces with chain-grate stokers the water-cooled surfaces covered with high-quality refractory blocks have made a good showing when applied to arches and side walls. The troubles with the arch support have been largely eliminated.

During the development stage the water-cooled furnaces had to be fitted to standard boiler designs. With such combination many downcomers were necessary to supply water to the water-cooled furnace walls and many risers to carry away the steam. Strong efforts are now being exerted to so modify and simplify the furnace and boiler design as to greatly reduce the number of risers and downcomers.

Although the development of the slagging-ash type of furnace is a comparatively recent one, its adoption has been rapid, particularly during the past year. Fourteen furnaces so equipped are in operation, and twenty more are under construction. The furnaces for the high-capacity boilers under erection at Hell Gate Station are of this type. They have proved particularly applicable to the handling of low-grade fuels.

Another development which may prove applicable to the use of low-grade fuels is the mechanical gas producer applied to boiler furnaces. Experiments being carried out in this country have given gratifying results. It is reported that several commercial installations have been ordered in England.

Stokers

The time elapsed since the writing of the last report has been marked by a keener competition between stokers and pulverized-coal firing, the stokers regaining some of the lost ground. The development of stokers has taken place along two different lines, in each case being a result of commercial demands. Stokers for large units have advanced principally in size, while the smaller units have been made more convenient. To meet the new demands, stokers have been increasing in size rapidly. Underfeed stokers have been installed for units of 500,000 lb. per hr. steaming capacity, and the manufacturers are ready to meet any demand up to 1,000,000 lb. per hr. The chain-grate stokers have lagged somewhat behind the underfeed, principally because of the type of fuel which they handle. Coincident with increases in size there have been increases in the working combustion rates of all classes of stokers. At the present time the practical limit of combustion rates is often determined not by the stokers but by the slagging of boiler tubes.

The use of air preheaters as a final heat-absorbing medium is widespread, and consequently stokers have had to be adapted for use of preheated air. This has been done by using improved materials, allowing for structural expansion, and increasing the size of the air openings in the various types of grates. The maximum air temperature allowable for use with stokers depends to some extent upon the fuel used. Some coals have a tendency to fuse at comparatively low temperatures, obstructing the passage of air through the grates. In some cases an air temperature of 300 deg. fahr. has been found to be the maximum allowable on this score. In general, it has been found that stokers may be operated with an air temperature of 350 deg. fahr. with only a slight increase in maintenance. Certain improvements in the materials used for tuyères and grates permit running with 500 deg. fahr. air in some isolated cases. However, the average allowable air-temperature range is already sufficient for a proper proportioning of the heat-absorbing surfaces in a complete steam generator.

The flexibility of stokers as to the range of statisfactory combustion rates and types of fuel burned has shown a marked improvement. The timing device of one stoker allows a hundredfold variation between the minimum and maximum rate of feed. The introduction of steam-turbine and hydraulic drives for stokers facilitates close regulation.

Concerning the types of coal burned by stokers, the progress made so far is closely connected with the furnace-wall construction and the temperature control effected by preheating the air on the one hand, and by water-cooled walls on the other. The overfire injection of air seems to be a success, especially with high-volatile coals. Small stokers developed for industrial boilers by many firms reached a high degree of efficiency and reliability of operation. Good practical results were obtained with an arch-less chain-grate stoker in which an early ignition of coal is secured from the grate bars upward. Many improvements in the mechanism and motion of the stokers have been effected, with the result that wear and tear is reduced.

The combustion efficiencies attained on stokers with improved draft distribution are excellent. With the deep ashpits the unburned carbon is reduced to a negligible amount—not higher than in the same size of pulverized-coal furnace.

Pulverized Fuel

Although recent improvements in stoker design have made possible the installation of large units, pulverized coal has proved more popular in most of the larger boiler furnaces. The new Hell Gate boilers, for example, which are the largest in the world, are to be fired with powdered fuel. This is due principally to the ease with which the pulverized-coal systems may be expanded, simply by multiplying the mechanical apparatus. An increase in size of stokers, on the other hand, generally means an entirely new design.

The storage and the direct-firing systems are now used both in central stations and industrial plants. The direct firing appeals strongly by its simplicity, especially for industrial plants where the steam-generating units are comparatively small, or where stoker-fired boilers are changed to pulverized coal. A number of central stations have also adopted the direct-firing system, and those plants that have been in operation for any length of time are obtaining satisfactory results. There are, however, few definite data available for comparisons of the economic performance of the plants using the direct-fired system with those using the storage system. There are still many engineers who prefer the storage system, at least for large installations, and they are able to present good arguments for their preference. In order to better compete with the direct-firing, the storage system is undergoing simplification. The driers are in most cases eliminated, and what drying is needed is done in the mill during the process of pulverization.

Although a great deal has been said and written about the possibilities of high rates of combustion of pulverized coal, the most practical rates are still between 1 and 2 lb. of coal per cu. ft. of total combustion space per hour, or, a rate of heat liberation of 12,000 to 25,000 B.t.u. per hr. There are a few exceptions where rates of heat liberation of 35,000 to 40,000 B.t.u. per cu. ft. of total furnace volume have been obtained, but such rates can be maintained only in water-cooled furnaces and with coals that have ash of a comparatively high fusion temperature. Generally the rates of heat liberation are kept lower on account of excessive erosion of furnace refractory and the slagging of boiler tubes.

In solid-refractory-wall furnaces and with coals of low ash-fusion temperature, rates of heat liberation of 10,000 to 12,000 B.t.u. are good practice; with coals having high-fusion temperature ash these rates are 14,000 to 17,000 B.t.u. In air-cooled-wall furnaces the rates are raised to 14,000 and 20,000 B.t.u. according to the fusion temperature of the ash. In water-cooled furnaces rates of 25,000 to 35,000 B.t.u. are practicable, provided that proper precaution has been taken to minimize the possibility of slagging the boiler tubes and stopping the gas passages through the boiler. Generally speaking, in smaller water-cooled furnaces the rates can be higher than in larger ones, because the ratio of water-cooled surface to combustion space is greater and the products of combustion are cooled to a greater extent by the time they enter among the boiler tubes, and there is less tendency for the ash to be deposited on the boiler tubes and stop the gas passages.

The above-mentioned rates of heat liberation are the average of the entire furnace volume. Near the burner where the combustion is very rapid the rate may exceed 100,000 B.t.u., while in the space near the boiler tubes it may be less than 1000 B.t.u.

There are three methods of firing in general use, namely, vertical firing, horizontal firing, and corner or tangential firing.

Vertical firing was the first to be developed, and many of the large plants burning pulverized coal are using this method. In most of the first installations only the primary air was supplied under pressure; the secondary air was drawn into the furnaces at low velocities through air ports in the front wall by the furnace draft. In more recent installations, and particularly where air heaters are used, the secondary air is supplied under a pressure of 1 to 2 in. of water, making it possible to admit the air into the furnace at high velocity. Part of the preheated air is also supplied under pressure through the burner bodies around the fuel nozzles. The air pressure and the resulting higher velocities produce intensive mixing and rapid combustion.

Horizontal firing is gaining in favor. Usually its installation is more simple and somewhat cheaper than that of vertical firing because no furnace arches are necessary. The burners are placed in the front wall, and generally all the secondary air as well as the primary air is supplied through the burner under a pressure of 2 or 3 in. of water. While passing through the burner the mixture of primary air and coal and the secondary air are given a somewhat rotary motion, which produces turbulent mixing in the furnace. These rotative burners are built in capacities of 2000 to 8000 lb. of coal per hr. Certain of these burners are adjustable so that the cross-section of the air passages can be decreased when the amount of coal to be burned is reduced, in order to make it possible to maintain fairly high velocities and good mixing.

In a few installations two sets of these burners are used, one in each of two opposing walls, so that the flames from the two sets meet in the middle of the furnace and produce intensive mixing. This is called "opposed horizontal firing," and it is especially well adapted to large units with deep furnaces in which it would be difficult to install enough burners in one wall and fully utilize the available combustion space.

In the tangential method of firing, streams of the mixture of coal and air are projected horizontally from the four corners of the furnace toward the center in such a way that the streams are tangent to a small circle in the center of the furnace. Preheated secondary air is supplied under a pressure of 2 to 4 in. of water around the burner nozzles in the same direction. The streams of coal and air impinge against one another and produce intensive mixing and rapid combustion. The furnace gases move in a helical path toward the gas exit from the furnace. This helical flow maintains the turbulence and rapid combustion. Rates of heat liberation as high as 40,000 B.t.u. may be obtained, with satisfactory results as to efficiency and continuity of operation. Inasmuch as the flames are confined by the furnace walls in their helical path, there is considerable impingement of the flames against the walls. Therefore tangential firing can be applied only to completely water-cooled furnaces. Refractory furnace walls would be rapidly wasted away.

A number of installations with tangential firing have been put in service during the last two years and show the highest rates of heat liberation of any of the powdered-coal plants so far installed.

Most of the pulverized-coal installations are designed for the removal of refuse deposited at the bottom of the furnace in granular form. In such installations the deposited ash is prevented from fusing by a water screen placed over the bottom of the furnace or by a water-cooled furnace bottom.

As mentioned elsewhere, a number of installations have been made within the last two years in which the ash deposited at the bottom of the furnace is fused and removed in the liquid state. A spray of water is generally used to chill and disintegrate the molten ash into granular form. The disintegrated slag is pumped away in suspension.

Inasmuch as no refractory will stand the erosive action of molten slag, it is essential for low maintenance that the walls of the furnace be completely water cooled. On the first installations

of slagging furnaces it was thought necessary to protect the furnace bottom with a layer of dolomite sand. Experience with more recent installations indicates that this is not necessary, provided that the tapping hole is not less than about 10 in. above the brick lining of the furnace bottom.

The slagging furnace is especially well suited for burning coals with very fusible ash. If the ash is of high fusion temperature the burners should be located so as to cause the flame to impinge against the refuse collected at the bottom of the furnace, heating the refuse to as high a temperature as possible.

Roller mills and ball mills are more extensively used for pulverization than other types, because they pulverize coal to a high degree of fineness, have high capacity, low power consumption, and low maintenance. They are built in capacities up to about 40 tons per hour. In the past they have been used almost entirely in installations using the storage system, but within the last two years they have been applied to direct firing with considerable success. It appears that in the future they will be used extensively for direct firing of the larger-size steam-generating units. They are now built with a continuous system of lubrication, and can be kept in operation indefinitely.

High-speed impact mills are used largely for direct firing of small and medium-size units. They are particularly well adapted for installations where the space available for mills is small. Being of high speed, they have a high capacity for their size. They are also less sensitive to the flow of air with variable output. However, the fineness of the coal is less constant with variable output and the maintenance is somewhat higher than with the roller and ball types of mills.

The ball or tube type of mill is used for milling anthracite, coke, and other hard and abrasive fuels, and in cases where extreme fineness is necessary. While with such hard and abrasive fuels the mill maintenance with other types of mill would be prohibitive, it is comparatively low with the ball- or tube-type mill. The tube mill being a machine of a very low speed, its size is large for a given output. It is used for direct-firing as well as for storage systems.

The fineness to which a coal should be pulverized is a controversial question and varies with the character of the coal and the size of the furnace in which the pulverized fuel is to be burned. The higher the fixed carbon content, the higher the fineness to which the coal should be pulverized. Thus, according to one authority, coke and anthracite should be pulverized to a fineness of 80 or 85 per cent through 200-mesh screen; Pocahontas and New River to 70 to 75 per cent, Eastern bituminous coal to 65 or 70 per cent, Illinois to 50 to 55 per cent, and Texas and North Dakota lignite to 40 or 45 per cent through 200-mesh screen.

In cases where the furnaces are of necessity very small, as in marine and locomotive boilers, all coal should be pulverized very fine to obtain satisfactory combustion results. A fineness as high as 80 per cent through 300-mesh screen is believed necessary for Scotch marine boilers.

The principal developments in pulverized-fuel burning during the past year are not so much improvements of the methods in use in central stations, but rather the adoption of powdered-fuel firing to other equipment. Experiments have continued on the problem of the marine use of pulverized fuel, and in most cases have been highly successful. Several ships were equipped during the past year and have given gratifying results. One vessel, three of whose six boilers were fired with pulverized coal, completed a voyage of 11,000 miles during which five kinds of coal were used with entire success. The results were so satisfactory that the remaining three boilers are to be equipped for burning pulverized coal.

The application of powdered coal to locomotives has apparently been successful in Germany, and at least one locomotive in this country is so equipped. There has been a growing interest in the use of pulverized coal in industrial furnaces of various kinds.

Much has been published recently concerning the use of pulverized fuel in Diesel engines. Although the idea is by no means new, the mechanical problems have in the past resisted solution. However, several European investigations have recently brought out designs which are said to be satisfactory and may prove to be popular.

Fuel Oil

With the continued overproduction of petroleum the price of fuel oil has remained low, and this fuel has become increasingly popular for certain classes of service. Partly as a cause of and partly as a result of the growing popularity of oil, there have been major improvements in burner design, and there has been a decided tendency on the part of the fuel user to adopt the more modern equipment. The home-made burner of pipe fittings which required large quantities of steam and still gave unsatisfactory atomization, is being replaced by more efficient steam atomizing burners and by mechanical atomizing burners which can be adjusted to give the type of flame desired with a minimum of excess air.

Diesel Engines

The greatest advance in this field during the past year has been in connection with the use of high-speed Diesel engines. Increases in speed and decreases in weight per horsepower have made possible new and interesting applications. Experiments have been made with a Diesel-motored airplane, and a plane so equipped was actually flown for several hundred hours. Investigations of Diesel-powered trucks have continued and give promising results. In Germany they have been in use for several years, and more than 100 are in regular service.

A recent development in the field of large Diesel engines is their use in central power stations to handle peak loads. Several European systems are now installing them for this service, but it is probable that their high first cost will preclude their rapid adoption for peak loads in this country.

Locomotives

It has been reported recently that an oil-burning locomotive of the Kansas City Southern Railroad has been equipped with a unit system of pulverized-coal firing and has given excellent results. It is stated that the fuel consumption is 25 per cent less than with a similar hand-fired furnace, and that the steaming capacity is equal to that of an oil-fired boiler. The fuel cost is only 40 per cent of the cost of oil firing. The coal fed to the pulverizer is 1-in. slack, costing only about half as much as run-of-mine.

Other than this there have been no fundamental innovations in the design of locomotive furnaces or spectacular reductions in fuel consumption in this country during the year. Superheaters, brick arches, thermic siphons, and mechanical stokers continue to be applied as a matter of course, but there have been no radical changes in their designs.

There has been a continued and perhaps an increased interest in the proper preparation of coal for locomotives and in delivering it on the tender in good condition. This last purpose has entailed some novelties in the design of coal chutes. Within the past four or five years there has been a considerable revival of interest in the design of locomotive grates, and this has received additional attention during the past year.

There continues to be a determined effort to make use of poorer grades of fuel where it is easily accessible, as, for example, the utilization of lignite in Texas and in the Northwest. On certain railroads this effort has been recently intensified.

In Europe the developments have been more radical. In ad-

dition to the Schmidt and Löffler-principle locomotives mentioned in last year's report, there is now under construction a turbo-locomotive the steam for which will be furnished by a Benson boiler under a pressure of 3300 lb. per sq. in.

Industrial Furnaces and Power Plants

There has been a noteworthy improvement in industrial fuel economy during the past year, particularly in the steam-generating end. There has been a decided attempt in the building of new units to select a pressure such that a proper balance is obtained between heat and power requirements. Several industrial plants have selected the present upper limit of American practice as the boiler pressure best suiting their requirements. In fact, one industrial boiler plant now being erected is intended to operate at 1800 lb. per sq. in., which will be the highest steam pressure in use in this country. Plant executives are waking up to the importance of fuel economy and are making much-needed improvements.

Heat-treating furnaces of various kinds have shown improvements recently. There is a strong trend in favor of continuous furnaces with automatic control. Insulation is being applied to a greater extent, although there are many cases where the high temperature level of the operation precludes the possibility of insulation without undue deterioration of the refractories. There continues to be a greater use of the fuels which lend themselves to ease of handling.

Domestic Heating

The demand of the householder for liberation from the drudgery of furnace tending is determining the developments in the field of domestic heating. There has been a great increase in the number of oil burners installed, and gas-fired furnaces also have had a steady growth. There are some isolated installations of electric house heating in which off-peak power is used.

The competition from gas and oil has caused the development of the domestic stoker designed for burning small sizes of anthracite and bituminous coal. During the past year these stokers have been improved, and many new designs have appeared which have been more or less successful. The major drawback to the general adoption of domestic stokers, not considering the fact that they require more attention than oil- and gas-fired furnaces, is their inability to handle all classes of coals. It is sometimes difficult or impossible for the householder to obtain the type of fuel for which the stoker was developed, and there are often great difficulties in attempting to burn coal for which the stoker is not adapted.

Refractories

Although the manufacture of refractories is not altogether a problem of fuel utilization, still refractories are such an important part of most combustion equipment that a short summary of the developments in this field will not be out of place.

During the past year there has been a general adoption of manufacturing methods in refractories which, while not entirely new, would have been considered revolutionary several years ago. The tunnel kiln has been adopted for burning fireclay, silica, and chrome brick, and many labor-saving devices have been installed. Several new refractories have come into prominence recently, among which are unburned magnesite brick, mullite, sillimanite, and refractory shapes made from a mixture of chrome and diaspore. Diaspore refractories which have been subjected to an unusually high heat treatment are available commercially, and development work is being carried out on the manufacture of light-weight cyanite brick which combine heat-insulating properties with high refractoriness. Progress has been made in the design of special refractory shapes for blast-furnace stoves and open-hearth regenerators. The new shapes are said to result in large gas savings.

Considerable research on the failure of refractories in service is under way in various laboratories, and studies are also being made on various phases of manufacturing methods.

Research

Fuel-research activities have shown a notable increase during the past year, both abroad and in this country. The subjects on which work is being done seem to cover almost the entire field, but unfortunately in the United States there is very little coordination of effort. There is a certain amount of cooperation between various professional societies, but this country has no really sound fuel-research program.

In spite of the handicap, however, research is going on and valuable results are being obtained. An important activity started two years ago and which is continuing is the study of the coking and gas-making properties of American coals conducted by the American Gas Association in cooperation with the United States Bureau of Mines.

The research projects sponsored by the American Petroleum Institute are being carried on by a large group of investigators located in various educational institutions throughout the country.

The subject of pulverized coal is receiving more attention than ever before; particularly its combustion and use, and including also the economics of pulverized coke as a fuel.

The work of the coal-classification committee of the American Society for Testing Materials, which work involves both pure and commercial research, is being continued and good progress is being made.

The fuels-research work of The American Society of Mechanical Engineers is being reorganized. A general conference of leading engineers and chemists was held in October for the purpose of considering and recommending subjects, plans, and methods.

Research work of the National Coal Association is progressing principally in the direction of marketing, distribution, and use.

During the year the Anthracite Operators' Conference has started studies of domestic heating appliances and the factors influencing their performances.

The United States Bureau of Mines, in cooperation with The American Society of Mechanical Engineers, has done a great deal of work on refractories and on the slagging-ash type of furnace. The Bureau is also resuming its study of brick kilns in cooperation with the University of Ohio.

Some of the university laboratories have made important contributions during the year and are continuing their efforts.

In general, it may be said that there is more fuel research now in progress than at any previous time, and the outlook is encouraging in spite of the handicaps. It is interesting to speculate as to what might be accomplished by an amply financed organization devoted to the cause of fuel research. It is to be hoped that such a speculation will not be altogether an idle one.

Acknowledgments

Thanks are due Messrs. N. Artsay, A. M. Beebee, Henry Kreisinger, E. C. Schmidt, R. P. Soule, and F. R. Wadleigh, all of whom contributed sections of this report, and without whose assistance this compilation would have been exceedingly laborious.

Progress in Steam-Power Engineering

Contributed by the Power Division

Executive Committee: F. M. Gibson, *Chairman*, Alfred Iddles, *Secretary*, V. E. Alden, V. M. Frost, and W. F. Ryan

THE developments in 1929 have followed the trend of 1928, and a continuance through 1930 is probable. The year has witnessed larger mergers of invested capital, larger interconnections of central stations, larger industrial heating loads as well as larger power loads diverted to central stations, larger stations, larger equipment units, and larger demands for electrical power. The single word that is most descriptive of this advance is "magnitude." Improvement has been made in more clearly defined fields of application of types of equipment rather than in any radical change in design. So great is the number of possible combinations of types of equipment that can be made to meet the singular conditions of the individual station, that the employment of a particular type of equipment in the design of a new station is not necessarily indicative of the general trend of practice.

Recent and anticipated mergers of large power corporations presage a hastening of the interconnection of major distributing systems, thereby making possible greater modern stations with larger equipment units, the reduction of investment in stand-by equipment, the more effective use of water power, and increased research, all of which tends toward a lower cost of production with a consequent increased demand for power.

Developments in Boiler-Plant Equipment

The most outstanding developments in boiler-plant equipment are the rapidly increasing capacity and continuity of service of steam-generating units. Within the current year there will be placed in service several such units, each having a maximum capacity of nearly one million pounds of steam per hour. One plant, equipped with water-cooled walls and pulverized-fuel firing, operated eight months with no outage at time of demand. The effect of water-cooled walls upon the elimination of outages by means of their reduction of repairs to furnaces and combustion equipment, together with their quicker cooling at times of repairs, has led to their almost universal application in larger installations and their more general use in smaller units. There are now available individual steam-generating units capable of operating a turbine of over 80,000 kw. capacity and having a reliability nearly equal to that of turbo-generators. This fact will probably have considerable influence upon the design of future power plants.

In stations with a high load factor there has been an increase in the number of plants designed for steam pressures of approximately 1400 lb. In the design of these plants there has been a decided tendency toward straight-tube, cross-drum boilers, although the more recent and improved design of bent-tube boilers may alter this trend. The advantage of limiting hot-metal spots in superheaters has evidently been sought in boilers and water-cooled furnace walls, resulting in a reduction of heat transfer per square foot in order to reduce maximum metal temperatures. A few stations of moderate load factors have been designed for 650 lb. steam pressure, while nearly all new stations of low load factor are designed for pressures of about 450 lb.

There has been no trend toward higher steam temperatures except for experimental purposes, and though designers have preferred greater reliability and less efficiency at 750 deg. fahr. (and probably will until less expensive materials are available), there are positive indications that higher temperatures will be used in the near future. Two installations for use in this country have been purchased for steam temperatures above 800 deg. fahr., and actual experience with these temperatures should be available soon. In one comparatively new station, interdeck superheaters with plain steel tubes have been operating at a steam temperature of 780 deg. fahr., and this temperature will be increased gradually to a point in excess of 800 deg. or until signs of distress develop. Experiments are being made on an oil-fired superheater of a capacity of 6000 lb. of steam per hour at steam temperatures of from 700 to 1100 deg. fahr. for the purpose of determining the effect of high temperatures upon superheater tubes, valves, piping, and fittings. Manufacturers are prepared to build superheaters, turbines, and piping for steam temperatures of 800 deg. fahr. Other trends in superheater design that will assist in promoting higher temperatures are in the direction of increasing the velocity of steam through the elements, reducing it through the inlet and outlet headers, thus insuring proper distribution of steam between elements, and in providing greater protection of the superheater with an intervening bank of boiler tubes.

With a steam temperature of 750 deg. fahr. practically all stations designed for pressures over 450 lb. are reheating the steam. Of two stations designed for a steam pressure of 650 lb. at 750 deg. fahr., one does not employ reheating while the other reheats to a temperature of 500 deg. In plants of steam pressures higher than 650 lb. the steam is universally reheated to the original temperature of the steam. Single-stage reheating has been used in all of these stations with the exception of two now under construction. In these two stations there is a combination of a steam reheater with a gas reheater. The temperature of the reheat is maintained nearly constant by thermostatically controlling the temperature of the steam from the steam reheater by the temperature of the steam leaving the gas reheater.

In high-steam-pressure stations the total heating surface of air preheaters, reheaters, bleeder heaters, water-cooled furnace walls, and economizers has increased until the actual boiler heating surface is only 12 per cent of the steam-generating-unit heating surface, and only 0.3 sq. ft. of boiler heating surface per kilowatt of plant capacity. Under these conditions the terms "boiler rating" and "boiler horsepower" have little or no significance.

Trend in Fuel Firing—Feedwater Heating

The trend in fuel firing in recently designed or constructed large stations is decidedly toward pulverized fuel. In the central stations the bin system seems to predominate, while in the industrial field the unit system is favored. Pulverizing mills with a capacity of 25 tons per hour are now in operation, and one station with larger boiler units is using as many as five mills per boiler. The largest steam-generating unit soon to be placed in operation is designed for pulverized fuel with the unit system. The rate of combustion in recently designed pulverized-fuel furnaces of large size range from 18,000 to 30,000 B.t.u. per cu. ft. of furnace volume. Several slag-tap furnaces are in operation with a combustion rate of 42,000 B.t.u. Although this type of furnace requires a minimum fusion temperature of ash of 2500 deg. fahr., it may be of special advantage where the disposal of fine ash from the furnace is a problem. There is as yet no completely satisfactory method for the removal of ash carried up the stack.

While the trend has been toward pulverized fuel and there seems to be no limit to the capacity of the pulverized-fuel-fired furnace, the progress of the underfeed stoker is impressive. Nearly every month of the present year has established a record in the number of retorts sold, that for August being 1900 retorts. There are now available individual stoker units capable of producing 500,000 lb. of steam per hour, each which with double-end firing makes possible the output of 1,000,000 lb. per hour from a single stoker-fired boiler. One manufacturer has produced a ram capable of feeding 40 lb. of coal per stroke. Experiences of the past year indicate that a gradual and complete redesign is taking place. The development has not been confined to any one part, but the most noteworthy improvement has been in the handling of the fuel bed. This has been accomplished by reduction of wind-box air pressures and better methods of conditioning to provide a light and spongy fuel bed.

There has been no outstanding change in the design or application of air preheaters. Accurate test and operating data are now available for determining design. Gas spacing has been determined for different fuels, and means provided to maintain this space free from slag or ash. Better provision has been made for expansion to prevent warpage of elements, and considerable attention has been given to the sealing against air infiltration.

Feedwater heating shows an apparent trend toward the more effective use of the regenerative cycle. Four-stage heating is quite common, and in one station the feedwater will be heated in five stages. Increase in steam pressure justifies an increase in the temperature of feedwater by means of bled steam. This is evidenced by the heating of feedwater to a temperature of 430 deg. fahr. in a station recently designed for a steam pressure of 1400 lb.

Never in the history of the profession has feedwater treatment been given as much attention, both in research and in practice, as in the past year. One significant trend is the practice of combining processes. Combinations of chemical and zeolite softening, addition of coagulants with softening reagents, the continuous blowdown system, and steam purifiers have brought a change in feedwater treatment and provided the designing engineer with a greater number of methods from which he can choose to treat a specific condition. Although research is still being made to determine the process by which electrolytic methods prevent corrosion, several successful installations have recently been made. There has been a decided increase in the use of sodium aluminate and phosphates.

Several instances of severe embrittlement in boiler steel have occurred during the year, and it has been found in highly stressed areas, in expanded as well as riveted joints. When the ratio of sodium carbonate alkalinity to sodium sulphate was established by the Boiler Code Committee, there were not sufficient operating data to warrant carrying the ratio above 250 lb. pressure. Later sufficient data were developed to warrant extending the ratio to 600 lb. pressure, the ratio increasing in proportion to the increase in pressure as indicated in the ratios for lower pressures. When the ratio is applied to higher pressures, the amount of treatment becomes excessive. Laboratory investigation indicated phosphates as a desirable inhibitor of embrittlement. Many stations began the use of di- and tri-sodium phosphates and, more recently, mono-phosphate. There have been no known ill effects to date, but the use of phosphates has not been practiced for a sufficient length of time to positively substantiate laboratory results.

Larger Turbine Installations

The growth of power systems has made larger turbine installations economically possible. During the past year several noteworthy installations have been completed, and orders have been placed for others of unusual interest. All of the larger installations are of special designs built to suit special conditions to fit in with the power systems and the economic policies of the power corporations. There are also quite a number of installations using simple turbines of a more standard design. In one instance a public-utility corporation has installed eight duplicate units with machine tolerances limited so that all parts of the machines are directly interchangeable. The largest single generator unit, 60 cycles, 1800 r.p.m., now on order is a 115,000-kw. and the largest system of units with three generators, 60 cycles, 1800 r.p.m., in operation is for 208,000 kw. One outstanding installation is a tandem compound turbine with a single generator having a double winding with a capacity of 160,000 kw. An interesting development of the year has been the purchase of three steeple compound units. An indication of another possible development is the recent construction of a small turbine with a welded steel-plate casing.

Recently designed stations indicate a decided increase in the use of single-pass condensers. The amount of condenser surface per kilowatt of turbine capacity shows a downward trend. Several stations have been designed for 0.8 sq. ft. and one station for 0.575 sq. ft. of condenser surface per kilowatt of turbine capacity. One outstanding development of the past year has been the general use of condensers with tubes rolled in at both ends and methods for taking care of the expansion of tubes and shell. There are four methods of accomplishing this, but no positive indications exist which forecast the method of the future. Another outstanding development has been the installation of a welded steel-plate condenser. This unit, of 27,000 sq. ft. of condenser surface, serving a 30,000-kw. turbo-generator, was designed, constructed, and placed in service in five months at a cost considerably lower than any quoted on a cast-iron condenser. The performance of this unit shows the air leakage to be very low.

Installations with steam pressures up to 1200 lb. with a temperature of 750 deg. fahr. are common, and stations with a steam temperature of 850 deg. fahr. are being constructed. Experiments with a temperature of 1000 deg. fahr. are being made. A 10,000-kw. turbine is being constructed abroad for installation in a central station in the United States for operation at 365 lb. inlet pressure, an exhaust pressure (absolute) of 1 in. of mercury and an initial temperature of 1000 deg. fahr. This unit is for experimental purposes to determine the behavior of the metal in the turbine, and especially of valves and joints, at high temperatures under operating conditions.

Industrial Steam Power

Industrial power constitutes only a small portion of the total power generated in the country, and the fuel consumed by industrial boiler plants, exclusive of railroad and gas plants, is several times that used by central stations. This condition illustrates the comparative importance of the generation and utilization of power with that of heat in the industrial field. The increased use of steam-flow meters has resulted in greater efforts to improve the efficiency in the utilization of heat. This has constantly reduced the heating load, while the installation of automatic machinery and materials-handling equipment has increased the power load. For this reason the balance of steam systems is destroyed in many plants. During the past year there have been a number of complete boiler and power plants installed as part of extension or modernization programs, but the greater part of recently installed equipment has been for the purpose of restoring the balance of steam systems. This has been the situation in textile, food, chemical, and paper plants, particularly in the latter. Advantages have been taken of higher steam pressures and high-back-pressure and extraction types of turbine delivering steam to process or to the original boiler-steam mains.

There has also been a decided increase in substituting high-back-pressure turbines for motors in power-plant auxiliary drives as well as in service-equipment drives. The increased use of refrigeration has been of considerable help in maintaining steam balances. When extraction turbines are used, particularly in the paper and textile plants, the bled steam is sometimes superheated to a temperature injurious to materials in process and desuperheaters have to be used.

Exchange of power between central stations and industrial plants is gaining in favor, and a number of plants report that it is working to the advantage of both parties. Also, in several instances, central stations have built plants to supply both steam for process and power to one or a number of industrial plants in the vicinity. In such cases non-condensing high-back-pressure turbines are employed, exhausting to the process-steam mains and floating on the line, electrically in parallel with the system; the electrical load supplied by them being governed by the process-steam demand.

Several manufacturers of pulverized-coal equipment report greatly increased sales of unit pulverizers to industrial plants, but pulverized coal has not had the field to itself for stokers have been installed in a great many of the new or remodeled plants. In several cities where smoke-abatement activities prevail, the smaller stokers have found a ready market in the smaller industrial plants.

More attention is also being given to the better utilization of waste heat either in boilers or in air preheaters. About one-third of the newer plants use air preheaters, and a somewhat smaller number employ economizers.

Much greater attention is being given to feedwater treatment, and technical supervision is more generally employed. The trend in methods used is similar to that in central-station practice. In some instances evaporators have been installed to take a considerable portion of the boiler steam, returning the condensate to the feed lines and delivering pure vapor to process.

In conclusion, it may be stated that the present status of research, design, and performance forecasts an even greater progress in 1930.

Grateful acknowledgment is here made to the many engineers whose assistance has made this report possible.

F. M. GIBSON, *Chairman.*

Psychology of Smoke and Fuel Waste in Ceramic Plants

By VICTOR J. AZBE,[1] ST. LOUIS, MO.

IN A BOILER plant fuel efficiency is very poor when it is only 50 per cent and very good when 75 per cent. In a lime plant efficiency can readily be as low as 25 per cent and can also be as high as 60 per cent. In boiler plants the range represents a loss of fuel for the poorer conditions of one-third, while in a lime plant the fuel loss in the poorest compared with the best is considerably over half. Plants can readily be found that have a ratio of $2^1/_2$ lb. of lime per pound of coal, as well as others, rather scarce ones, that have a ratio of 5 lb. per pound of coal.

In boiler plants the efficiency leans in the upper, while in lime plants it leans decidedly in the lower, poorer direction. Efficient lime plants are extremely scarce, and what is even sadder is that definite information as to what is a good lime plant also is scarce. If one needs a book on lime-kiln design, about the only way to get it is to write one. To make conditions still worse there are only few qualified to write such a book, even if they had inclinations to do so.

In the brick industry, conditions, while not quite so backward as in the lime industry, are also very bad. Some time ago the author was escorting a German fuel technologist on his visit to St. Louis. While passing a brick plant this European had a hearty laugh at the crowned updraft kilns used, which he said had not been in use in Germany for 25 years. In this industry also the information is meager, and only some years back there was hardly anything available on the subject of fuel economy. There is a lack of definiteness, great disagreement, individuals are groping in the dark. What the industry needs very badly is trained combustion engineers with an inkling of ceramic knowledge, fully as much as ceramists.

The lime and brick industries are a great deal alike. Ordinarily they have small plants, kilns with small outputs, high-temperature operation, smoke, desirability for long flame, old kilns, older ideas, rule-of-thumb control, about the same type of managing and operating personnel, many old timers that have grown up with the business, and almost complete lack of agreement. What are the reasons for all this?

Not so long ago a survey of equipment and operating methods was made in a number of plants. It was thought that it would be interesting also if the survey would cover in a confidential manner the characteristics and opinions of the managing and operating personnel that such information might possibly reveal reasons for apparent backwardness of the industry. The opinion was that no plant could be better than the managing personnel. Abatement of smoke was the underlying reason for this survey. Following are excerpts from this report with comments:

The first plant visited, a brick plant, uses both updraft and downdraft kilns. The company has in the past made efforts in trying to overcome smoke. This is evidenced by the installation of steam jets in most of the updraft and some downdraft kilns. The jets have not been a success, and are no longer used to a great extent. Mr. —, the superintendent, a man of a naturally cheerful nature, seems to be a pessimist by development. Whereas in the past new ideas have been welcomed, due to past failures, new ideas are now regarded with suspicion.

Commenting on the foregoing, one must say that this is a sad case, a good man, willing to make improvements, disappointed and turned a pessimist. And this is a common case, too; new ideas are tried and fail. Sometimes the ideas are half-baked, sometimes the trial is not fair, and all the expense and hope go for nothing. Ordinarily, after all is over, it is not even known why the experiment was a failure. Ordinarily, no tests are made; the whole is gone into with crudeness; the so-necessary combustion engineer does not come anywhere near the experiment.

There are many lime plants pouring smoke of the very highest density into the sky. In these cases to try to use steam jets to reduce smoke would be absolutely senseless. The purpose of the jet naturally is to create turbulence and bring the oxygen in contact with the carbon, but in these cases there is no excess oxygen, and no amount of turbulence will reduce smoke. Injection of steam will make it even worse, because its equivalent amount of air will be displaced. The experiment fails if instruments of proper nature are not used by a man knowing how to use them to obtain definitely either positive or negative information about the value of what is being tried. Human senses are too imperfect; even the physician invariably uses a fever thermometer, although he can tell without it if the patient has fever. He wants the exact answer and so should the manager of a plant.

Mr. —, the head of the second plant visited, is a large, explosive sort of person, who will probably fill a stranger with terror or awe. The plant has not changed materially in 35 years. Mr. — seems to be the essence of the older heads of the brick industry, i.e., very much under the power of mental inertia, resisting progress.

A most unfortunate case, because the described gentleman is large and explosive, and one of the older heads. Due to his physique, glibness of tongue, and set mind, he can do a great deal of harm resisting progress, not only in his own plant, but due to his influence on others also. The only way he can be successfully controverted is with reliable figures, unquestionable information and proofs, and if they are lacking, as is the case in these two industries, then one has an uphill battle indeed.

In the third plant visited, the man in charge is a most interesting and accommodating person. He keeps up with modern ideas, is of an experimental turn of mind, and does a lot of experimental work himself. He is interested in smoke abatement, willing to accept suggestions, would like to observe tests, and would probably be willing to have tests conducted in his plant.

Fortunately, there are some like this. They are hungry for information, but do not know where to get it. They want to improve their plant and do improve it, but if conditions are not favorable, they are likely to revert into the type of the first man described, into pessimists by development. Due to the very meager amount of technical information presented in an understandable practical form, such men have their difficulties. They are willing, but do not understand the language of the college-trained technician to whom they are complemental.

Some brick plants make a dark colored brick, which is used as an excuse to make smoke. There are great arguments over this required smoke—the ethics of making it in a populous district, etc. This remark is made to make the next paragraph more lucid.

The next plant visited was a brick plant. Mr. —, the superintendent, is a very genial old man and quite friendly. The ware

[1] Consulting Engineer.

Presented at the Third National Fuels Meeting of the A.S.M.E at Philadelphia, Pa., October 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

manufactured does not require smoke, but they produce it just the same. One kiln is equipped with a stoker, but it has been used with rather indifferent success. The stoker is used only when absolutely necessary for production.

Evidently another experiment went wrong. Some miscalculation possibly on the part of the salesman anxious to sell the stoker, but knowing nothing about the very peculiar conditions under which it was to be used. All of it turned into more than wasted effort. One such wrong installation can delay progress in a score of plants.

The superintendent of — plant was a rather cynical man with a sense of humor. He, like a successful poker player, seemed to conceal behind an easygoing exterior an inquiring and alert mind. He was willing to talk about the industry and his own plant. Thought the tunnel kiln was the thing for any plant having enough business to use the output. He seemed dissatisfied with the conditions of the industry in general. "The brick industry has been too long in its infancy," was his comment. As to need of smoke to obtain color, he was truly skeptical. He believed the same results could be obtained in other ways, as for example by the use of manganese or similar material.

Both the brick and the lime industry were in their infancy too long a time. Most of the plants of both are now still in the stages where the steel industry was 50 years ago. Very little progress has been made and there are very few progressive workers. Inefficiency is subsidized by high prices. Recent keen competition and price cutting caused a tremendous howl on the part of those having plants with high production costs. They now are between the devil and the deep sea. When prices were good, they had money to modernize their plants, but did not do so because they were making money anyway. Now they have to sell their output for a low price and do not make any profit, and do not have any money available to make the necessary plant changes. Keen competition, elimination of the weak, and survival of the fittest do more for conservation of natural resources than all the commissions, conferences, etc., combined. The average small industrialist seldom foresees; and how can he, when the sea he sails is foggy, his charts are incorrect, the actions of his compass are awry—even the trained navigator, the engineer, becomes confused. The brick and lime industries need charting, need sharp-cut, practical information based upon technical data, and more than anything else they need men having experience, perspective, and the necessary information and imagination to do this charting. The whole must be boiled down from the state of partially sound and mostly unsound confusion into as few as possible of evident facts and be clearly presented. That this is necessary is further proved by the characteristics of the next man, who is quite an influential factor.

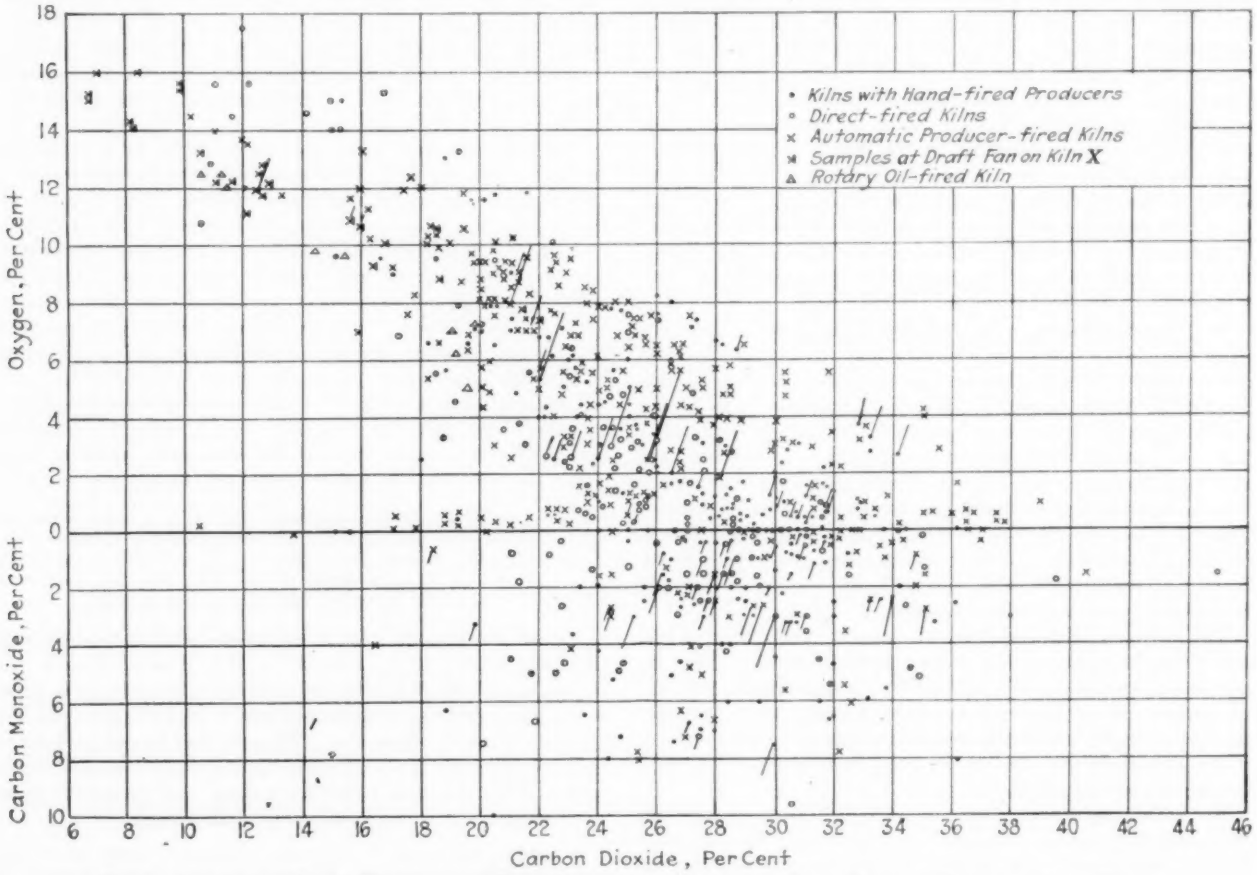

FIG. 1 ANALYSIS OF SEVEN HUNDRED AND FIFTY GAS SAMPLES OBTAINED FROM VARIOUS TYPES OF LIME KILNS

Mr. —, the superintendent of the — plant, was quite cordial during the visit. He is very suave and seemingly open minded, but, at the same time, his opinions are very deeply rooted and it is hard to conceive of him as being moved by anything but most striking and well-founded facts. This company enjoys the reputation of being hard boiled, not willing to give information and very willing to acquire information. Experience shows that this reputation has not been justified.

To cope with such a man, to convert him, needs not only technical training, it needs a knowledge of human nature, it requires the matching of wits, and a rather clear practical insight—as clear as his own anyway.

Mr. —, superintendent of the — street plant, was about of the

same type and even more hospitable. He admitted that on the question of smoke there was basis for complaint in some quarters, and that public opinion must be regarded in this respect. He raised the question of priority rights of people who have moved into the vicinity after the existence of the plant to complain of the plant as a nuisance.

But there is no question of moving or padlocking the plant, and not even a question of pollution of immediate vicinity. First, a brick plant and a lime plant can be operated smokelessly. Second, when they do smoke, the air is polluted more or less for miles. In fact, aerial investigations show pollution extends under certain conditions for hundreds of miles, which with increased air travel and desirability for maximum visibility will become quite a problem.

Some time ago two tests were run on a certain kiln. Both were under observation of qualified engineers, but, during the first, the firemen fired as they thought proper, heavy infrequent firing, of course, and the smoke was almost continuous. For the second test, the firemen used were entirely green men, who never had fired a kiln before. They were told by the engineers how often and how much to fire, light and often, of course, and there was practically no smoke. This proves that the practical experience of many years' duration is valueless if a man is set in his ideas. The fact that the quality of ware, length of burn, etc., during the second test with green men, were at least as good as during the first test, proves that what is needed in a plant is one man thoroughly trained, who knows a great deal; the rest need be men who know little, but are willing to do what they are told.

At plant —, the head burner was interviewed, a man of some twenty years' experience. One kiln is equipped with — type firebox and they are not at all satisfied with it. From the conversation it was gathered that this was largely due to personal dislike of the inventor, rather than the performance of the box.

Prejudice enters into the problem on all hands. It is likely that there may have been considerable reason for the dislike of the inventor. It will be noted that the investigator quoted here gained a desirable reception in every plant, even in those of bad repute for sociability. It is not at all hard to get along if one is charitably minded and approaches the operating force in a sympathetic manner. They are all doing the best they know how; they may have been doing it in this way for years and years, and is it not too much to expect to see them change immediately without even being convinced of the right or wrong of the matter? A knowledge of human nature and ability to get along and make friends is as important to the engineer striving for improvement of plant operations as is technical and practical knowledge. This is particularly so in industries with stagnated development where the processes are regulated by empirical rather than scientific rules.

Mr. —, owner and operator of this plant is one of the brick men who most stanchly ridicules the idea of the need for smoke in brick making. In his 35 or more years' experience he claims that the idea of the need for smoke is a new one. In his plant the coal is burned in an external box, instead of inside the kiln as is the usual practice. Nevertheless, smoke is produced in the same volume as with the older type box. He is willing to try to reduce smoke—anxious in fact. He wants to install steam jets and will do that if he can find any one to advise their use. He asks every visitor to his plant for their opinion on the use of steam jets.

A long radiant flame is very desirable in both the lime and brick industries. The lime and brick turned out are then more uniformly burned. With short flame, temperatures are not so uniform in the burning zone, and overburning and underburning result. A smoky flame ordinarily means delayed combustion; it is for this reason that there is so much disagreement on the subject of smoke. Further, if there is more coal distilling its volatile matter than there is air to cope with it, then no matter what kind of box or steam jets are used, there will be smoke. If the boxes would be arranged with baffles for downdraft burning with insufficient air, and an additional delayed supply of secondary air, then volatilization would have to be constant instead of intermittent, and the flame long without smoke. Then why is recirculation of kiln gases not tried for lengthening out of flame? It is used in the lime industry, and there long flame while desirable is not as important as in the brick industry.

The — Company has been interested in smoke abatement and improvement of conditions for years. Efforts during the past year have been particularly productive. The smoke record during that period has changed from worst to best among the ceramic industry in St. Louis.

If one can do it, why not the others? The reason is that experience obtained in one plant only is not the best of experience. It is culled experience, the findings of many plants applied, that is best. Why is one plant smokeless and efficient and the other not? It is because the interchange of ideas is too slow. Each man proceeds in very much his own way, and often is too conceited to admit that the other man has something worth trying. If he is unusually open minded he may try it, but not with any great degree of enthusiasm. He, because the thing is not his own idea, may even be subconsciously prejudiced against it; he may be unfair, and so the whole may be assured of becoming a failure.

The — Company presents a strange mixture of ancient and modern ideas. They have well-trained ceramic experts, a well-equipped laboratory, and yet are very slow to change existing practices. Mr. — gives the impression of a cold wet blanket at first acquaintance. Future relationship may or may not cause a change in this feeling. He is willing for new ideas to be tried, with the ever-present idea of low cost in view.

Not only small concerns, but large also, can be backward. In some respects it is hard to blame them. Suggestions for improvement too often are of too revolutionary a nature, too costly for a large plant. Assurances for their success are not always without some doubt, and with competition to keep prices low, there is little wonder if the manager turns into a wet blanket, particularly if he had some sad experiences in the past.

In a large plant there are many kilns, and supervision becomes divided, and often this supervision leans first toward upkeep of mechanical equipment, then to quality of the output and the various attending troubles. There is little left over to be applied to combustion, and almost none to develop new firing methods.

There are still other types of men with characteristics not so far exemplified. There is the one who does not care, who completely lacks any sense of duty, any pride of accomplishment, who is physically as well as mentally lazy. Fortunately, however, he very seldom finds his way into any of the governing positions. Then there is the still worse type, who is positively unscrupulous, untruthful. Under certain conditions he may deliberately maneuver to wreck an experiment. He is even more scarce. Then the visionary who if left alone would bankrupt the company with "improvements" without any reason to them. Then the man who after gathering in a little knowledge thinks he knows it all, not realizing that a little knowledge may be very dangerous. Then the obstinate one who never changes his mind; whom nothing can change from his preconceived idea. And finally, there is the man who never makes a mistake.

All of these characteristics are reflected in the conditions of plants of these two industries and in many others as well. Lime kilns are found with fire on top and brick kilns with gas burning in the chimney. At one time the fuel is burned with a large amount of excess air escaping at temperatures from 1000 to 2000 deg. and at another carbon monoxide in waste gas as high as 10 per cent. In a lime plant the desirable gas analysis is 32

per cent. In a lime plant the desirable gas analysis is 32 per cent CO_2, and 2 per cent oxygen and no carbon monoxide. The accompanying chart shows 750 gas analyses. How many are of the desirable characteristics? Most of them range all over the field from 10 per cent oxygen to 10 per cent carbon monoxide. This is a terrific waste even for a boiler plant, and much more so for an industrial furnace with a high temperature level. The brick man does not realize that the heat generated by the carbon burned to CO during the latter stages of the burn is all wasted, and while he may need reducing conditions, he does not need 7 per cent of CO in the waste gas as was found on tests run under actual operating conditions. When the stack temperature is 1500 deg., there is a tremendous difference if the stack gases contain 10 per cent oxygen or only 4 or 5 per cent, still both conditions are oxidizing.

To make improvements in the lime- and clay-ware manufacturing plants, due to the indefiniteness of the general technique, is very much of a battle and requires considerable persistency. If it were always possible to rip down the old plant and build a new tunnel kiln for clay ware or large kilns equipped with modern automatic gas producers for lime, then the whole would be comparatively simple, because with such equipment not so much is dependent upon the operating force. But this is not always possible, even though in most cases it would be advisable. Ordinarily, one has to fight forward inch by inch. For example, the change to more frequent light firing, simple as it sounds, is ordinarily not easy to accomplish. The whole depends upon how strong the convictions of the superintendent are and how determined he is.

One plant, completely converted by construction of new kilns, increased its product per ton of coal from a ratio of 2.8/1 to 4.3/1. The investment made was very great, even somewhat speculative, but final results proved that it was more than justified. In another plant complete change may not be possible, and one has to do the best with the existing equipment. The accompanying chart shows the results of such a plant. It represents very interestingly the performance from the fuel ratio and capacity standpoints over the period of five years, extending over the régime of three superintendents. Under the first man, the improvement began. The beginning, however, was slow; he was not entirely sure of himself. The second man was practically green, but very open minded. He realized that he knew but very little, but was willing to act upon good advice as well as willing to try out his own ideas. This man was about the best of all the author has encountered in a hundred plants or so. He was without education, but had the will which often is more important. He brought the plant to a high state of efficiency, if the type of equipment he had is taken in consideration. During the third régime, plant performance slumped again. The superintendent, although a good man, was just simply misplaced.

The peak in efficiency is 2.85 tons of lime per ton of coal. At the beginning of the four-year battle, it was only 2.1 to 1; this means a reduction in fuel consumption of 25 per cent. In addition, the output was increased 38 per cent, and there was but little difference in appearance of the plant before and after. The whole can be laid to the operating men. Of course, efficiency at 2.85 to 1 was still far from good. If the management had decided to build a new plant, the ratio would have been $4^1/_2$ to 1 with the somewhat low grade of coal burned, but the management did not see fit to do so and therefore the superintendent proceeded to do the best in his power with what he had.

FSP-52-4

Economics and Design of Water-Cooled Furnaces

By J. S. BENNETT[1] and P. N. OBERHOLTZER,[2] PHILADELPHIA, PA.

Experience of one manufacturer in designing and operating water-cooled furnaces is given in this paper. It deals particularly with water-cooled furnaces for underfeed stokers, and a study of results and conditions of several actual installations is presented. Determination of the proper amount of water cooling is an economic rather than a combustion problem. Ordinarily the most critical portion of the furnace is the rear wall, so that if but one wall is to be cooled, it should be the rear wall. Sometimes the sizes of stokers used in older-type plants are limited by the ability of the furnace to withstand temperatures resulting from higher combustion rates. In many such cases a moderate investment in water cooling will give a substantial increase in steam output.

THE object of water cooling is to permit the generation of cheaper steam than with the ordinary type of furnace. Specifically, the objects of water cooling for underfeed-stoker furnaces are:

1 To prevent fused ash from adhering to the furnace walls.
2 To prevent mechanical abrasion along the fire line.
3 To prevent failure of brickwork in the upper part of the furnace due to erosion and undercutting of the furnace construction along the firing line.
4 To reduce boiler outage.
5 To reduce furnace maintenance.
6 To reduce stoker maintenance.
7 To reduce slagging on the boiler tubes.
8 To simplify ash removal.
9 To permit increased capacity.
10 To increase overall efficiency
11 To permit the burning of poorer coal.

The value of water cooling is well accepted, but the selection of the proper amount of water cooling for a specific case is more difficult. By presenting a study of the surrounding conditions of actual installations, it is hoped that some of the debatable points will be cleared up and that the engineer selecting the furnace design for his specific case will be aided in reaching a decision.

The first water-cooled furnaces of the modern type were installed at the Saginaw River plant of the Consumers Power Company, Zilwaukee, Michigan, and at the Hell Gate plant of the United Electric Light and Power Company, New York. These two water-cooled furnaces were put into service at approximately the same time. At Hellgate, side walls only were protected with water cooling. Nearly half of the water-cooled surface was covered over by refractory blocks, as it was believed that the exposure of a greater amount of water tubes would have an unfavorable effect on combustion, and the danger of blow-torch action on the tubes and mechanical erosion along the fire line was recognized.

The results obtained at Hell Gate were remarkable, but the full possibilities of water cooling were not realized because the most critical points, the rear wall and the side wall at the overfeed sections of the stokers, were not protected. This naturally hindered the ash-disposal system, and in turn had an unfavorable reaction on the whole fuel bed.

The application of this same refractory-protected side wall

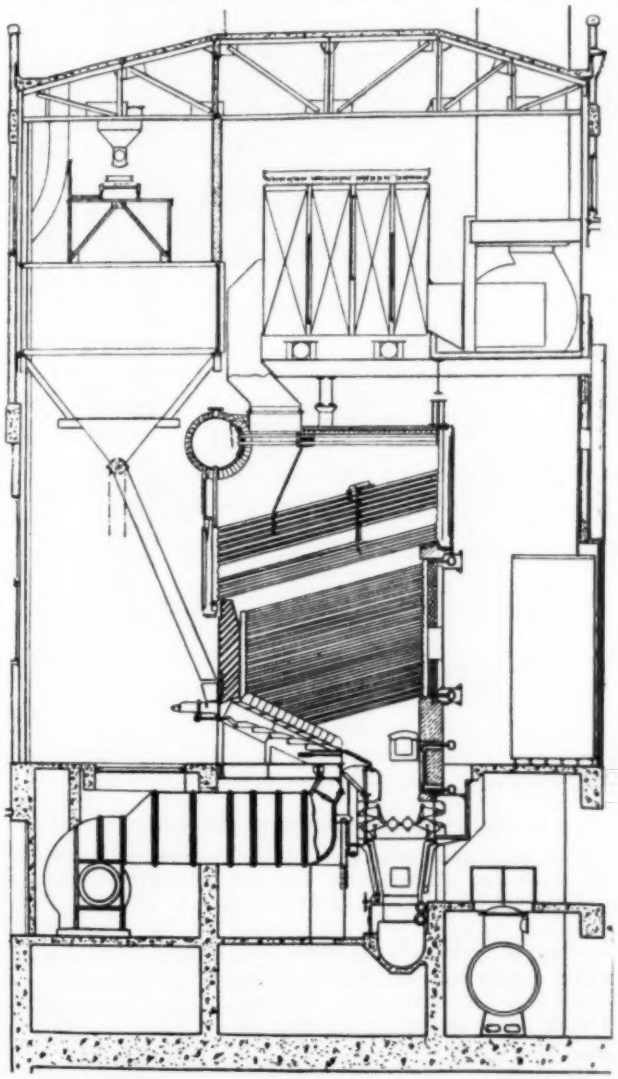

FIG. 1 WATER-COOLED WALLS AT THE SAGINAW RIVER STATION OF THE CONSUMERS POWER COMPANY

at other plants with lower grades of coal has demonstrated the need of cooler surfaces along the fire line to prevent adhesions of slag. Also, it has been found that the brickwork washes away very quickly with certain grades of coal, especially when using preheated air. In one case, the brickwork was washed away down to the tubes in seven days of operation.

The Saginaw River installation (Fig. 1) differed from the

[2] Engineer, American Engineering Co. Jun. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Fuels Division, Philadelphia, Pa., Oct. 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Hell Gate installation in that the side walls were formed by sloping tubes instead of vertical tubes as at Hell Gate. The protection along the fire line at Zilwaukee was better than at Hell Gate, but the side walls along the lower end of the stoker were not protected by water cooling, and the rear water wall did not run down far enough into the ashpit, so that the small sections of brickwork between the stoker aprons and the bottom of the water wall were worn away, forming a shelf which obstructed the flow of ashes to the rolls.

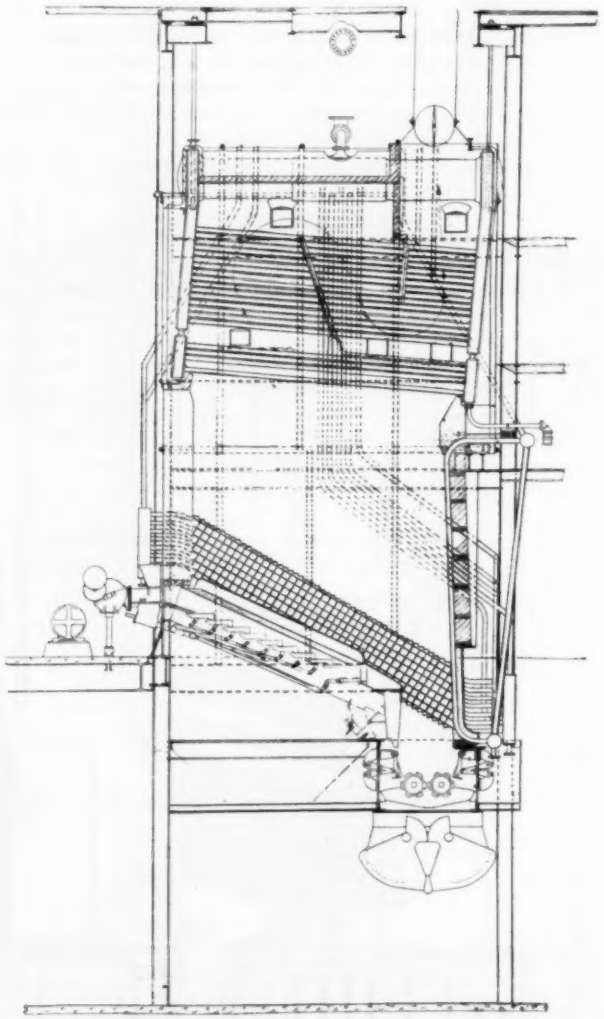

FIG. 2 JUDICIOUS USE OF WATER COOLING AT THE NEW TERMINAL PLANT OF THE CONSOLIDATED GAS AND ELECTRIC COMPANY OF BALTIMORE

At Zilwaukee, the tubes along the fire line were protected by cast-iron blocks shrunk on the tubes. It was demonstrated at this plant that the combustion of the fuel was not affected adversely by this cool surface along the fuel line, as had been feared.

The first Hell Gate units operated at 338 per cent of boiler ratings for 25 hr. with three-hour peaks of 450 per cent and a ¾ hour peak of 540 per cent. The Saginaw installation, with a somewhat greater ratio of stoker to boiler surface, operated repeatedly for prolonged periods at boiler ratings in excess of 450 per cent continuously. There was 485 per cent of boiler rating maintained for 48 hr. and 505 per cent of rating for 24 hr.

Experience at these two plants and with many other of the earlier water walls has shown that the best construction along the fire line consists of a smooth bare-metal surface. A number of means have been employed to provide this. The best method is undoubtedly the renewable metal block. This construction permits the replacement of blocks which have been scoured away mechanically by the abrasive action of the fuel bed, and also prevents flame impingement against small spots on the tubes, which, with the bare tube, has proved very objectionable.

In contrast to the older water-wall installation at Hell Gate, there is the modern unit installed at the new Terminal Heating plant of the Consolidated Gas and Electric Company of Baltimore. (See Fig. 2.) The side and rear water walls along the fire line are faced with renewable, cast-iron blocks. The side walls above the fire line, where the duty is light, are brick construction. The overfeed section of the stoker and the ends of the ashpit are protected by a band of water cooling, extending down into the ashpit.

This unit went into service on Dec. 22, 1928, and was operated at boiler ratings as high as 400 per cent with frequent prolonged peaks of 360 per cent, and at a normal rating of 250 per cent. This boiler was kept on the line until the early part of May of this year. The unit was then taken off the line and presented the appearance shown in Figs. 3 and 4. Absolutely no repairs of any kind were necessary to the brickwork, water walls or stoker.

DETERMINATION OF THE PROPER AMOUNT OF WATER COOLING

So far as combustion is concerned, there is no possibility of too much water cooling being applied in the furnace with underfeed-stoker firing. It is obvious, however, that the application of more than the economic amount of water cooling cannot be justified, so that the determination of the proper amount is an economic problem, rather than a combustion problem.

Table 1 presents a number of installations which will be discussed in this paper, and an effort will be made to analyze the conditions and reasons for the selection of the amount of water cooling employed in each instance. In presenting these figures, for simplicity it has been assumed that all makes of bent-tube boilers cost the same per boiler horsepower and that the same applies to straight-tube boilers. The ratio of the costs of the two types of boilers has been taken as 7 to 9, as it has been found the price of straight-tube boilers generally exceeds that

TABLE 1 DATA ON WATER-WALL COSTS FOR SIX PLANTS

Name of plant	Boiler hp.	Water wall cost in per cent of boiler cost	Maximum boiler rating, per cent	Tons of coal burned per year	Water wall price in per cent of annual coal cost	Walls water cooled	Coal	Remarks
Terminal Heating Co. . .	1261	37.5	400	14,400	19.6	Side and rear	Good	Note (1)
Brown Corporation	518	33.0	300	8,300	12.4	Side front and rear	Very bad	Note (2)
Brown Corporation	764	76.0	350	13,400	20.0	Side, front and rear	Very bad	Note (2)
St. Croix Paper Co.	745	28.3	310	13,000	7.5	Rear	Good	
Ball Bros. Co.	507	58.0	300	10,500	13.0	Side and rear	Poor	
Ohio Public Service Co. (Lorain)	1464	60.0	500	35,000	13.3	Side, front arch and rear	Poor	Note (3)

Data based on same price of coal, and on same boiler prices, with bent-tube boilers priced at 78 per cent of horizontal-tube boilers.

(1) Heating plant has low load factor. Coal consumption expected to increase.

(2) Furnace maintenance would be very high with this coal especially on front walls, without water cooling.

(3) Coal consumption expected to increase.

of bent-tube boilers approximately in this ratio. It is realized that this ratio may not hold with some manufacturers and that in some cases the bent-tube boiler of one type might cost more per horsepower than a straight-tube of another type. Any one who wishes may apply a corrective factor to the figures given to conform with his own views. The water-wall costs used are the present selling prices.

The annual coal costs used are based upon the same price of coal delivered at the plant for all installations shown. The figure taken is a representative one, and is the same for all installations, for simplicity in comparing ratios of costs.

In order to illustrate the application of the data in Table 1, two typical cases will be taken, as follows:

Case I Completely Water-Cooled Furnace:

Water walls costing 35 per cent of annual coal cost
Fixed charges 15 per cent
Coal at $4.25 per ton

Water wall fixed charges = $4.25 × 0.35 × 0.15 =	$0.22 per ton
Efficiency without water walls = 80 per cent	
Efficiency with water walls = 83 per cent	
Coal saving per ton = $\frac{0.03}{0.80} \times \$4.25$ =	$0.16 per ton
Reduction in furnace maintenance with water walls	0.15 per ton
Reduction in stoker maintenance with water walls	0.03 per ton
Total saving per ton of coal	$0.34

A saving of $0.34 per ton of coal burned results from the use of a completely water-cooled furnace, which is $0.12 per ton more than the fixed charges on the water wall.

FIG. 3 INTERIOR OF FURNACE AT THE TERMINAL PLANT AFTER FOUR MONTHS' RUN

Case II Partially Water-Cooled Furnace:

Water walls costing 14 per cent of annual coal cost
Fixed charges, 15 per cent
Coal at $4.25 per ton

Water-wall fixed charges = $4.25 × 0.14 × 0.15 =	$0.09 per ton
Efficiency without water walls = 80 per cent	
Efficiency with water walls = 82.5 per cent	
Coal saving per ton = $\frac{0.025}{0.80} \times \$4.25$ =	$0.13 per ton
Reduction in furnace maintenance with partial water cooling	0.10 per ton
Reduction in stoker maintenance with partial water cooling	0.01 per ton
Total saving per ton of coal	$0.24

A saving of $0.24 per ton of coal burned results from the use

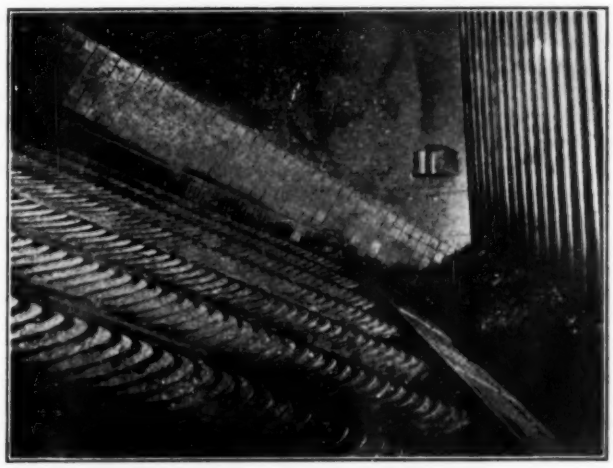

FIG. 4 SIDE VIEW OF FURNACE SHOWN IN FIG. 2 WITH SLAG REMOVED TO SHOW EXCELLENT CONDITION OF WALLS AND EXPANSION JOINT IN CENTER OF SIDE WALL

of a partially water-cooled furnace. This saving is $0.15 per ton more than the fixed charges on the water wall.

Complete Water Cooling

Total saving	$0.34 per ton
Fixed charges	0.22 per ton
Saving over and above fixed charges	$0.12 per ton

Partial Water Cooling

Total saving	$0.24 per ton
Fixed charges	0.09 per ton
Saving over and above fixed charges	$0.15 per ton

These figures show that a partially water-cooled furnace results in a net saving per ton of coal burned of 3 cents per ton greater than the saving secured by using completely water-cooled walls.

This comparison can be made directly because the capacity of the completely water-cooled furnace is practically the same as that only partially cooled.

However, in comparing any water-cooled furnace with a refractory furnace, it must be borne in mind that the extra capacity secured from the water-cooled furnace may be sufficient to justify the cost of the water walls without considering any of the other factors involved.

Ordinarily the most critical portion of the furnace is the rear wall. If one wall only is to be cooled, the rear wall should be the one. The rear water wall is always used with rotary ash-discharge stokers, as the successful operation of this type depends upon the ash being fed by gravity to the rolls. Obviously fused ash sticking to the rear wall upsets this condition.

The benefits of water cooling of rear walls with the dump type of stoker are beginning to be realized. A typical installation of this type is that at the St. Croix Paper Company (Fig. 5), Woodland, Maine, burning New River coal with a heating value of 14,000 B.t.u. per lb. as fired. Fig. 6 shows the furnace interior after the unit had been in operation for about one year. A

careful check of the operating results for the four months immediately preceding the application of the water wall, and during the four succeeding months showed that the operating efficiency jumped from 80.8 per cent to 81.8 per cent with a normal boiler rating of 210 per cent with peaks of 310 per cent of one hour's duration four or five times daily.

Eighteen per cent make-up water was used with 2.32 grains of total solids per gallon with 17 parts of hardness per million.

It was found that the capacity of the stoker was increased, and that the maintenance of the rear wall which had been a substantial item was practically eliminated. Taking the annual coal consumption as shown in the table on this installation at 13,000 tons at $5 per ton, it is found that the annual coal bill would be $65,000. One per cent increase in efficiency is equivalent to a coal saving of $65{,}000 \times 1/80.8 = \$810$ per year annual coal saving. Assuming that the annual rear-wall maintenance was $200, it is found that $\$810 + \$200 = \$1010$, which capitalized at 20 per cent will justify an expenditure for water

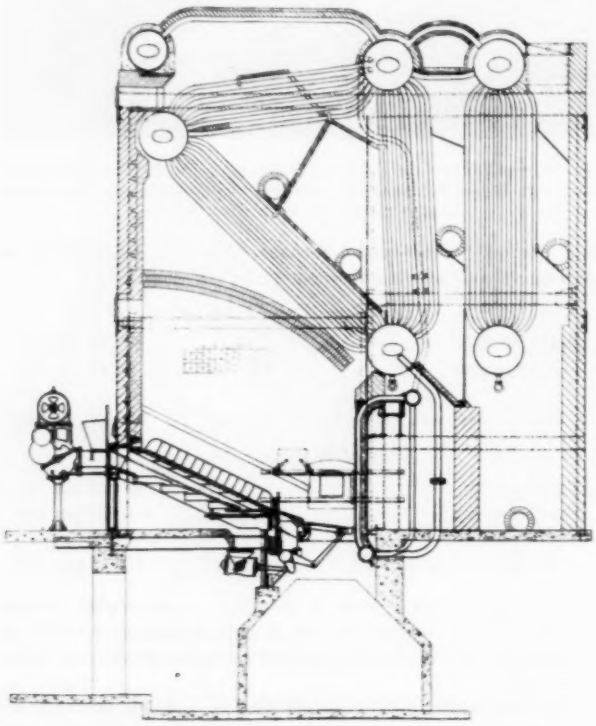

FIG. 5 A MODERATE AMOUNT OF WATER COOLING WILL GIVE A HANDSOME RETURN

walls of $5050. This, of course, does not allow credit for the reduced stoker maintenance which inevitably results, nor for the increased boiler capacity available, generally the most important factor.

In Table 1 it is seen that the water-wall cost is 28.3 per cent of the boiler cost and $7\frac{1}{2}$ per cent of the annual coal cost.

REVAMPING EXISTING BOILERS

Not infrequently the size of the stokers used in older plants was limited by the inability of the furnace to withstand the temperatures resulting from higher combustion rates. In many cases of this kind a moderate investment will give a substantial increase in steam output.

For example, the La Tuque plant of the Brown Corporation needed more steam from existing boilers set in battery. This condition was met by installing underfeed stokers and water walls on all four sides. (See Fig. 7.) A radiant superheater above the rear water walls provided the added superheat needed. For two years these units have been operated normally at 250 per cent of boiler rating, and have a capacity of 300 per cent continuously. Twenty-five per cent make-up water caused no difficulty.

The operating efficiencies of these units, excluding economizers

FIG. 6 REAR WALL OF ST. CROIX PAPER COMPANY'S FURNACE AFTER ONE YEAR'S SERVICE

or preheaters, is approximately 75 per cent, which in view of the high exit-gas temperatures shown in the summary of tests is a very remarkable result. Dominion slack coal with an ash-fusing temperature between 2000 and 2100 fahr. and containing 32 per cent iron oxide is used.

As a result of experience for two years with the units described, the new unit, Fig. 8, going into service will operate at an average boiler rating of 300 per cent (50 per cent more than the old units), using the same type of furnace construction as on the older boilers, but with the addition of extended water cooling in the front to permit the use of a longer stoker.

The cost figures as shown in Table 1 on the old and new installations are very interesting. It will be seen that in the old installation, the cost of the water walls is only 33 per cent of the boiler cost and 12.4 per cent of the annual coal bill, while with the new installation these figures are increased to 76 per cent and 20 per cent, respectively. A number of factors influence this, as will be noted by referring to the illustrations, Figs. 7 and 8. The amount of water cooling used in Fig. 7 of the old installation is reduced, because a radiant superheater forms part of the rear wall. The new installation with a bent-tube type of boiler requires more extensive water cooling of the front wall, but this is offset by the lower cost per unit horsepower which is used for the bent-tube boiler.

The new furnace undoubtedly will show a higher efficiency

than the one in Fig. 7, as the furnace designer was not limited by existing conditions.

The selection of water walls by engineers of large public utilities is a decidedly different problem from that confronting the designer of an industrial plant. The return on the investment in the case of the industrial plant must ordinarily be higher, as the management of the industrial plant is continually seeking funds for improvement in the manufacturing portion of their works, which, of course, is the very heart of their existence. In the central station, however, the business of manufacturing steam is one of the main items, and can be given much more attention by the highly skilled designers and carefully trained operators. Under equal conditions, therefore, it is naturally expected to find more extensive water cooling used in the large central stations, especially as the steam output per square foot of floor area generally exceeds that in the industrial plants by a large margin.

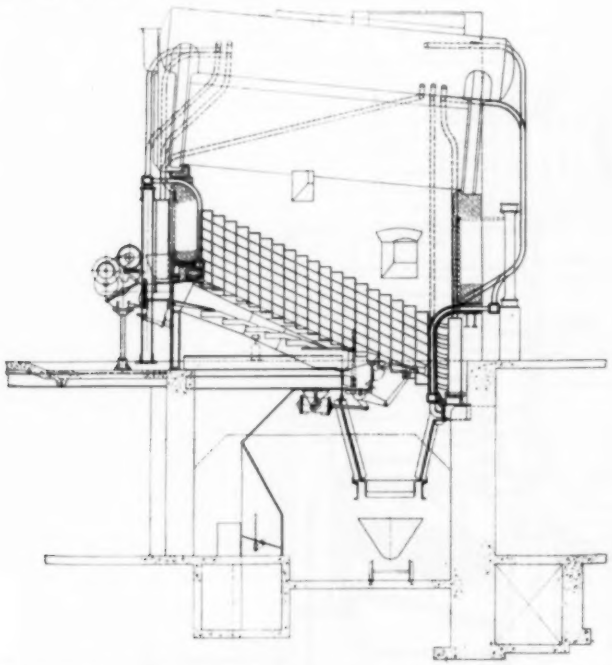

FIG. 7 WATER COOLING ON EXISTING FURNACE IN COMBINATION WITH THE USE OF STOKERS MET STEAM REQUIREMENTS WITH LOW CAPITAL INVESTMENT

The large public-utility operators were the first to recognize the economic advantages of water cooling and have devoted much time and thought to the best disposition of the component parts of the furnace. Their need for a large amount of steam delivered from a restricted floor space has led them to the use of combustion units of large size, which in many cases have outgrown the old conventional furnaces. This has been met by extended water-cooling surfaces, as for example, at the Lorain plant of the Ohio Public Service Company (Fig. 9) designed by the H. L. Doherty Company to burn coal with the following typical analysis:

Ohio Bituminous Coal

	Per cent
Moisture	4.0
Volatile matter	32.0
Fixed carbon	54.0
Ash	10.0
Sulphur, separately determined	3.0
Ash-fusing temperature	2150 deg.

Both the rear and front walls have been extended by water cooling, the rear wall forming a slag screen for the boiler, while the sides have been protected by a wall of economic height.

Table 1 shows a water-wall cost amounting to 60 per cent of the boiler cost, and with the water-wall cost 13.3 per cent of the

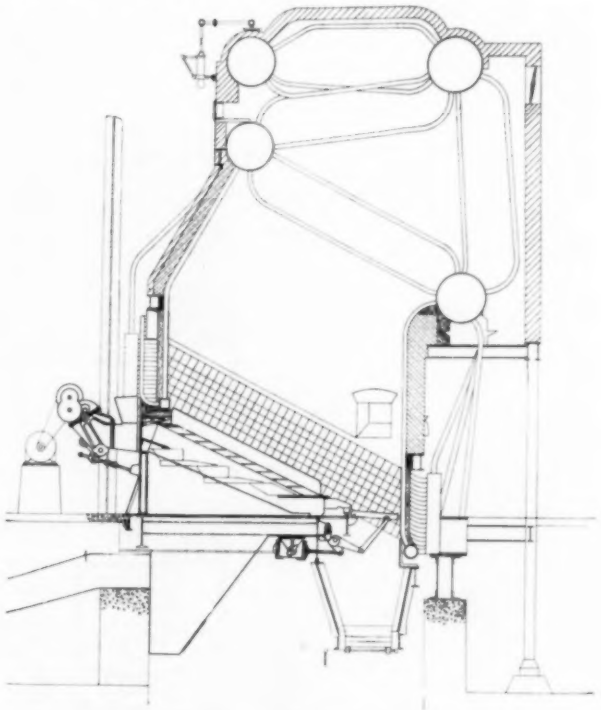

FIG. 8 FURNACE SETTING AS USED AT THE BROWN CORPORATION, LA TUQUE, CANADA

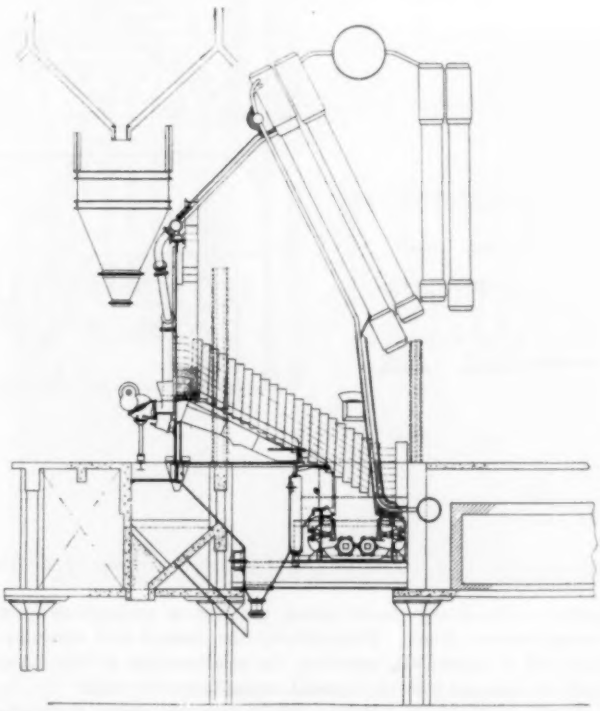

FIG. 9 WATER-COOLED FURNACE WITH EXTENDED WALLS TO PERMIT THE USE OF A LONGER STOKER

annual fuel bill. The cost of the water wall as compared to the boiler is high, but this may be explained by the fact that the water wall really becomes part of the boiler, forming a slag screen. The boiler construction requires a water-cooled extended-furnace front. Undoubtedly the annual coal consumption will be increased, reducing the relative cost of the water wall as compared to the annual expenditure for coal.

In the ordinary installation, the brickwork above the water walls is subjected to very little punishment, but where the service may be more severe, the refractory construction can be protected by air cooling, which also permits recovering the hot air in the upper portion of the boiler room and securing the benefit of combustion with preheated air at a very moderate extra cost.

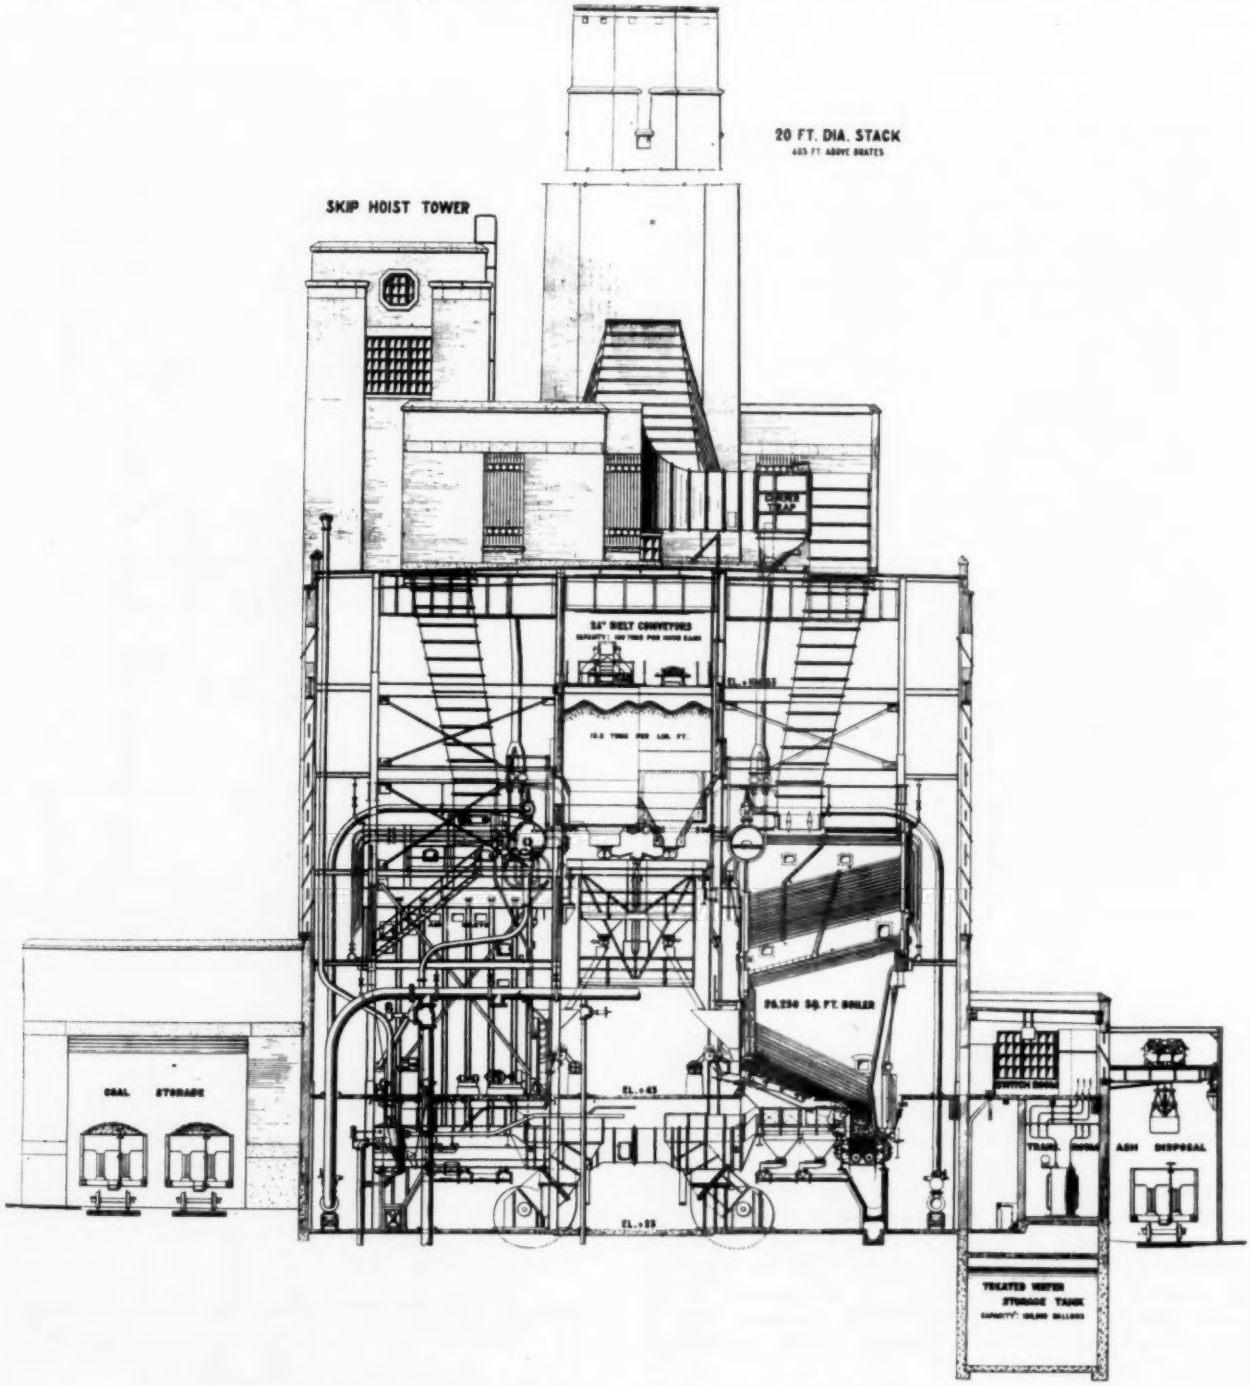

FIG. 10 AIR COOLING IN COMBINATION WITH WATER WALLS CAN BE USED TO ADVANTAGE

The new West Philadelphia heating plant of the Pennsylvania Railroad, designed by the United Engineers and Constructors, will employ this method. Air before delivery to the stokers (Fig. 10) is drawn through the side and front walls by forced-

draft fans placed in the basement. The boiler will be 2623 hp., fired by 15-retort 45-tuyère stokers, with electro-hydraulic drive, having a speed range of 20 to 1. Each boiler is designed for a steam output of from 34,500 lb. per hour to 276,000 lb. per hour continuously; a range in steam output of 8 to 1, with peaks substantially higher.

Water Walls for Preheated Air

The effect of preheated air on combustion is to produce a fuel bed with characteristics similar to that with a fuel of somewhat inferior grade. The almost universal use of water walls with preheated air therefore has been the result of the same experience which made water walls popular with low-grade coal. Contrary to the belief of some engineers, the harmful effect of preheated air on the furnace walls is not due so much to the

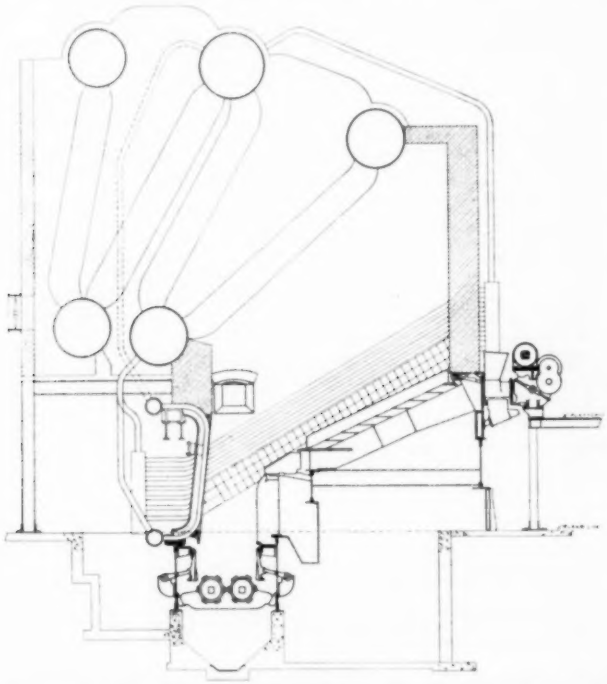

Fig. 11 Water-Cooled Furnace Designed to Burn Indiana Coal With High Preheat

increase in furnace temperature, which may be very slight, as to the greater fusion of the ash. For this reason, portions of the brickwork in the furnace not subjected to erosion and washing away by the fluxed ash are not affected adversely. A novel installation employing this principle and designed to burn Indiana coal with high preheat (Fig. 11) operates at the Noblesville plant of the Ball Brothers Company. These furnaces (Fig. 12) use air for combustion heated to a temperature of 400 deg. The fifth vein Indiana coal used has the following typical characteristics:

B.t.u. per pound as fired	11,220
Moisture	10.30 per cent
Volatile matter	36.30 per cent
Fixed carbon	41.65 per cent
Ash	11.75 per cent
Sulphur	4.20 per cent

The stokers are placed completely above the normal floor line, as the boilers replaced were fired by pulverized coal with manual removal of ashes from the furnace. The building used for powdered-coal firing permitted the installation of modern rotary ash-discharge stokers with more capacity than the unit-mill equipment removed.

Where high preheat in combination with high wind-box pressure

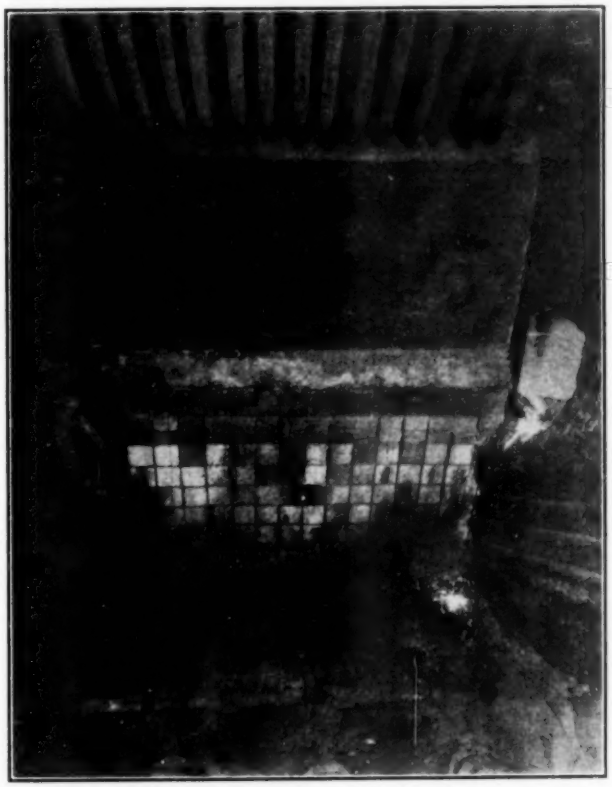

Fig. 12 Interior of the Furnace Shown in Fig. 11

Fig. 13 Effect of Slag Running Down an Insulated Wall

is employed, extra care must be taken to prevent the fused ash on the walls from melting and running down into the fuel bed, interfering with the normal functions of the stoker.

When the furnaces for the high-pressure boilers at the Edgar

plant of the Boston Edison Company were designed, this possibility was realized, but the fear that the large amount of water cooling might interfere with the combustion of the gaseous products led to the installation of insulated water-wall blocks above the fire line with bare metal blocks along the fuel bed. The design was so arranged that this could be modified, if necessary. When subjected to high furnace temperatures, however, it was found that these insulated walls did not give the protection required due to the running of the slag (Fig. 13) and its attachment to the fuel bed. When part of these insulated water-wall blocks were replaced by the bare metal type, the operation was much improved. A still further extension of this principle to the side and rear walls of the two latest units shows still greater improvement.

DESIGNING WALLS FOR SEVERE CONDITIONS

In anticipation of this same condition, at the new Westkraft station in Berlin, Germany, the side walls are being constructed with eight bare tubes (Fig. 14), overhanging the lower section of metal-block covered tubes on the side walls, thereby forming a drip ledge to prevent slag interference with the normal action of the fuel bed. The rear wall is entirely water cooled, with cast-iron protection on the tubes in the lower portion.

This installation, which is the most important power-plant development in Europe, will consist of eight Borsig boilers, with a horsepower of 2580, operating at 410 lb. per sq. in. pressure and with 800 deg. fahr. steam. The combustion-air temperature will be approximately 500 deg. The Taylor stokers firing these boilers will be 20 retorts wide, and 49 tuyères in length, having a total projected area of 713 sq. ft. These units, based on American practice, have a continuous steam output of approximately 500,000 lb. of steam per hour. The coal to

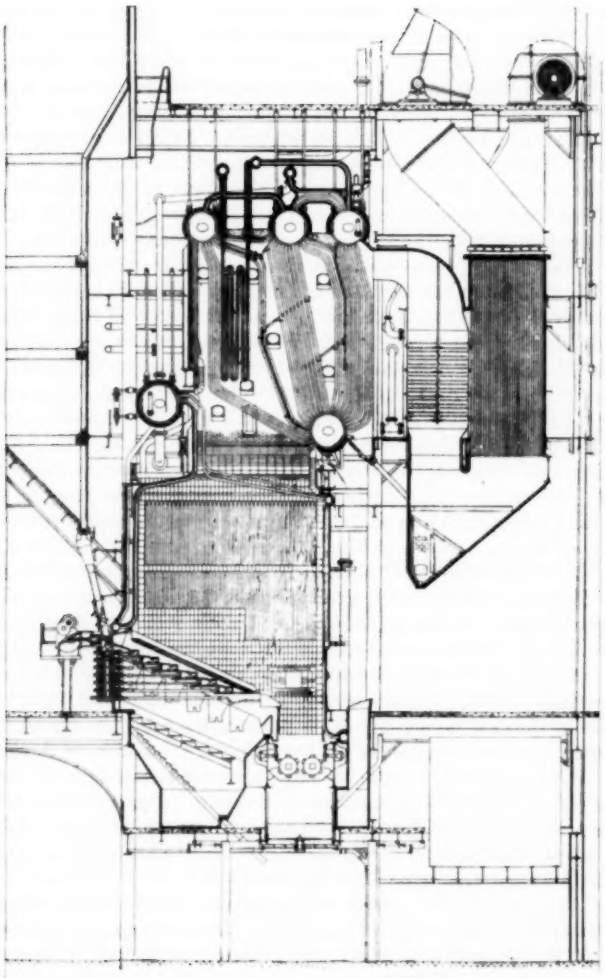

FIG. 15 COMPLETELY WATER-COOLED FURNACE DESIGNED FOR HIGH DUTY AND PREHEATED AIR

be used will vary in heating value from 11,000 to 14,000 B.t.u. per lb. as fired.

For extremely high duty, using preheated air, the maximum amount of water cooling should be used. Such an installation (Fig. 15) is operating at the Delray station of the Detroit Edison Company, where all four sides are water cooled. The sides and rear have bare metallic blocks, carried well above the fire line, while the front wall is completely covered by insulated blocks.

At the time this is written, the full capacity of these units has not been utilized, but they are expected to generate approximately half a million pounds of steam per hour.

FUTURE DEVELOPMENTS

Future developments will undoubtedly include more extensive use of the extended furnace, such as is shown in Fig. 16. Furnaces of greater width than the boiler have also been employed. An increasing use of these ideas may be expected, resulting in furnaces much larger than the old conventional ones.

Discussion

JAMES W. ARMOUR.[3] In the application of water walls one of the main points to decide is to what extent the tubes should be covered. The authors' statement is that tubes should be covered to prevent abrasion and impingement. If this is true, is it to be assumed that, in cases where the rear wall is inwardly inclined where impingement must exist the entire height of the wall, the entire wall should be covered? If this must be done, then the heat transfer would of course be reduced, requiring an increased amount of water surface to obtain the cooling effect desired.

This immediately brings up the question as to whether impingement of the flame on the water wall is detrimental to the functioning of the wall or to the material of which the wall is composed. Impingement of flame on water walls having natural circulation may cause localized formation of steam pockets and possible burning out of the wall tubes at that point. It would seem as if forced circulation would be the answer to this problem, for if operation of the wall is such that impingement of the flame against it is not detrimental, then the tubes can be left bare and full advantage of the absorption surface obtained. The wall would be more efficient and less costly.

The authors gave comparisons of completely and partly cooled walls to bring out the economical point of coverage. From their figures the main saving is from increased efficiency. With a wall of 14 per cent coverage, efficiency is only $^1/_2$ of 1 per cent less than

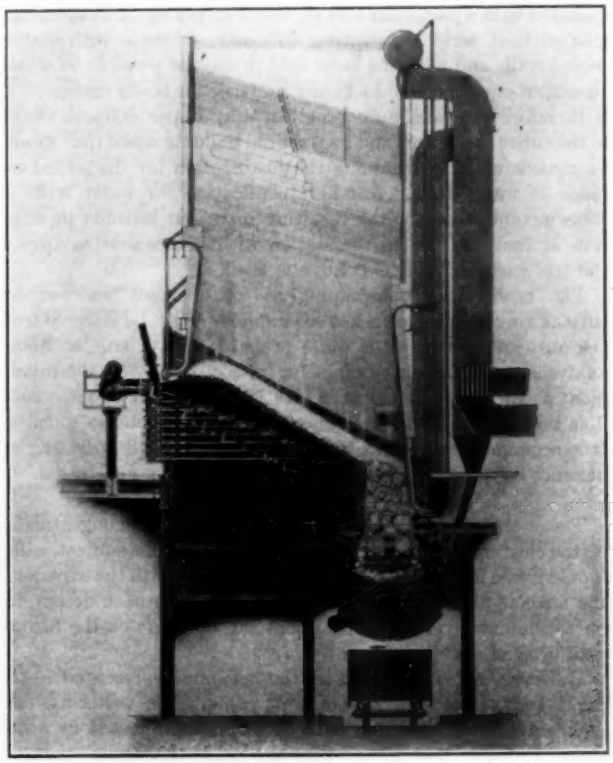

FIG. 16 PREVIOUS LIMITATIONS OF FURNACE DIMENSIONS NO LONGER EXIST IN THIS MODERN UNIT WITH EXTENDED FRONT AND REAR WALLS

with 35 per cent coverage. Would it not be difficult to measure this difference in efficiency or to determine that it was primarily due to variation in amount of coverage?

Interest in design of the wall is primarily as to how the amount of wall necessary can be predetermined. It would be interesting to know what basis can be used to predetermine the increased efficiency due to the addition of varying amounts of wall coverage.

The authors have made no mention of the amount of heat

[3] Vice-President and Engineer-Manager, Riley Stoker Corporation, Worcester, Mass.

liberation in the furnace and its effect on determining the economic effect of the wall coverage. It would seem as if this was of prime importance and should be the main basis for determining the amount of wall coverage to be used in any particular case. High heat liberation means high furnace temperature, consequently high refractory maintenance, high stoker maintenance, and poor operation due to formation of clinkers in the fuel bed. It would seem that a proper balance between heat liberation in the furnace, characteristics of the fuel, together with heat absorbing capacity of the water wall, would be the basis for determining the amount of water cooling to be installed.

S. B. Flagg.[4] The authors refer to the "extra capacity secured from the water-cooled furnace" which they state may be sufficient alone to justify the cost of water walls.

There are two viewpoints from which this statement may be considered. If a major portion of the furnace is water cooled, there will be a credit against the cost of the water wall due to the replacement of expensive refractory construction otherwise required, and a further credit because the water-wall surface will, at times of maximum output, absorb heat at several times the average maximum rate of absorption for the boiler surface proper.

The other viewpoint is, in most cases, the more important. Without water cooling, a boiler of given heating surface may be operated with a particular fuel at, say, 7 lb. per sq. ft. evaporation rate without serious operating difficulty, whereas with water-cooled walls and with the same fuel it may be possible to attain an output equivalent to 14 lb. per sq. ft. of the boiler surface. It is therefore the maximum practical output per dollar invested in the entire boiler unit and its required building space that should be considered in determining the justification for the added expense of water walls. Another justification for water walls in some instances may be the resulting increased latitude in selection of fuels for use in the station with consequent savings in the fuel cost per million B.t.u. absorbed.

The problem of determining to what extent water-cooled surface may be justified is not so simple as might be inferred from the authors' paper. It is quite probable that a true economic analysis would show a diminishing rate of return on the investment as the water-cooled area was increased, but in most cases it is believed that the decisions are predicated not so much on true economic analyses as upon the judgment and operating experience of those responsible for steam or energy generation.

Theodore Maynz.[5] The authors are to be congratulated on the clear manner in which they have treated this subject, which is of extreme interest to all power engineers. With the experience the authors and their company have had in furnace design and operation data, very little comment can be made on the furnace wall designs that are shown.

However, a few remarks on the economics presented in this paper may be pertinent and of some value. The writer has been among the early engineers who have been interested in water-cooled furnaces, and many years ago made the remark that "refractories had no place in modern furnaces," purely from an engineering and thermodynamic standpoint. However, as we must pay for everything that we get, there are many things that are purchased, which, though inherently good, are economically bad. This is frequently, too frequently, the case with water-cooled furnaces. This applies to industrial plant boilers more often than to central stations, but also at times to them. That large boilers can be designed to operate economically and with low maintenance with refractory furnaces has been proved by the 3060-hp. boilers of the Cleveland Electric Illuminating Company, where the experience gained at the Lake Shore Station led to its duplication at Avon Station for both the first and succeeding units. The coal used is similar to that shown in the paper; in fact, the analysis shown for Ohio Coal is superior to that usually obtained, the ash content being more often 12 to 13 per cent and the fusing point as low as under 2000 deg. The writer takes exception to the coal cost in case 1 and case 2, believing that $4.25 is too high and therefore too favorable. A cost of $3.50 per ton would more nearly equal the true cost of coal at the stoker in the Eastern and Middle Western part of this country. This would change the coal savings to $0.13 per ton, the cost of the water walls to 0.42½ per cent, the total savings to $0.31, and the net savings to $0.09 per ton of coal. This is a net return of 6 per cent on the cost of the walls, after fixed charges. This might be permissible for a public utility, but it is doubted if any board of directors of an industrial plant would allow such an expenditure with so little net return if these facts were brought to their attention. Using the coal cost as shown in the paper, which is very much more favorable, the net return on the investment is only 8 per cent.

With partially cooled walls and $4.25 coal a return is obtained that begins to look attractive, provided there is any money left after paying for the essentials such as boilers, stokers, pumps, and building. With this coal cost the net return is about 25 per cent, and with $3.50 coal and water walls costing 17 per cent of the annual coal cost (which would be the case under this cheaper fuel), the coal savings are $0.11 per ton, the total savings $0.32 per ton, net savings $0.10 per ton, and the net return on the investment slightly under 17 per cent, not quite so attractive. The writer is using the same figures as given in the paper on the increase in boiler efficiency, which seem reasonable, and for reduction in maintenance, which seem rather high, when considering a well-designed refractory installation.

In considering the cost of water walls one cannot consider only the cost of the wall. When higher pressures are used (over 250 lb.) the cost of blowoff valves, drains, piping, and insulation brings the cost of this equipment considerably higher than one is led to believe from the bare-wall price quotation. As an example, in a certain installation the cost of the walls (side and rear) cost $8 per rated b.hp., $23 per square foot of wall (total water wall was 3½ per cent of the boiler heating surface), the blowoff and drain valves cost almost 15 per cent of the water-wall cost. These boilers are of medium high pressure and cost $2.30 per square foot, delivered and erected, so the high cost of water-wall construction can be compared. In respect to increased capacity and efficiency, in a new installation, the increase in capacity and efficiency can be obtained cheaper in additional boiler-heating surface than in water-cooled walls. At $2.50 per square foot of heating surface 10,000 B.t.u. can be obtained, or 4000 B.t.u. per dollar. In water-cooled walls at $25 per square foot about 30,000 B.t.u. is obtained, or a 1200 B.t.u. per dollar, a ratio of 3½ to 1 in favor of boiler-heating surface.

However, when the manufacturers bring their costs down to a reasonable figure, then a real economic use of water walls will result, and industrial boiler plants can justify their use by economics, rather than their present methods of lavishly following central-station practice, whether these practices are applicable to their own conditions or not.

The use of clinker grinders on stokers necessitates the use of water-cooled surfaces on the rear wall, otherwise operation is very bad, but, then, it is very doubtful if a clinker grinder pays for its cost on medium- and small-sized boilers (5000 to 12,000 sq. ft.) even with $4 coal and good load factors, exclusive of the extra cost in the required water-cooled bridge wall.

[4] Fuel Expert, Electric Bond and Share Company, New York, N. Y. Mem. A.S.M.E.

[5] Consulting Steam-Electric Engineer, Cleveland, Ohio. Mem. A.S.M.E.

I. E. Moultrop.[6] The most important factors justifying the use of water-cooled furnace walls are undoubtedly greater furnace capacity as mentioned by the authors, and, secondly, greater availability. These two factors are important because of their relation to the question of the unit cost of construction. Since the greatest problem today is to find ways to lower the unit cost of construction, any apparatus that helps in this direction should be developed and used to the fullest extent possible. The one drawback to the even greater use of water-cooled furnace walls is the high cost of such apparatus. There does not appear to be any inherent reason why these costs should not be reduced materially, and undoubtedly the manufacturers' intensive study along this line will be greatly appreciated by all users and potential users of water-cooled furnace walls.

From information available at this time it would appear that the authors are crediting the water-cooled furnace walls with a greater increase in overall boiler and furnace efficiency than has been obtained in practice. If an increase of 3 per cent in efficiency is possible, as stated in case 1, all would like to know how it can be accomplished. A careful study of the problem fails to show that such an increase in efficiency is "in the wood," or probably it should be said, is "in the water wall."

In the case of the side furnace walls well above the fuel line they are subjected to terrific punishment in furnaces operated at large heat releases per cubic foot. This experience and other similar experiences would indicate that for best results the water cooling should be carried well above the fuel line.

Furnace maintenance costs from modern central stations indicate that the figured saving in furnace maintenance given in the paper is too high. For a furnace burning $12^1/_2$ tons of coal per hour and operating at a load factor of 40 per cent a saving of 15 cents per ton for furnace maintenance would amount to $8750 per year. The maintenance on such a furnace would probably not approach this figure, and it would therefore appear rather optimistic to credit the water walls with any such saving.

Experience so far has shown that greater capacity and availability are the real factors justifying the installation of water-cooled furnace walls.

Edwin Smiley.[7] The paper seems to be a step forward in the field of commercial engineering, as applied to underfeed-stoker installations. Referring to the two cases cited—namely, a completely water-cooled furnace and a partially water-cooled furnace—the difference is all the more marked if higher fixed charges are assumed. It is felt that a 15 per cent fixed charge allows for too little depreciation on water-cooled walls. This figure of course can be more accurately determined with further use of water-cooling.

The authors state that "extra capacity secured from the water-cooled furnace may be sufficient to justify the cost of the water walls without considering any of the other factors involved." This is especially true regarding the revamping of existing installations. However, in the case of new installations, extra boiler capacity can be obtained more economically by a wider or longer boiler for an underfeed-stoker installation. A square foot of water wall usually costs more than 1 b.hp.

Based on the measured evaporation from water walls it usually takes 1 sq. ft. of water wall to generate 1 b.hp. This raises the cost of boiler capacity from water walls to more than the cost in boiler heating surface. Boiler capacity from boiler-heating surface has the added advantage of more positive circulation and lower tube maintenance due to scale trouble.

It is felt that the design of the new West Philadelphia Heating Plant of the Pennsylvania Railroad, as described in this paper, is representative of the best modern practice.

The type of sectionally supported air-cooled walls used on such an installation will usually show a higher return on the investment than water walls, with possibly the following exceptions:

a Lower rear walls with rotary ash-discharge stokers
b Sections of the grate line exposed to abrasion
c Whenever furnace temperatures exceed fusion point of ash
d Extremely high-duty installations with preheated air.

Incidentally, air-cooled walls on a job of this size cost very little more than a solid firebrick setting.

As to "future developments on extended furnaces on underfeed-stoker installations," the use of sectionally supported walls is to be recommended for walls overhanging the fuel bed. On the rear wall of such installations, the fire face of the tile should be protected by some form of water cooling.

It will probably be found more convenient, on front walls, sectionally to support and insulate these, rather than to use water cooling or air cooling.

The tendency to use comparatively thin tile walls on high boiler settings because they are sectionally supported is certain to cause excessive radiation losses at higher ratings. Provision should therefore be made for air cooling the tile to recover this radiation loss wherever possible.

H. W. Leitch.[8] In reading over the enumerated lists of advantages of water-cooled underfeed-stoker furnaces it seems that the set-up is not such as sufficiently to emphasize the chief reason for water walls. The most valuable benefit of such an installation is to permit increased capacity. This increased capacity is obtained in three ways: The first way is by the reduction of boiler outage, enumerated as No. 4 on the list. If there was a reduction in boiler outage of, say, 10 per cent by the use of water walls, this would be the same as a 10 per cent increase in capacity in a plant where there is a multiplicity of boilers. The second is the ability to operate at higher rates of combustion. This of course is a direct effect of increasing the available capacity. The third is by the addition of very effective heating surface. This is the most valuable quality of water-wall surface in that it is directly exposed to radiant heat, and so introduces a surface of high rate of heat absorption.

With these facts before him, the writer does not agree with the comparison set-up which shows a saving by installing partial water cooling over complete water cooling. The authors state that the comparison can be made directly because the capacity of completely water-cooled furnaces is practically the same as only partially cooled. This is certainly not true where the furnace is fired by powdered fuel, and in a well-designed completely water-cooled furnace it is not true for stoker firing. It is apparently true for the latter in situations in which it has not been necessary to operate at very high ratings. Therefore, in a set-up as given, there should be added a fixed charge on capacity which would change the conclusions given by the authors and perhaps in some cases give entirely different results.

Again, it is questionable whether there should be any substantial gains in efficiency credited to any kind of water cooling alone—certainly not more than 1 per cent.

Another advantage which should be credited to water walls which is particularly applicable to powdered-fuel furnaces is the reduction in the tendency of slag formation in the tubes. This works in favor of the 100 per cent cold furnace.

The paper states that if only one wall is to be cooled it should be the rear wall. This is true, but for a further reason that on ac-

[6] Chief Engineer, Construction Bureau, Edison Electric Illuminating Company of Boston, Boston, Mass. Mem. A.S.M.E.

[8] General Superintendent, Power Plants, United Electric Light and Power Company, New York, N. Y. Mem. A.S.M.E.

count of the inclination of the stoker the absorption of the rear wall is greater than that of either side wall. This in turn protects the stoker and reduces maintenance. The side walls, however, are desirable to eliminate refractory maintenance.

It should be pointed out that the design of such furnaces has not yet been so standardized that errors are not apt to creep in. There are certain essentials that must be borne in mind in order to have a successful installation. Some of these are as follows:

1 A circulation arrangement to insure adequate hydraulic head as insurance against overheating of metal
2 Rapid circulation and absence of inclination of tubes in a direction favorable to application of heat to steam-bound surfaces
3 Simplicity and symmetry, eliminating numerous special tube sizes and other parts
4 Freedom from parts exposed to furnace heat not in homogeneous contact with water tubes. The ability to withstand severe impingement depends largely on this feature of construction
5 Adequate provision for expansion without injury to the system or external walls
6 Adaptability to various boiler designs without excessive design or development costs.

A. G. Christie.[9] The subject of water cooling of furnace walls is one in which the writer has had an intensive interest for many years. In 1922 he advocated the more extended use of water-cooling for the walls of powdered-coal furnaces, but encountered considerable opposition in many quarters. This resulted in the preparation of a report on the influence of water-cooled walls on furnace performance which was published in condensed form as a paper in *Power* in 1923. This paper aroused much interest and discussion. While the general ideas of this early paper were sound, its arguments would undoubtedly now stand some modifications in view of the more extended study of the subject since that time, the more complete data available, and the extended experience in the use of water-cooled walls that has accumulated.

The paper is a valuable contribution to the knowledge of water walls, for it indicates a more complete and more accurate appraisal of the economic effects of water cooling of furnace walls.

The authors state that "so far as combustion is concerned, there is no possibility of too much water cooling being applied in the furnace with underfeed-stoker firing." Some engineers have feared that the cooling effect of the water-cooled furnace walls would seriously affect combustion with low-volatile coals. This statement should allay those fears.

One may ask what is the effect of the water-cooled walls on the fuel bed of an underfeed stoker. The authors show that the water-cooled rear wall will decrease the slagging and sticking of the ash in the ashpit. But let us assume that a high-volatile, high-sulphur coal with low-fusing ash is being burned. The furnace will be filled with luminous flame which tends to shield the fuel bed from the walls. Will the presence of water-cooled walls in such a large furnace prevent the ash from slagging on the main body of the fuel bed?

Mr. Craig in his paper indicates that any gains in boiler thermal efficiency with water-cooled walls are due to the use of a smaller quantity of air together with a higher percentage of CO_2 than would be permissible with refractory walls. These considerations of decreased air and higher CO_2 must therefore have been assumed in this paper in estimating the increased efficiencies resulting from the use of water-cooled walls.

The authors of this paper also indicate that water-cooled side walls are necessary with preheated air. Engineers would be interested in information concerning the allowable degrees of preheat that can be used on stokers with various classes of coal when different areas of water-cooled walls are used.

The authors base their economic gains on the improvements in boiler efficiencies that result from the use of water-cooled furnace walls. The paper indicates that boiler capacity is increased by the use of water walls. These walls are expensive when compared to costs of equal boiler surfaces on a square foot basis. However, from a plant designer's point of view, one of the most important economic gains from the use of water walls is the saving in total investment in the boiler plant for a given total steam output. Such increased steam outputs can often be secured through the use of extensive water-wall surfaces at a lower total cost than by additional boilers, stokers, coal bunkers, and boiler-house space. This is a consideration that cannot be overlooked.

The authors show many boiler designs with water cooling along the fire line of the stokers. Experience has shown that this greatly improves operation and maintenance. Its use should be extended with both underfeed and chain-grate stokers, and even in the small sizes an improved performance would result therefrom.

Authors' Closure

It is very gratifying to have this paper supplemented by such carefully prepared discussion. Several speakers have questioned the increased efficiency attributed to water walls. The difference in efficiency mentioned in the paper is that obtained under operating conditions. When tests are run with refractory

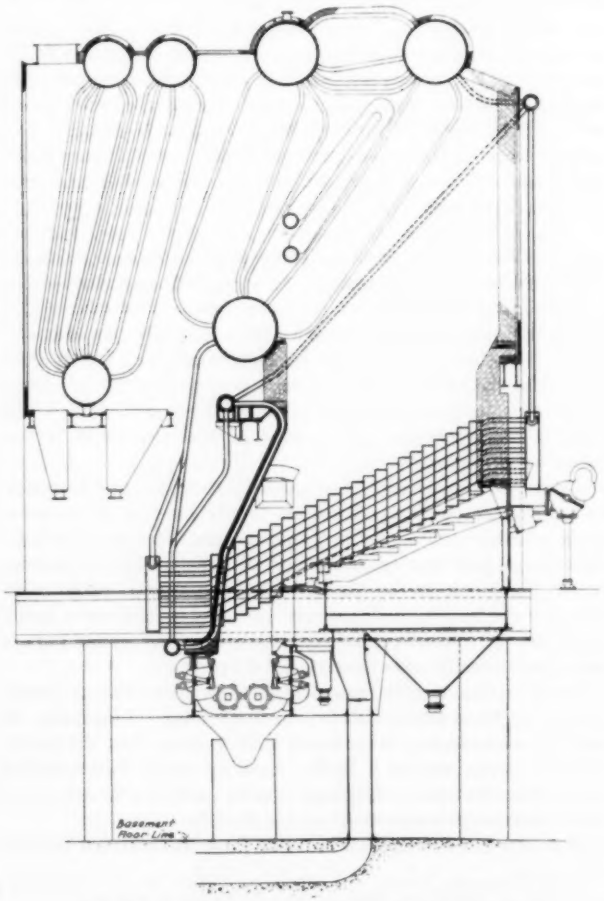

Fig. 17 Boiler Equipped With Water Walls

[9] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

furnaces, it is common practice to raise the CO_2 much higher than could be used in daily operation; with water walls, test conditions can be maintained in every-day operation. The combustible lost in the refuse with refractory furnaces is greater than with water walls, especially with inferior grades of coals, due to the interference with the proper combustion conditions produced by growth of slag on the side and rear walls. This condition does not occur with a properly designed water-cooled furnace.

Fifteen per cent CO_2 is commonly maintained in water-cooled stoker furnaces, while much lower figures are usual with entirely refractory-lined furnaces. It is a well-known fact that water walls show less increase in efficiency with good coal than with poorer grades, yet N. E. Funk (A.S.M.E. Trans., 1926, page 373) has reported an increase of from 2 to 3 per cent with water walls burning excellent eastern coals.

H. W. Lietch (A.S.M.E. Trans., 1926, page 129, fig. 8) shows tests on three boilers, Nos. 51, 63, and 73 with partial water cooling, and boiler No. 13 with no water cooling. Up to 150,000 lb. evaporation per hour, the three water-cooled furnaces show an average of 3 per cent higher efficiency even though the boilers are substantially smaller and the stokers have 25 per cent less grate area than that in the refractory furnace.

An interesting test was conducted on two boilers arranged as shown in Fig. 17 equipped with American Engineering Company's water walls and fired by Taylor stokers. The two units

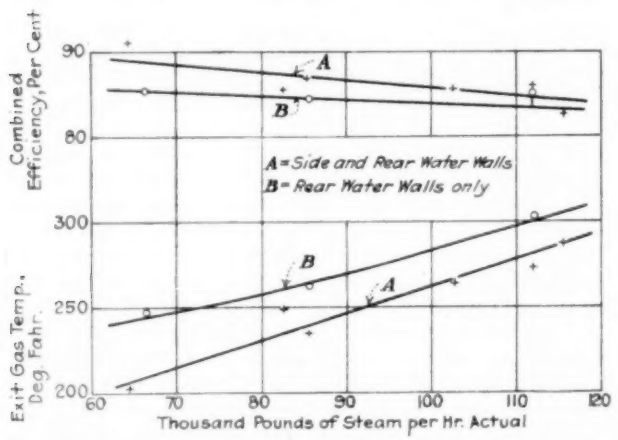

FIG. 18 PERFORMANCE GRAPHS SHOWING EFFECT OF VARYING WATER-WALL SURFACE

(1014-hp. Stirling boiler; 11 retorts, 37 tuyère Taylor stoker; 11,300 B.t.u. average per pound of coal as fired; 323 sq. ft. rear water wall; 143 sq. ft. side water wall.)

were exact duplicates but with the side water walls omitted from the second unit, decreasing the total water-wall surface by 32 per cent. The test results obtained are indicated in Fig. 18, showing an average gain of about 2 per cent for the side walls alone.

With reference to Mr. Moultrop's comment on the possible reduction in brickwork maintenance, the authors have found cases where the maintenance on completely refractory-lined furnaces averaged as high as $0.27 per ton for one year. Over a three-year period at one plant, it was found that the partially water-cooled furnaces effected a saving of $0.13 per ton over the complete refractory furnaces even though the water-cooled furnaces were subjected to more severe service.

Mr. Maynz brings out the fact that coal at $3.50 instead of $4.25 per ton would change the entire financial set up. This is true, but he has not credited the water walls with the increased capacity at which the boiler can be operated when equipped with a water-cooled furnace.

Boiler outage, which is a factor of prime importance in industrial plants, is also materially reduced by water walls. As the authors understand it, however, Mr. Maynz's criticism was

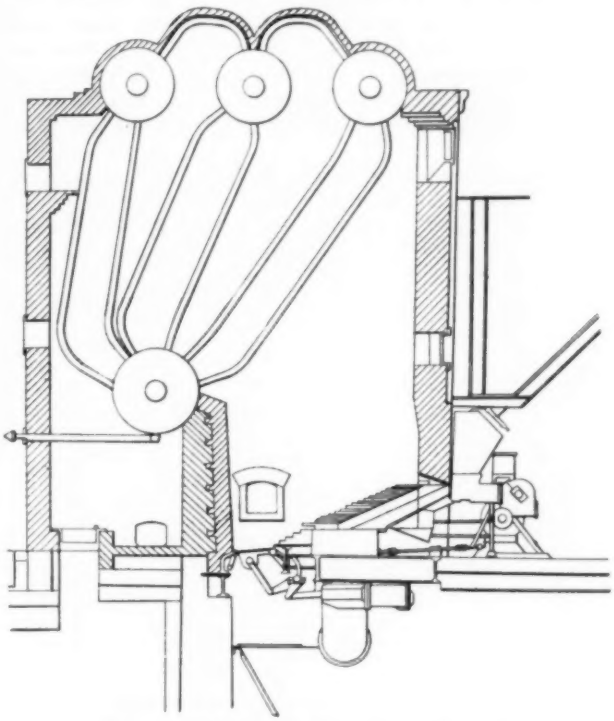

FIG. 19 BOILER WITH DUMP-TYPE STOKERS

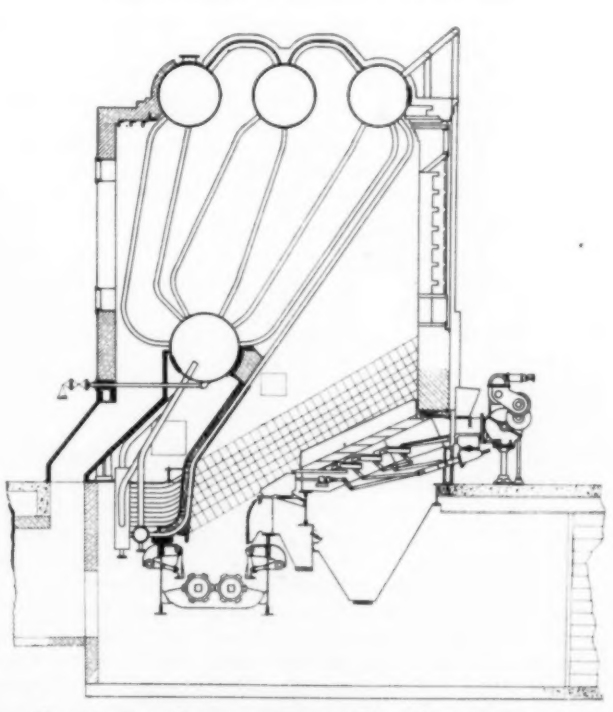

FIG. 20 SAME BOILER AS FIG. 19 WITH TAYLOR STOKERS

directed at the completely water-cooled furnace for the smaller boiler, whereas the partially water-cooled furnace shows a much better return.

The authors do not agree with Mr. Maynz that the rotary ash-discharge stoker cannot be justified for smaller boilers. Their use is increasing rapidly in the industrial field. In one case, an 823-hp. boiler, fired by a dump-type underfeed stoker, burning Ohio coal at $3 per ton, was replaced by a slightly larger rotary ash-discharge stoker with a rear water wall. The annual coal saving, using the same fuel, was $8400 per year, which, capitalized at 20 per cent, would justify an extra expenditure of $42,000 on the rotary ash-discharge stoker and water wall, far less than is required.

The dump-type stokers shown in Fig. 19 were replaced by Taylor stokers and American Engineering Company's water walls (Fig. 20) and gave 60 per cent more steam with a higher efficiency than before, at a cost of only $1.30 per pound of steam per hour extra capacity on a 312-hp. boiler.

Professor Christy asks about the effect of water-cooled walls on the stoker fuel bed when a high-volatile, high-sulphur coal, with low-fusing ash, is being burned, and the furnace is filled with a luminous flame which tends to shield the fuel bed from the walls.

Stoker practice has shown that an even flow of fuel across the width of a stoker can be maintained if the movement of the fuel at the sides is not retarded. When brickwork or other construction permits the fused ash to adhere to the wall, the flow of fuel along the sides is retarded, and, as the burning continues, the hindrance to the flow increases. Likewise, fused ash may accumulate on a refractory rear wall, impeding the discharge of the ash and consequently upsetting the combustion conditions in the entire fuel bed. Obviously, the use of water walls rectifies this condition. It is doubtful whether water walls have any real effect in modifying the furnace temperatures at points considerably distant from the walls.

Smoke-Abatement Progress in Salt Lake City

By J. BILLETER,[1] SALT LAKE CITY, UTAH

An observation tower 267 ft. above the street provides a convenient means of observing smoke conditions in Salt Lake City. A decrease in smoke from 10,891 min. per week in 1921 to 1050 min. per week in 1925 resulted from an active campaign. In 1925 active smoke-abatement work was discontinued, but was resumed again in 1927. During this time the minutes of smoke per week increased from 1050 to 2482. Police-court prosecution is found to produce but temporary results, and should be avoided if possible.

THE smoke department in Salt Lake City has conducted an active campaign against the making of smoke by industrial plants, larger heating plants, railroads, and residences. Observations are taken from an observation tower, of all dense-smoke periods (No. 3 or greater density of Ringelmann chart) of one or more minutes' duration. The observation tower is located centrally in the downtown district, 267 ft. above the street (on the top of the Walker Bank building).

It provides a view of the stacks of about 1300 heating and industrial plants. Many of these are operated smokelessly, so that actual contact and careful supervision from the tower are restricted to about 700 plants (not including railroads) at the present time. Telephone service enables the observer to communicate with any plant. Smoke violations observed are checked up as soon as possible by inspectors. If it is the fault of a new man firing at the place, instructions in proper firing methods are given. In case the plant is not in proper condition, pressure is brought to bear upon the responsible party to have the plant repaired. The primary duty of inspectors is the instruction of all firemen in the districts assigned to them. They caution firemen who show carelessness and inefficiency, and give any assistance that may be necessary when smoke occurs from breakdowns or other unexpected conditions.

Elimination of smoke from railroads consisted at first in equipping roundhouses and locomotives with smoke-prevention appliances, such as blowers, side-induction tubes, arches, and ring blowers. At present more attention is paid toward vigilance work and seeing that the equipment is kept up to date and used properly.

By far the most difficult problem is with residences. Experimental work done in 1922 and 1923 in small areas in the instruction of householders in the proper method of firing domestic equipment and supervision of operation after instruction proved conclusively that residence smoke could be reduced quite materially. Last year for the first time this work was carried out on a large scale. Each instructor was assigned a territory, over which he was held responsible. Results have been unusually good. Of course it is realized that this is only temporary relief and that the final solution will depend upon the use of smokeless fuels.

Inspection and supervision of the installation of new heating and power plants, including furnaces installed in residences, are important. The office directs all work and maintains coordination between the different activities of the smoke department.

[1] Chief Smoke Inspector, Salt Lake City Corp. Jun. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Fuels Division, Philadelphia, Pa., Oct. 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

EXPLANATION OF TABLES

Observation from the tower and the patrolling of heating and industrial plants are usually started some time during October, the date depending upon weather conditions. The average duration of a campaign is about 25 weeks, the maximum having been 28 weeks and the minimum 20 weeks. The first part of a campaign comprises the period from October to December 31, which has been marked B in the tables, while the period from January 1 to the end of a campaign has been denoted by A. In several tables, plants have been divided into five groups: Hotels, apartment houses, business houses, manufacturing, and miscellaneous plants.

TABLE 1 TOWER OBSERVATIONS

Year	Total minutes of smoke observed	No. of weeks	Minutes of smoke per week	Average length of smoke period	Mean temperature
1921 A	119,800	11	10,891	11.7	40
1921 B	40,588	9	4,510	7.3	41
1922 A	78,094	15	5,206	5.8	31
1922 B	31,771	10	3,177	4.0	38
1923 A	40,959	15	2,731	3.6	35
1923 B	28,491	13	2,192	3.8	42
1924 A	31,725	15	2,115	3.6	35
1924 B	12,912	10	1,291	3.8	35
1925 A	11,547	11	1,050	3.6	39
1927 B	34,742	14	2,482	4.9	43
1928 A	33,385	15	2,226	4.3	38
1928 B	13,691	12	1,141	4.1	40
1929 A	12,279	11	1,116	3.7	30

Table 1, prepared from data taken on the observation tower, shows the best means of determining the effectiveness of the work done. All sources of smoke except the railroads and residences are included. The smoke decreased from 10,891 min. per week in 1921 A to 1050 min. in 1925 A or 90 per cent. The decrease has been steady except in 1922 A, which shows an increase over 1921 B. Figures for 1921 B may be considerably low, since they are available for nine weeks only, or 72 per cent of the average period of a campaign.

TABLE 2 LIST OF WORST VIOLATORS

	Hotels		Apartments		Business		Manufacturing		Misc.	
Year	C[1]	D[1]	C	D	C	D	C	D	C	D
1922–1923	16	1670	31	5270	25	2739	11	2759	1	145
1923–1924	18	3005	34	3866	29	3318	8	752	2	79
1924–1925	14	1364	24	2232	32	2183	5	540	0	0
1925	4	270	10	715	3	210	5	296	0	0
1927–1928	19	2434	41	5320	23	2549	8	1042	1	40
Total	71	8743	140	17,473	112	10,999	37	5389	4	264
Average per plant	1	123	1	125	1	98	1	145	1	66

[1] C = No. of plants. D = Min. of smoke.

The average length of each smoke period in 1925 A was 3.6 min. This is a decrease from 11.7 minutes in 1921 A, or 60 per cent. For about two years the average length of each smoke period remained fairly constant, indicating that the lower limits had been reached.

In the year 1925 active smoke-abatement work was discontinued, finally resuming again in the fall of 1927. The retrogression during the time smoke-abatement work was stopped is surprising. Results show 1927 B was as bad as 1923 when compared with minutes of smoke observed, and as bad as 1922 when compared with the average length of each smoke period. However by 1928 B, within a year, the records of 1925 A were being approached. A further decrease in smoke, and particularly the shortening of the average smoke period, depends directly upon the elimination of habitual and continual smoke violators.

Table 2 gives a list of the worst violators, segregating them into five groups of hotels, apartments, business houses, manufacturing plants, and miscellaneous plants. The number of plants in each group and the amount of smoke observed are given. So far as smoke production is concerned, individual plants of different groups do not seem to differ materially one from another. This table, as well as all other tables, emphasizes the fact that much ground is lost when smoke-abatement work is discontinued for any great length of time. Considering the groups independently, apartments contribute the largest amount of smoke, business houses come second, hotels third, and manufacturing and miscellaneous plants fourth and fifth, respectively

Two separate lists of violating plants have been kept, one of plants that violate once during any one week, and the second of plants that violate two or more times during any one week. Table 3 has been prepared from the latter list, while the two figures with an asterisk are taken from the former. The sum of the two would equal the total number of violations observed.

TABLE 3 NUMBER OF VIOLATIONS RECORDED AT OBSERVATION TOWER

Year	No. of weeks	Total violations	Violations per week	
1923 B	13	587	45	*44
1924 A	16	599	37	
1924 B	1	366	33	
1925 A	14	519	37	*49
1925 B	12	306	26	
1927 B	13	516	40	
1928 A	15	709	47	
1928 B	5	145	29	
1929 A	10	200	20	

TABLE 4 VIOLATIONS DIVIDED AS TO GROUPS

		Violations in per cent				
Year	Total violations per week	Hotels	Apartments	Business	Manufacturing	Misc.
1923 B	45	22	38	35	4	1
1924 A	37	22	36	31	9	2
1924 B	33	23	24	37	3	3
1925 A	37	18	37	33	6	6
1925 B	26	20	43	27	5	5

1928 A	47	22	45	22	6	5
1928 B	29	20	43	22	9	6
1929 A	20	19	43	21	9	8

TABLE 5 POLICE COURT PROSECUTIONS

Year	Hotels	Apartments	Business	Manufacturing	Total
1921–1922	4	1	6	2	13
1922–1923	3	7			10
1923–1924	1				1
1927–1928	10	22	12	7	51
1928–1929	2	1	3	2	8
Total	20	31	21	11	

In Table 4 violations observed per week (as shown in Table 3) have been separated into the five groups, and are expressed in percentages. It is evident that violations of business houses have been decreasing and those of apartment houses increasing, while those of hotels have remained practically the same. As would be expected, apartment houses lead in number of violations, business houses are second, hotels third, manufacturing and miscellaneous plants fourth and fifth, respectively, thus confirming the observations of Table 2.

Police prosecutions have been resorted to only in extreme cases when other means of getting cooperation have failed. Results, usually, are not permanent. The effectiveness of police-court prosecutions has generally been overestimated. (See Table 5.)

Inspection work and calls at heating plants are a necessary part of smoke-abatement activity. While the number of inspections may in time be decreased, a certain amount of this work will always be necessary. The immediate checking up of violations by inspectors has been one of the most effective means of stopping the smoke. (See Table 6.)

Real progress in smoke abatement is best measured by the permanent improvements made in plants. Due to their nature, they must be done during mild weather, or when plants are not in use. At first, improvements consisted mostly in the installation of arches and the getting of proper chimneys, while lately the installation of stokers and air-panel doors has predominated. The present ordinance requires all plants except in residences to be equipped with a smokeless device and connected to a properly built chimney. (See Table 7.)

TABLE 6 INDUSTRIAL INSPECTIONS

	Hotels	Apts.	Bus.	Mfg.	Misc.	Total
Number of plants investigated	23	12	20	2	2	59
Minutes of smoke per plant—1 yr.	1382	1433	1097	1327	420	5659
Minutes of smoke per plant—2 yr.	190	285	166	11	84	736
Reduction in smoke, per cent	86	80	85	99	80	87

Table 8 shows the reduction of smoke through the installation of smokeless devices. All plants investigated were operated under identical conditions before and after the change. The figures include all types of equipment. With the predominance of stoker installations at present, still greater reduction in smoke may be expected.

Permits are required for all boiler and furnace installations, but it is useless to require permits unless ample means for enforcement are provided. During the first few years shown on Table 9, the per cent of unapproved installations was large. The excess of approvals over permits in 1926 and 1928 is due to the fact that permits were taken out one year and finally approved the following year. Since 1926 practically all installations have been approved.

* Full-time men.

During the winters of 1922–1923 and 1923–1924, some experimental work was done in giving proper instructions to operators of furnaces in residences. Part-time men (university stu-

dents) were employed, working about 2½ hours each morning beginning at 6:30 a.m. In 1928 this work was carried out on a large scale with good results. Besides university students, several full-time instructors were employed, working in two shifts, four hours in the morning beginning at about 6:30 a.m. and four hours beginning about 2:00 p.m. During the first part of 1929 university students were replaced by men from the engineering department such as surveyors, paving inspectors, etc. who have little work at that time of the year. It is believed that this method will not only provide them with additional work, but also insure that the smoke department has competent instructors and inspectors with a minimum amount of loss from labor turnover. This method may also help in securing the budget money needed to carry on this work.

Miscellaneous calls	312	194	321
Total	2633	2545	5115

The public is cooperating whole heartedly as seen from Table 11. Miscellaneous calls are those made to homes where a chimney is smoking and nobody is home, or other cases where instructions cannot be given. Out of 2351 instruction calls in 1928 B and 4794 instruction calls in 1929 A, 94 per cent and 95 per cent, respectively, were friendly and cooperative, while only 6 per cent and 5 per cent, respectively, were indifferent. Those actually hostile are included in the figures for "indifferent" and amount to less than 1 per cent in each case.

Three Stages of Smoke Abatement

An important part in any smoke campaign is the creation of a favorable attitude of citizens and officials toward smoke elimination. Public support is essential for success in any public undertaking, especially in smoke-abatement work.

Smoke abatement in its broadest term includes elimination of smoke as, (1) smoke cloud, especially during early morning hours, also toward evening, (2) visible smoke from all plants, and (3) invisible smoke.

Smoke Cloud. This is a mixture of smoke, carbon, and condensation or fog. The only means of judging the proportion of smoke and fog in the atmosphere is the color of the cloud. Smoke appears dark and black, while fog has a light grayish color. The shade of the color of the cloud obviously depends upon the relative proportion of smoke and fog.

The formation of the "cloud" usually takes place in the morning, and less frequently toward evening. The building of fires produces a large amount of smoke, while atmospheric conditions are favorable for fog formation. Salt Lake City is surrounded by mountainous regions covered with snow continually during the winter months. Due to large radiation the air is cooled below its dew point, separating the vapor into visible water drops. This condition is most pronounced in the morning when new fires are being built.

Smoke increases the tendency of fog formation, while fog in turn is favorable to smoke-cloud formation. Air movements are unusually low, and the direction of the wind changes constantly, creating an "eddy-current" effect, with the result that all smoke is collected into a dense cloud. This cloud hovers over a certain section of the city for some time, and later is blown to other sections with great rapidity. The density of such a cloud is almost impossible to determine. It varies in different parts of the cloud at different times and never remains constant. As the distance to the cloud increases, the apparent density increases. Several city blocks from the cloud, its density appears much greater than it really is. While it may be impossible to eliminate this cloud entirely at the present time, its size, density, and duration can and have been greatly decreased.

The public judges success in smoke abatement by the decrease of the "smoke cloud" more than anything else. The average person is not accustomed to watching smoke, and notices only general conditions of the atmosphere at the time he leaves home. By decreasing the morning cloud, his attention is gradually directed toward observations of smoke conditions generally, which later leads to observation of individual smokestacks. This process is slow, but nevertheless effective.

Visible Smoke. With the observation of smoking chimneys on the part of the public, a desire grows to eliminate that smoke. It is realized that the expense of keeping clean and healthy is unusually high and can be cut materially.

The most widely adapted means for smoke elimination is the use of proper methods of building and replenishing fires. Even with poor equipment, proper firing improves smoky conditions.

There are many useful smokeless devices on the market which help eliminate smoke from the larger hand-fired boilers. The use of smokeless fuels and automatic appliances has greatly increased. This factor has contributed more than any other toward permanent smokelessness. There are in Salt Lake City at present 275 small and 175 large stokers, 390 oil burners, and 128 gas installations.

Invisible Smoke. Invisible smoke includes undesirable, practically colorless gases, very small soot particles, dust, and other impurities. It constitutes a further step after elimination of visible smoke. Very little work has been done up to the present, except in industrial plants. This phase of smoke abatement is not included in the public's conception of smoke elimination. It has not been considered in this discussion.

Conclusions

1 With present equipment the amount of smoke made from all plants, except residences, can be kept low enough so as not to create a smoke cloud.

2 Elimination of the smoke cloud depends upon the elimination of a few heavy smokers, rather than many light smokers.

3 Most of the visible smoke is produced by a minority of plants which are continual and persistent in creating smoke.

4 Plants in different groups produce the same amount of smoke (except some industrial plants).

5 The percentage of cooperation from the different groups is the same.

6 Smoke performance of plants is not necessarily measured by the number of violations.

7 Results obtained from employing good firemen are only temporary, unless the plants are improved.

8 Police-court prosecution usually brings only temporary results, and should be avoided whenever possible.

9 Permanent smoke elimination may be obtained by installation of smokeless devices, especially stokers, and by burning smokeless fuel.

10 With proper care and attention, stoker fires can be cleaned and flues blown without making any smoke.

11 Smoke from the downtown district, due to better supervision, has been diminished greatly.

12 Violations from apartment houses have increased. This is due to the rapid increase in apartment houses, their scattered locations, and the difficulty of adequate supervision.

13 Violations from hotels have remained practically constant.

14 Effective smoke-abatement work requires a certain minimum number of inspectors over a long period of years. (The number of inspectors depends upon size and population of city.)

15 Smoke from residences can be reduced materially by giving instructions in the proper methods of building and replenishing fires.

16 Residence furnace operators are willing to cooperate if approached properly.

17 There is no relation between the mean monthly temperature and the amount of smoke made.

18 Smoke hours observed by the U. S. Weather Bureau apply to changes of the smoke cloud, and do not indicate the amount of visible smoke eliminated.

The Preparation of Anthracite

By T. M. CHANCE,[1] PHILADELPHIA, PA.

This paper covers the development and present practice of the methods used in the manufacturing process called "preparation," necessary to the conversion of the raw anthracite produced from the mines into the finished products consumed. The paper is divided into three main sections covering the crushing, sizing, and cleaning of the coal and into supplementary ones dealing with breaker design, operation, and efficiency.

THE TERM "preparation" is used in the anthracite industry to define the complete conversion of the raw run-of-mine product into the various sizes commercially consumed. It covers a complicated manufacturing process requiring the following steps: (1) Crushing, (2) sizing, and (3) cleaning.

Anthracite as mined is a heterogeneous mixture of pieces of coal, intergrown coal and refuse, and refuse, ranging in size from lumps of a hundred pounds or more to the finest dust. This material, containing from 12 to over 50 per cent of refuse, must be so crushed, sized, and cleaned as to meet the following general specifications:

PREPARATION STANDARDS

Size	Over hole, in.	Through hole, in.	Oversize, %	Undersize, %	Slate, %	Bone, %
Broken	3 7/16	4 7/16	5	10	2	2
Egg	2 8/16	3 7/16	5	15	2	3
Stove	1 9/16	2 8/16	5	15	3	4
Nut	11/16[3]	1 9/16	3	10[3]	4	5
Pea	9/16	11/16	5	10	7.5	7.5
Buckwheat	5/16[1]	9/16[1]	5[1]	20[1]	...[1]	...[1]
Rice	3/16[1]	5/16[1]	..[1]	20[1]	...[1]	...[1]
Barley	3/32[1]	3/16[1]	..[1]	20[1]	...[1]	...[1]
No. 4	3/64[1]	3/32[1]	..[1]	..[1]	...[1]	...[1]
Silt[2]	..	3/64[2]	..	..	...	...

[1] No common standard in use; size, etc., depends on contract requirements, most of these sizes being sold to users of large tonnage. Ash is reduced to from 12 per cent to 18 per cent depending on size.
[2] Generally a waste product.
[3] Nut, if made over 3/4-in. screen, can carry 15 per cent undersize.

Sizes larger than broken, known as lump and steamboat, are shipped but rarely, and broken itself is not produced at many collieries, the general trend in domestic demand being toward the smaller prepared sizes.

Those sizes larger than pea are termed "prepared sizes;" pea and smaller, "steam sizes;" and the material passing a 1/16-in. or 3/64-in. round-hole screen, "silt." Pea is sometimes included with the larger sizes, those above buckwheat then being called "domestic sizes." Silt is generally a waste product. There is, however, a limited use of it, both for sintering iron ore and for briquetting, but no extensive demand as a powdered-fuel source has yet developed.

The ratio of prepared to steam sizes is of vital importance to the anthracite producer as this determines the average selling price ("realization") for the shipped product. The prepared sizes used for domestic purposes naturally command very much higher prices than the steam sizes, and therefore the average realization from the coals of the Northern Field, running from 65 to 75 per cent in prepared sizes, is higher than in some parts of the Southern Field, in which less than 50 per cent of prepared sizes can be expected.

These differences in possible yield of prepared sizes are due either to (*a*) natural crushing of the coal underground by flexures or faults in the enclosing strata, (*b*) inherent weakness in physical structure of the coal itself, or (*c*) a combination of these two causes.

[1] Consulting Mining Engineer.

It must not be concluded from the foregoing that all coals of low prepared yield are necessarily of less intrinsic value, because it frequently happens that the total cost of production of coals of a smaller average sales realization is sufficiently low to make up for the handicap in selling price.

Whenever coal is handled, a certain amount of breakage, or degradation in size, is unavoidable. This occurs in every department of the preparation process, and the aim of the entire plant design should be to reduce it to the minimum possible.

That breakage which results in the production of silt constitutes a direct loss in shipped product, or yield, but in many cases the degradation of prepared sizes to those of steam grade is of equal economic importance. Thus, if the average difference in selling price between the prepared sizes and steam coal is taken at $4.50, then each per cent of loss in prepared means a direct loss of $0.055 per ton of shipped coal, and a plant increasing the prepared sizes from 60 to 65 per cent will show a direct increase in average sales price of $0.275 per ton.

The reduction of impurities below those at which the coal can be passed as merchantable would appear to constitute a direct economic loss, and this view was long held by the industry in general. The experience of the last few years has demonstrated the fallacy of this viewpoint, and it is now the aim of some of the largest producers to clean the coal to the highest standard possible. The gain from this policy is either the direct one of selling the product at a premium or the indirect one of maintaining output through periods of poor market demand.

Crushing

History. Anthracite was originally shipped in large sizes, lump and steamboat coal being used as a blast-furnace fuel and the chestnut and smaller sizes being left in the mines, loading being accomplished by tine forks. Such crushing as was practiced was done by hand, at the surface.

Rolls were introduced at an early date, and various types of smooth, corrugated, and toothed-roll faces were developed. It was soon found that the toothed roll most nearly approximated the efficient result that can be obtained manually with a pointed pick, and this type of roll came into general use.

Present Practice. Rolls were originally operated at peripheral speeds of 1000 ft. per min. or more, corresponding to the trajectory velocity of the falling material. These machines are directly belted to the lineshaft and are known as "high-speed rolls."

At present, geared rolls, operating at speeds of 250 to 300 ft., are generally used for crushing lump coal to broken and smaller. These machines are called "compound-geared rolls," and it is believed that their use has resulted in measurably improved crushing efficiency. In rolls of this type but one roll is power driven, the other being geared from it. This second driven roll is held up to its work by springs that provide a release should uncrushable material occur in the feed.

The favorite type of tooth is a curved pyramidal one with the hook facing forward—one such shape in common use being known as the "hawk's bill." The teeth are generally made of manganese steel and are either inserted in the roll shell or cast in segments attached thereto.

Fluted-face or corrugated high-speed rolls are generally used for crushing bone and refuse to free intergrown pure coal prior to rewashing. Both jaw and gyratory rock crushers are used

for breaking down large refuse, and high-speed hammer mills are used for comminuting the final breaker refuse when the latter is to be used for mine filling.

It is the present practice to crush the feed in two or three stages, as this results in larger yield of prepared sizes. Thus the lump may be crushed to steamboat, the latter to broken, and the broken to egg, the material smaller than each of these sizes being removed by screening ahead of each set of rolls. When no coal larger than stove is to be shipped, it is doubtful whether the reduced degradation by installing a fourth set of rolls would cover the increased cost of such extended crushing and screening.

With modern slow-speed rolls the material after crushing should contain at least 90 per cent prepared sizes, if the usual reduction per roll is adhered to and rolls of proper diameter are used. Lump rolls should be not less than 42 in. in diameter, and a diameter of 54 in. has been found to give results justifying the increased cost. Rolls crushing to egg should not be less than 36 in., and 42 or 46 in. diameters are efficient in service. The width varies with the tonnage to be handled, ranging from 34 to 50 in.

Modern roll frames and gears are generally made of cast steel, this material well withstanding the heavy shocks to which the rolls are subjected. The drive is by belt or rope, either of these providing the necessary slip when choking occurs.

Sizing

History. The first sizing of anthracite was carried out on stationary bar screens. At an early date, revolving screens, similar to stone trommels, were introduced, and these persisted in practice down to the last decade. It was found that serious breakage was caused by this type of screen due to the rolling of the coal. Further, blinding of the holes occurred if much clay were present in the coal; but a small area of the screen was available for actual use; and the wear per ton of coal was excessive when acid water was present.

These defects led to the adoption of the shaking type of screen, and today this is generally used, although stationary-bar lump screens are still retained at a few of the older collieries. Eckley B. Coxe, the greatest contributor to the mechanical side of anthracite preparation, experimented with various types of gyrating, traveling-bar, and other screens, but these have all been abandoned.

Present Practice. The most commonly used shaking screen is of the wood side-type suspended by flexible wood hangers and driven by wooden driving arms fitted with spring pieces to provide flexibility. It has the advantage of cheapness, low weight, and a snap at the end of the stroke tending to clear the mesh. Supporting legs at times replace the hanger boards. The capacity varies with the size of screen and character of feed, 125 tons per hour being a fair figure for a four-deck shaker 5 ft. wide and 17 ft. 3 in. long.

The following data cover most of the structural features in common use:

Shaker sides—3-in. or 4-in. by 6-in. oak or longleaf pine; 6-in. ship channels; various sizes of steel angles.

Hanger boards or supporting legs—1-in. by 8-in. oak or hickory spring boards; pin-connected wood hangers; pin-connected steel members; steel chains.

Segment side support—segment flange itself most desirable; side angles sometimes used, but objectionable due to loss of screen area.

Segment cross support—$2^1/_2$-in. and larger steel angles.

Screen segments—punched plate of steel, copper, Monel metal, bronze, and/or iron-chromium alloy, cast segments being at times used for lump coal; wire mesh is at times used for fine sizes, but not suited to coarse sizes due to blinding and wear.

Driving arms (usually in pairs)—3-in. or 4-in. by 6-in. wood arms, with wood spring pieces; wood, bar steel, or steel pipe with wristpin connections to shaker sides.

Driving shaft—$3^{15}/_{16}$-in. to 6-in. steel shaft fitted with cast-iron plain, babbitted, or bronze-bushed eccentrics or provided with forged crank throws.

Drive—belt, rope, or special drive, such as Texrope.

Horsepower—3 to 12 hp. per deck, depending on length and width.

Decks per driving arm—one, two, or, rarely, three.

Weight per deck—1000 to 6000 lb.

Crank or eccentric layout—two arms at 180 deg.; three arms at 120 deg.

Shaft speed and stroke—lump shaker, 120 to 150 r.p.m., 5 to 6 in.; prepared shakers, 145 to 160 r.p.m., 5 to 6 in.; steam shakers, 150 to 200 r.p.m., 3 to 6 in.

Screen dimensions—4 to 7 ft. inside width; 12 to 70 ft. length.

In general, the latest practice involves shorter stroke and higher speed for the steam sizes, and a preference is given by many to crankarm drives, although eccentrics predominate.

The screens are set at a pitch varying from $^1/_2$ to $1^1/_2$ in. per ft., this being largely a matter of individual judgment. Increased pitch decreases screening efficiency, but increases conveying capacity, while lump coal will travel forward faster than fine coal on a light pitch. A $^3/_4$-in. pitch is frequently used for prepared coal, with the hanger boards inclined forward perpendicular to the screen pitch. With this arrangement, a conveying speed of 60 ft. per min. is reached at 160 r.p.m.

Screen decks are usually superposed, each finer size descending to the next lower deck. Screening is also at times carried out on a single deck, the sizes being removed in series with the finest first.

Some designers incline the hanger boards to the rear at about $1^1/_2$-in. pitch, giving a positive vertical arc of travel. This tends to jerk the material forward at the end of each stroke, increasing capacity and cleaning the mesh. The screen can be set level or even slightly up-grade, which is advantageous in saving breaker height. The practice is not general, as there is a divided opinion as to its relative merits.

High-speed vibrating screens (familiar to the bituminous industry) set on a pitch at which the material will flow have not yet given the accurate sizing demanded by the anthracite industry. It is believed that these may be applied to sizing and dewatering fine coal and in a more nearly horizontal form to the sizing of larger coal.

Hydraulic classifiers, of the Dorr rake type, are successfully in use for sizing and dewatering silt, the operation being a combined cleaning and sizing one.

Cleaning

History. The first cleaning of anthracite was confined to underground hand-picking at the working "face." This is still practiced in flat dipping measures, but is impossible where the coal is loaded by gravity on steep pitches. The efficiency of such "face" preparation has steadily decreased with the working of thinner, dirtier coal beds and with the desired increased output per loader, causing more and more work to be done outside the mine.

When surface preparation came into practice, it was at first confined to hand-picking. Later, various types of mechanical separators were used, hand-picking being retained for the larger sizes and for recleaning the separator products.

Mechanical separators were generally called slaters or pickers and involved the use of: (*a*) Shape—coal, cubical; slate, flat. (*b*) Friction—coal, low coefficient of friction; slate, high coefficient of friction.

The simplest form of slater consists of a slot too narrow to pass the more or less cubical coal, but wide enough to admit the slate. This device is sometimes incorporated in the shaker screen itself. It is also built as a series of small-diameter rolls

revolving in the same direction, the slate passing through the spaces between the rolls and the coal traveling over them, a device of this latter type now being built by one manufacturer.

The frictional type of slater functions by causing the coal to jump a gap after passing over a frictional surface that retards the slate more than the refuse, the separating effect being produced by the greater kinetic energy acquired by the coal.

The latest and most successful type of frictional slater is known as the "spiral separator." It consists of a chute wound as a vertical helix, the coal and slate running down this spiral chute receiving differential centrifugal accelerations by reason of their different coefficients of friction and thus being in effect centrifugally separated. This type of machine may be operated either on wet or dry coal, but it does not do the best work unless the operation is a wholly wet or dry one.

Another late development is the "Ayres picker," using the frictional characteristics of a moving belt for separating the larger sizes.

Mechanical separators do not approach a metallurgically perfect result because:

1 Some coal is flat and some refuse cubical
2 Pieces of laminated coal and slate will go with coal or refuse in a frictional machine, depending on which side is under. Thus a thick piece of refuse with a thin surface of coal may be retained with the coal or a thin piece with a thick layer of coal sent to the refuse
3 Screening methods do not permit a sufficiently close approximation in size.

Hand-picking of the separated products has been generally required to produce a finally satisfactory separation. However, these mechanical devices served their purpose very well in the old dry-preparation breakers of the Northern Field. Their relative importance has steadily diminished with the increasing severity of the preparation problem, and there is little hope that they can be so improved as to become an important factor in future anthracite preparation.

In the Southern Field, the high proportion of refuse, coupled with an exceedingly wet product, caused an early adoption of wet cleaning methods. Hand-picking was retained for the larger sizes, but the hydraulic method of jigging was used for the smaller prepared sizes. There was thus a division of preparation practice into the dry breakers of the Northern Field, combinations of dry and wet breakers in that and other fields, and purely wet breakers in some parts of the Southern Field.

At the present time plants employing dry preparation are gradually being displaced by those using the various methods of wet cleaning, and in the latest installations in every district the newest plants are being equipped with wet cleaning devices throughout. This is due to the increased purity demanded in the product, the higher efficiency of the wet breaker, and the wet character of many breaker feeds. It is therefore thought unnecessary further to describe the essentially dry methods of operation formerly in favor, and the following notes on present practice and flow sheets in use will be confined to wet methods, even though some future breakers may be built to operate without wet cleaning of the crushed pure lump coal.

It is not thought that pneumatic tables of the type used for bituminous-coal cleaning will be adopted by the anthracite industry because these as now built require a dry feed, a condition not generally present in anthracite practice.

Present Practice—Preliminary Preparation. Lump coal is generally hand-picked to remove the large refuse. Picking is carried out on stationary platforms or on moving picking tables of the apron-conveyor or shaking type. From 2 to 16 men are usually required for this work, and 25 per cent of the raw feed sent to the breaker is frequently removed as refuse. In many cases 6-in. lump and 6 in. by $4^7/_{16}$ in. are separately picked, and at times the 4 in. by $3^7/_{16}$ in. broken is also cleaned. At a few collieries the mine rock is sent to the breaker and the good coal picked before transport to the refuse bank. If a large amount of bone or laminated coal and refuse occurs, this may be removed separately for further treatment.

All new collieries are being provided with moving picking tables, the platform being obsolete. When these tables are of the shaking type, they are either operated at long stroke (6 in.) and low speed (90 r.p.m.) or at short (2 in.) stroke and high speed (160 r.p.m.). The shaking table is supported on flexible, or pin-connected, legs and is vibrated by mechanism similar to that used for screens. This type appears to be in greatest favor where large pieces of refuse are to be removed. It is from 4 to $5^1/_2$ ft. wide and from 12 to 24 ft. long.

Principles of Cleaning by Hydraulic Methods. All wet methods now in use, with the exception of the sand-flotation process, depend on differences in the falling velocity in water of particles of coal and refuse. These differences may be utilized in either free-falling or hindered-settling apparatus, the jig and concentrating table being examples of the latter, the launder method a combination of the two, and the rake classifier an example of the former. Rittinger's formula for velocity of fall in water may be reduced to the following simple ratio for particles of like shape but unlike specific gravity:

$$V_c = \sqrt{D_c(\phi_c - 1)}$$
$$V_s = \sqrt{D_s(\phi_s - 1)}$$

When V_c = velocity of fall of coal in feet per second
V_s = velocity of fall of slate in feet per second
D_c = diameter of coal in feet
D_s = diameter of slate in feet
ϕ_c = specific gravity of coal
ϕ_s = specific gravity of slate

Hence if we wish to group particles of like falling velocity:

$$D_c(\phi_c - 1) = D_s(\phi_s - 1)$$

and for anthracite of 1.6 and slate of 2.4 specific gravity:

$$D_c = 2.333\ D_s$$

or a piece of coal 2.333 times as large as a piece of slate will fall with equal velocity if of the same shape. Hence, a smaller piece of coal will fall at less velocity and position itself above the slate, so that if the coal and slate are sized to within this ratio, a separation can be effected. A comparison of these ratios with those obtaining for bituminous coal of 1.4 and refuse of 2.4 specific gravity gives:

For anthracite: $D_c = 2.33\ D_s$
For bituminous: $D_c = 3.5\ D_s$

It will therefore be understood why apparatus satisfactory for the washing of bituminous coal may fail to meet the more rigorous requirements of anthracite preparation—a fact not always appreciated when apparatus from bituminous practice is installed in an anthracite plant.

The foregoing ratios apply to the free and unchecked fall of particles in what is termed a "free falling" process. As already stated, this process has had but a limited application in anthracite practice, a further development of this method known as "hindered settling" being the controlling principle in the apparatus used for hydraulic cleaning.

In hindered settling, the particles are permitted to approach each other until they touch, forming a heterogeneous mixture, or "bed," with the interstices filled with water, the hindered settling effect being produced by:

(*a*) Upward currents through the beds, as in jigs, classifiers, and trough washers

(*b*) Horizontal agitation, as in tables and trough washers.

The relative falling velocities of different-sized pieces of refuse cannot be calculated by a simple formula for hindered-settling conditions. However, the ratio of size of particles that can be separated by this method is considerably larger than that possible in free settling and, further, much lower velocities are needed in the upward-current water.

Jigs. The anthracite jig is a development of machines of similar character used in ore dressing, consisting of a screen supporting the bed of coal and refuse in a wooden or steel tank provided with means for introducing the raw feed and for removing the separated products, including the slush passing through the jig screen. In operation, the refuse is stratified above the coal by water pulsations passing up through the jig screen and collects thereon. The refuse is periodically or continuously withdrawn from this screen and the coal continuously removed from the upper portion of the bed. Anthracite jigs are of two generic types—plunger jigs and pan jigs. In the former, pulsations of the water are produced by a reciprocating plunger operated by eccentrics, while in the latter the jig screen is itself vertically reciprocated.

The coal is sometimes discharged by a water overflow, but in most cases a scraper conveyor is used for such discharge, overflow jigs operating with less breakage of the cleaned coal. Both plunger and pan jigs may or may not produce suction in the jig bed. The suction jig separates the materials by a series of harmonic pulsations of equal amount, the heavy material being elevated less rapidly and falling more rapidly than the light material. The non-suction jig utilizes a series of unidirectional pulsations to secure the separating result, the fall between pulsations occurring in comparatively still liquid. Both types have their adherents, and no marked advantages appear to be present in either system. The non-suction effect may be produced by introducing the overflow water under the plunger by operating the plunger or pan by a quick-return motion, or by fitting the plunger or pan with non-return valves (producing the effect of a single-acting pump).

Special types of plunger, pulsator, and pan jigs have been introduced for treating the various sizes of coal. Of late years the pan jig has come into extensive use and has been well liked by those using the jig method of preparation.

Various methods of mechanically removing the coal and refuse from the jig tank are in use, including conveyors, elevators, the Tench plunger, slate wheels, etc. The amount of refuse withdrawn is either automatically effected by a weighted pan, is manually regulated, or is controlled by gates in a manner similar to the cup-and-dam discharge common in ore-dressing practice.

Jigs treat each size in separate machines, the capacity of the units varying from 6 to 20 tons per hour, depending on the material treated and size of the jig.

Tables. Wet concentrating tables of the type used in ore-dressing plants are used at many collieries for the treatment of buckwheat and steam coal. The table consists of a plane rhomboid surface called the deck, adapted to be reciprocated rapidly by a quick-return motion and to be tilted both axially and transversely. The deck is covered with low steps or riffles running longitudinally in the direction of motion and is provided with a feed box at its upper inner corner and a wash-water launder along its upper edge. A fixed clean-coal-collecting chute runs along the lower longitudinal edge and a fixed refuse chute under the upper transverse edge.

The deck is supported on flexible, or hinged, legs and moves faster on its in-stroke than on its out-stroke, propelling the materials in the riffles toward the outer discharge end. The reciprocation produces a vibratory movement that agitates the material in the riffles and permits it to stratify under hindered settling conditions. The coal thus rises to the top and is sluiced down from the riffles by the wash water while the refuse travels longitudinally in the riffles toward the refuse discharge.

The zone of separation between the pure refuse and pure coal consists of a "twilight middlings zone," containing good coal, refuse, and intergrown coal and slate. The location of this zone may be controlled by the inclination of the table, the quantity of wash water, and the character of the table vibrations.

Tables have not come into extensive use for sizes larger than buckwheat coal, and their principal field appears to be in the cleaning of rice and smaller sizes. They treat from 3 to 15 tons per hour, dependent on the size of the material and character of the feed.

Trough Washers. The concentration of heavy minerals in hydraulic sluices has been practiced since the beginning of the ore-dressing art, and the same methods have been long employed in coal washing. In the simplest form, a long inclined sluice, provided with dams or riffles, is used, the coal washing down over these riffles and the refuse collecting therein. To avoid the manual cleaning of these riffles, moving dams consisting of flights carried on conveyor chains, or in some cases taking the form of a spiral flight within an inclined revolving drum, have been used continuously to remove the refuse. In other types classifier pockets are located along the bottom of the trough, the refuse falling in these pockets either unretarded or against an upward hydraulic current.

One of the latest types of trough washers of the last-mentioned type is the Rheolaveur, a machine that has been widely introduced on the Continent, especially in France and Belgium, where various types of trough washers have long been in favor. In this machine the difficulty of making a satisfactory separation, without either troughs of great length or the shipment of a middling product, is met by:

1 Continuously recirculating the middlings (consisting of pure coal, intergrown coal and refuse, and pure refuse) in a section of the trough between a primary refuse discharge and the middlings discharge. This builds up a thick bed between the pure coal and refuse similar to a jig bed and permits the discharge of the purer coal from the top of this bed as it passes over the middlings discharge.

2 Rewashing the refuse in additional troughs to free it of mechanically entrapped pure coal and middlings.

3 Rewashing the fine coal in separate troughs designed for this particular purpose.

In practice the unsized feed is sent to the primary washing trough. The larger refuse and middlings are removed from this primary trough by water-sealed elevators, and the clean coal is discharged from the end, after which it is screened into the various market sizes of coal. The steam coal passing through the screen is sent to the steam-coal-washing troughs for further treatment. The refuse from the primary trough is re-elevated for further treatment in the refuse-rewash trough.

The Rheolaveur would appear to use a combination of hindered-settling and frictional methods of separation, as the material rolling down in the trough is assisted in its stratification by differences in frictional resistance, while in its passage over the refuse and middlings discharges an upward current may be utilized for producing hindered-settling conditions. Further, in some of the discharges from the fine-coal trough free-settling conditions may be allowed to exist. Shape also plays an important part, the flat slate not being as readily transported through the trough by the washing water as the more cubical coal.

Classifiers and Settlers. Hydraulic classifiers are used to some

extent in the preparation of anthracite coal. These include series machines, designed to retreat the refuse—such as the "Hydrotator;" direct-flow classifiers of the Menzies, Grant, and other types; and free-settling rake classifiers such as are built by the Dorr company. The various types of classifiers are generally confined to operation on buckwheat and finer coal and function in a manner similar to that of their ore-dressing prototypes. Rake classifiers have been principally used to dewater tabled coal, and incidentally to secure a concentration by washing out the very fine high-ash material, this latter being carried to waste with the overflow water.

Settlers are either rectangular or conical settling tanks. They may or may not be provided with conveyors or other means for continuously removing the settled product. They serve to clarify the washery water either for reuse or before discharging it to waste. Of late years the Dorr type of circular thickener has come into considerable use for this purpose, thickeners upward of 80 ft. in diameter having been installed.

Résumé of Hydraulic-Cleaning Methods. The present separating methods successfully prepare anthracite to the normal slate and bone percentages with reasonable losses of coal in the refuse. If an improved standard is required, it can be attained only with the loss of excessive amounts of coal to the refuse, or if a better refuse is demanded, this is gained at the expense of decreased purity of the cleaned coal. Tabling is limited to the smaller sizes of coal, requires large building volume, but on the finer sizes does better work than most jigs. Jigging requires constant supervision. If the refuse gate draws slate too rapidly, good coal passes to the refuse, and if the slate is drawn too slowly, refuse is removed with the coal. Neither jigging nor tabling is an exact process; hence flat slate caught broadside in the separating currents may go with the coal and flat coal caught on edge go to the refuse. This particular defect is so troublesome at some Schuylkill collieries that the flat material (coal and slate) is removed by slot slaters and treated separately in "flat coal" jigs.

The existing methods of hydraulic cleaning all require storage of the feed for efficient operation. In addition, they demand either close sizing of the raw coal or recirculation of a middlings product to secure the desired results. Storage, close sizing of the raw coal, and middlings circulation all contribute to breakage of the coal, resulting in the degradation of the valuable prepared sizes to the cheaper steam coals and practically worthless silt. In addition, considerable breakage is caused within the separating machines themselves due to the attrition caused by the particles rubbing against each other in the relatively compact separating bed.

In considering the necessity of close sizing in the operation of anthracite jigs as generally installed, it should be noticed that, even with the small differences in screen opening allowed in the present anthracite-sizing scale, the largest pieces of coal will be three or more times that of the smallest pieces in any given size, because the coal breaks into particles of almost every conceivable shape. In practice the largest pieces in any one particular size weigh from two to five times as much as the smallest pieces. This great variation in size, shape, and weight causes the principal difficulty in the jigging of anthracite.

The Rheolaveur presents the great advantage of treating an unsized feed. It, however, requires a continuous recirculation of a part of the product under process, this middling treatment inherently producing breakage that, partially, at least, offsets that produced by close sizing of the raw coal. If the shipped product and refuse are of higher grade than that produced by jigging with an equivalent retreatment of the refuse, then this process should be a successful competitor because of the large tonnage which may be treated in a single unit. As it has already been used at five collieries on mixed sizes, one on steam coal, and two on silt, its future should naturally depend upon its success in meeting the rigorous standards now required by the anthracite industry.

Sand Flotation. The sand-flotation process is a commercial application of the float-and-sink method of testing coals in which a solution of density sufficient to float the coal, but permitting the refuse to sink, is used. It has been developed in the belief that it would overcome some of the difficulties inherent in the older methods of anthracite preparation.

Solutions of solids in liquid are so expensive and so difficult to recover from the separated products that attempts commercially to use them have not been successful. In sand flotation, the heavy solution is replaced by a high-density mechanical mixture of a comminuted solid (such as sand) and water, this mixture being termed a "fluid mass." It is maintained in a highly mobile condition by hydraulic agitation, and is thus caused to assume the general physical characteristics of a liquid of high density. The densities used in anthracite operation vary from 1.6 to above 1.75.

A steel-plate cylindro-conical type of separator has been generally used in commercial plants, this providing an efficient method of withdrawing the refuse from the high-density fluid mass. In this type of apparatus the lower part of the fluid mass is supported on an upwardly rising column of the hydraulic water required for agitation.

The conduit containing this column is termed the "classifier column," and the agitation water rises therethrough at a velocity permitting the refuse to fall, but sustaining most of the sand. The coal is discharged by causing some of the fluid mass to overflow, and the refuse is withdrawn through a water seal by interlocked slide valves at the base of the classifier column. A mechanical agitator is used with machines operating at the higher densities (this effecting a diffusion of the very small quantities of agitation water required for these densities), and additional agitation water may be introduced through the walls of the cone. The sand discharged with the separated products is reclaimed by screening and returned to the separating tank.

Sand flotation has been introduced at 31 anthracite collieries. When properly operated it can practically duplicate the results of the float-and-sink test. As it separates the coal by a purely flotational method, particles of any desired size, down to the smallest that can be separated from the sand, may be treated. Size, shape, and frictional characteristics therefore play no part in the separating process, the only property employed being that of specific gravity. The ash-content curve closely follows the specific-gravity curve in any given coal; therefore, such a specific-gravity separation affords close control of the ash in the washed coal and refuse.

The operating results of the last eight years have indicated that the use of sand flotation permits, among other things:

Shipment of pure coal
Minimum breakage
Low attendance
Plants of low first cost
Intermittent feed
Radical changes in quality of feed
Treatment of unsized feed.

Sand-flotation cones have been built to ship from 20 tons per hour to 200 tons per hour, ranging from 7 ft. 8 in. to 15 ft. in diameter, and 18-ft. diameter cones are now under construction of greater capacity.

Breaker Construction

The entire preparation plant is called a "breaker," and it is

built either as an integral unit, from mine-car dump to loading pockets, or as two detached structures—a rock house for preliminary treatment of lump and steamboat and the breaker proper handling a feed crushed to broken or egg.

Breakers are built to ship from 300 to 7000 tons per 8-hour day, and single-shift operation is the rule, although one company has operated some double-shift plants and another is contemplating an extensive two-shift program.

Construction is of:

Wood throughout
Steel frame with wood floors
Steel frame and concrete
Reinforced concrete (rare).

Sheathing is of wood, corrugated steel, asbestos-covered steel, or corrugated asbestos. Concrete and gypsum are at times used for roofing. Considerable areas of the siding are now glazed, metal sash being much used.

Breaker heights range from 60 to 200 ft., dependent on the flow sheet used. Gravity handling of all materials is sought for, and this increases the height. In all breakers the vibratory stresses due to the shaking screens is excessive, requiring much bracing, and high-concentrated loads are caused by pockets and tanks.

The present trend is toward fire-resistant construction, with steel frame, concrete floors, fireproof siding and roofing, and steel or concrete pockets. Chutes and hoppers in the newer breakers are of steel or concrete and are sometimes lined with tile.

The clean coal is either loaded from pockets into the railroad cars or storage of the prepared sizes is eliminated by the use of loading booms, pockets being retained, however, for the steam sizes. Loading booms reduce the breakage, as they do away with crushing in the pockets. Their use on all prepared sizes has been confined to four sand-flotation breakers, the Laflin colliery of the Hudson Coal Company being the first to adopt this practce.

Materials are handled by:

Scraper conveyors
Belt conveyors
Chain bucket elevators
Shaking chutes
Gravity chutes.

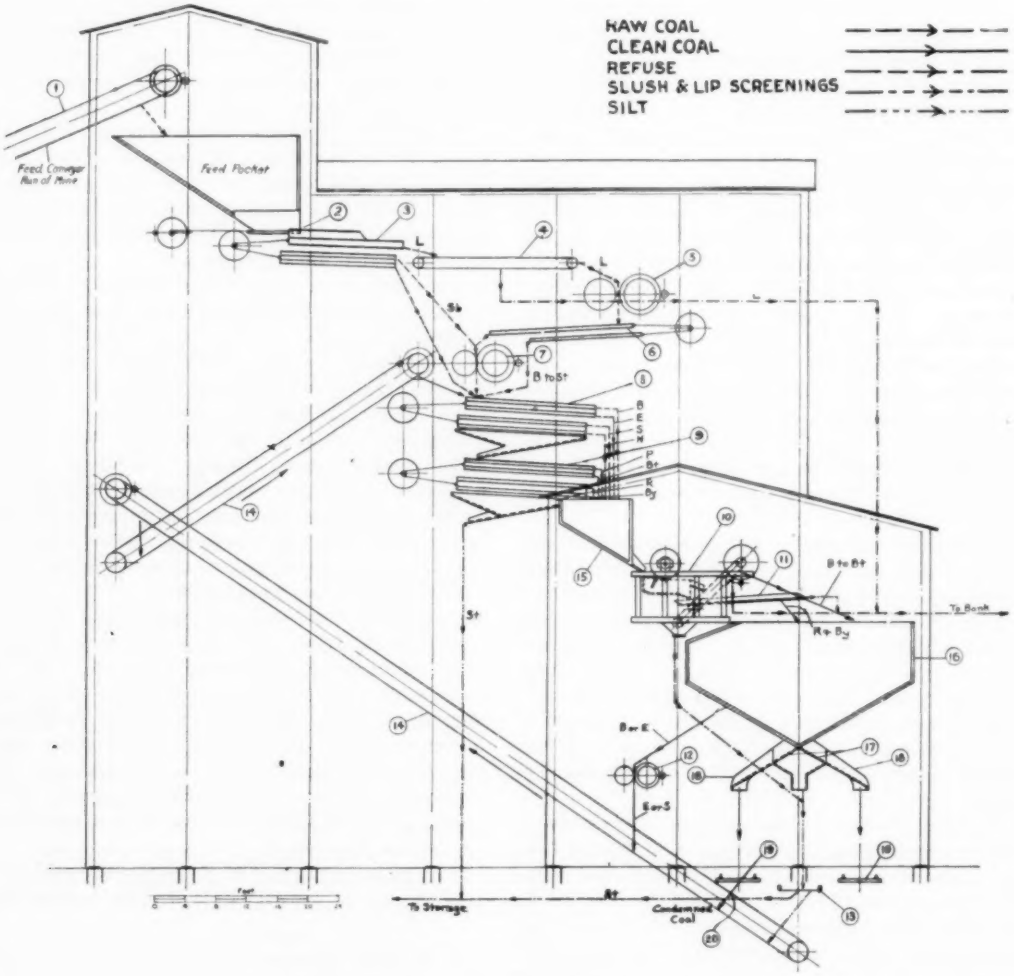

FIG. 1 TYPICAL FLOW SHEET FOR THE JIGGING SYSTEM

Scraper conveyors are in greatest favor, the breakage from the discharge of belt conveyors somewhat offsetting their other advantages. Bucket elevators should be used only for refuse and bone, because of breakage, but they are sometimes used on coal where room is limited. Elevation by scraper conveyors is common, a pitch as high as 37 deg. being used in some cases. Shaking chutes, designed similarly to shaking screens, are

efficient, but are confined to horizontal or lowering transport.

The feed to the breaker is by:

(*a*) Hoisting mine car to breaker dump—minimum coal breakage
(*b*) Inclined scraper conveyor—high maintenance
(*c*) Inclined belt conveyor—not suited to lump coal
(*d*) Self-dumping skip—increased breakage over (*a*).

Breaker Flow Sheets and Operation

The drawings, Figs. 1 and 2, illustrate typical flow sheets for the two systems now most widely used—the jigging system, requiring screening before cleaning, and the sand-flotation system, employing screening after cleaning. A Rheolaveur breaker could employ a flow sheet generally similar to the sand-flotation plant, but without the removal of silt before washing.

The flow sheets, with their accompanying legends, are self-explanatory, but it will be understood that the jigs are intended to represent any hydraulic cleaning device requiring screening before washing, such as classifiers and the like, and that various forms of refuse treatment for the recovery of laminated coal and bone may be employed.

The drawings have been prepared as diagrammatic vertical elevations of simple forms of breakers of the two general types. In Fig. 1, a scraper feed conveyor, apron conveyor, picking table, final sizing by removing the large sizes first, and pocket loading are illustrated. Fig. 2 shows a direct mine-car dump, a shaking picking table, final sizing by removing the large sizes last, and loading booms for the prepared sizes. It will of course be understood that all of these individually different devices could be, and in many cases are, used in either type of breaker. Further, hand picking of the steamboat, washing the steam sizes in separate sand-flotation units, special treatment of the bone, etc., while frequently practiced have not been shown in these simplified layouts.

The coal and refuse produced by the breaker are continuously inspected, and the operation of the plant is governed accordingly. In the past such inspection has been generally confined to hand picking and screening, but the float-and-sink method of testing is now coming into use at some collieries.

Every car of prepared coal that does not meet the standard of impurities and sizing is condemned and retreated. The cost of such retreatment (including that due to breakage) will run from $0.60 to upward of $1 per ton, and for this reason every effort is made to reduce condemnation to a minimum.

The labor employed naturally varies with the tonnage, from 70 to 125 men being used at many collieries. The number of men in some of the older breakers has increased in the last few years because of the higher standards to which the coal is being prepared.

That improved methods of preparation can result in marked savings is shown by the operating results of the new plant of the

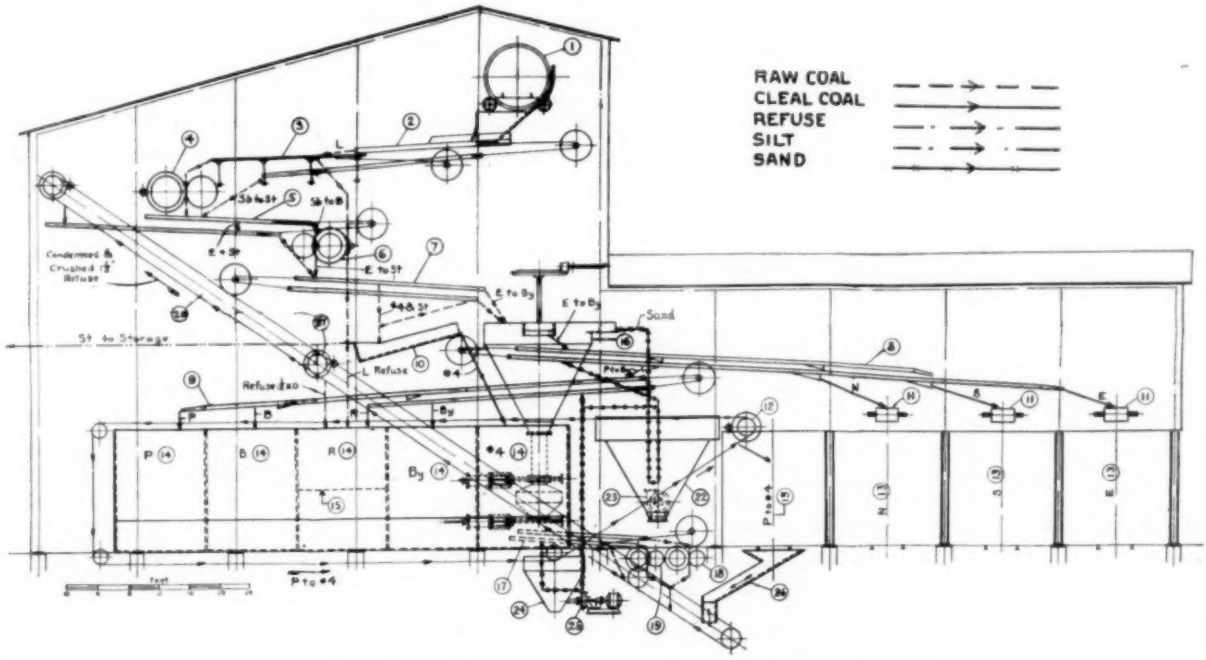

Fig. 2 Typical Flow Sheet for the Sand-Flotation System

St. Clair Coal Company, which replaced an old jig breaker designed some years ago. These are as follows:

Per cent of prepared sizes—increase of 6 per cent
Prepared yield—stationary, but with less refuse in coal
Total yield—stationary, but with less refuse in coal
Steam sizes ash—decrease of 10 per cent
Labor—decrease of 53 men.

The old breaker had a building volume of 1,260,000 cu. ft. and employed 80 to 90 men, depending on the preparation required. The new one has a volume of 492,000 cu. ft. and employs 27 men.

Water Supply

The water requirement of anthracite breakers is about 1 gal. per min. per ton shipped per day, although this quantity may be exceeded if care is not exercised in operating car-washing pits, lip screens, etc.

This water is used for shaking-screen sprays, operating wet cleaners, lip screens, and the like, and as it frequently consists of acid mine water, the wear on machinery is high. In the latest breakers, neutralization of the water, with adequate water recovery, is being introduced, with corresponding savings in first

cost of equipment (it being possible to eliminate much of the acid-resisting equipment now in use) and in renewals.

Breaker Efficiency

If the per cent of merchantable coal, of refuse, and of silt in the feed are known, then the ratio of coal shipped to coal fed would represent the efficiency of the plant as a whole. Such a figure is rarely obtainable because of the lack of accurate tests of the feed, but to indicate what may be expected of a modern well-designed plant, the figures of a 1100-ton test recently conducted are given.

CRUSHING, SCREENING, AND CLEANING EFFICIENCY OF BREAKER AND ROCK HOUSE

Feed of Steamboat (Lump Refuse Previously Removed)

$$\text{Efficiency} = \frac{\text{Shipped free coal on } 1/16 \text{ in.}}{\text{Net feed free coal on } 1/16 \text{ in.}}$$

$$\text{Efficiency} = \frac{81.245}{84.161}$$

Efficiency = 96.5 per cent

Loss in Per Cent of Feed

	Per cent
Silt produced in breaker	2.850
Coal sent to refuse bank	0.066
Total loss	2.916

Weight Reconciliation

	Per cent
Free coal shipped (egg and smaller)	81.245
Bone shipped with coal	1.309
Slate shipped with coal	1.336
Slate and bone sent to bank[1]	10.894
Coal sent to bank	0.066
Silt in feed	2.300
Silt made in breaker[1]	2.850
Total	100.000

[1] Lump refuse previously removed and feed crushed to steamboat before sending to rock house. All refuse crushed to nut before final rejection, to recover laminated coal and bone.

Discussion

H. E. Walter.[2] Improvements have been made in anthracite preparation during the last 15 years. In 1914 the average breaker had a production capacity of 500 to 700 tons per day. At present a number of breakers will produce in excess of 5000 tons per day, with fewer employees than were required in the old 500-ton breaker. The ash content in domestic sizes of anthracite varies between 8 and 12 per cent as against the old figure of from 12 to 15 per cent, and it is not unusual to find anthracite today with a heating value of 13,500 B.t.u. per lb. dry.

MAP OF ANTHRACITE COAL REGIONS OF PENNSYLVANIA AND ADJOINING COUNTIES

Economics of Reclamation of Anthracite Silt Coal and Culm

BY FREDERICK H. DECHANT,[1] READING, PA.

The paper deals generally with the production of fine-sized anthracite coal, its preparation for market, and its present uses. It defines several of the most important present markets, and the ultimate essential market to be created. It develops that anthracite can be most cheaply prepared for market by the coal companies themselves, taking in all sizes down to and including pulverized fuel. It recommends complete preparation by the coal-producing companies as the method of attaining the best economic position.

FINE anthracite coal or silt coal is the product of the wet preparation of standard market sizes of anthracite coal. It amounts to from 7 per cent to 13 per cent of the entire production of anthracite depending upon the particular field under consideration; being less in the northern, and greater in percentage of output in the southern fields. Its size ranges from $^{3}/_{32}$ in. diameter to dust, and it ordinarily is mixed with about 25 per cent of non-combustible foreign matter such as slate, rock, etc. as it is discharged from the colliery breaker. About 9,000,000 tons of fine anthracite coal are produced annually. Culm is a mixture of rock and coal, and is the product of the dry preparation of anthracite coal. Culm banks are of early origin, and may or may not contain valuable amounts of coal depending upon the methods employed at the mining operation where they are located.

According to statistics of the U. S. Bureau of Mines, Table 1 gives the quantities of culm, silt, and mixed materials by fields, in long tons.

The large deposits of culm are the result of market conditions which confronted the coal-mining industry of earlier days while their counterpart is now occupied by the deposits of silt; both the result of fundamental economics. This statement is more readily understood when it is realized that within a comparatively few years there has been created a market for anthracite coal in sizes smaller than pea coal, while prior to this time so-called undersized coal was relegated to the dump or culm bank. Since the creation and development of active markets for steam-sized anthracite coals down to No. 4 buckwheat (bird-eye) in size, the silt coal is now being deposited on silt banks at the rate of about 9,000,000 tons annually. Inasmuch as from 60 per cent to 80 per cent of this quantity of material is combustible, it represents an important item in the economics of anthracite-coal production both presently and in the future.

The solution of the problem lies in the development of uses for this fuel, and the resultant creation of markets which will relieve the mine-production costs of the burden of this waste, in proper ratio with its fuel value.

PRODUCTION AND CONSERVATION OF FINE ANTHRACITE COAL

Anthracite silt coal and coal from old culm banks is reclaimed by hydraulic processes of various nature. Briefly these processes depend upon the difference in specific gravity between the coal itself and the fluid in which it is in suspension. The fluid may be water, water mixed with rock dust and coal, water and sand, or water and oil. Various mechanical devices are employed in the operation of the processes, but the result achieved

TABLE 1 QUANTITIES OF CULM, SILT, AND MIXED MATERIALS BY FIELDS, IN LONG TONS

Field	Culm	Silt	Mixed	Total
Southern	37,745,000	36,815,000	10,000,000	84,560,000
Western Middle	43,785,000	40,735,000	17,175,000	101,695,000
Eastern Middle	2,430,000	6,200,000	1,385,000	10,015,000
Northern	8,125,000	8,035,000	1,795,000	17,955,000
Total for all fields	92,085,000	91,785,000	30,355,000	214,225,000

[1] W. H. Dechant & Sons, Consulting Engineers. Mem. A.S.M.E.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., October 7 to 10, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

by them is generally the same, although some are better adapted to the reclamation of the finest sizes of coal. The trade names of the processes in common use are: Chance process, the principle of which is the flotation of coal on a fluid mixture of sand and water in which slate and other refuse sinks; the Rheolaveur process using water as the carriage medium, and the Rheolaveur box for coal and slate separation; the Hydrotator using a fluid mixture of coal and water, and sometimes oil with counter water currents in sequential stages of separation.

Combined with these processes of separation there are three well-known thickening devices for the concentration of the coal slush, and the separation of it from its carriage water, namely, the Hydrotator, Hardinge, and the Dorr thickeners. Undoubtedly, one of the most difficult problems in the preparation of fine anthracite is its dewatering, but the simple piling of the prepared silt in protected conical banks as it is produced, and then the using of the material from such storage piles will cause a sufficient reduction in moisture content by gravitational action to justify the rehandling of the material.

It is reasonable to conclude therefore that there are today well-known methods, and the machinery for the accomplishment of the methods has been sufficiently developed to make practical the recovery of 95 per cent of the combustible material produced in the mining of anthracite coal, and for reclaiming the combustible material contained in existing culm banks.

Present Uses of Anthracite Silt Coal and Culm

Statistics reveal the fact that of the 9,000,000 tons of fine anthracite produced annually only 14 per cent is now being used, while the balance is being dumped, used for mine filling or permitted to flow directly to the streams draining the coal regions.

The uses now made of fine anthracite coals can be grouped into: (*a*) Direct-stoker firing under boilers; (*b*) pulverized and used as boiler fuel; (*c*) agglomerated into fuel briquettes with a binder; and (*d*) as fuel in the metal trades for such processes as sintering, and for the washing of foundry molds. These four groups combined show a present consumption of fine-anthracite coal of about 1,200,000 tons per year divided approximately as shown in Table 2.

TABLE 2 COAL CONSUMPTION IN TONS PER YEAR DIVIDED INTO FOUR GROUPS

Group (*a*)	375,000
Group (*b*)	500,000
Group (*c*)	300,000
Group (*d*)	25,000
Total	1,200,000

Screen tests indicate that an average of 30 per cent of all silt coal produced and in silt banks in the anthracite region will be retained on a $^{3}/_{64}$-in. mesh screen, and will contain particles ranging from $^{3}/_{16}$ in. down to $^{2}/_{64}$ in. in size. Silt coal of this sizing is suitable for direct firing on traveling-grate stokers such as the Coxe at combustion rates up to 24 lb. per sq. ft. of effective grate surface per hour.

As nearly as can be ascertained, pulverized anthracite coal is always produced from fine silt coal or so-called river coal, none of the larger sizes being pulverized. Several large and efficient pulverized-anthracite power-generating plants are in operation on this fuel giving excellent operating results. Pulverizing is best accomplished by means of the Hardinge type of mill, and combustion rates of 12,000 B.t.u. per cu. ft. of combustion volume are sustained.

Fuel briquettes made of anthracite silt have been more successfully produced since the war as a substitute for fresh-mined anthracite. Much care is needed in their preparation, and at best they constitute a substitute fuel to which the public must be educated gradually, and at great expense. While they may be developed to a greater degree of perfection for domestic use, it is believed they still will occupy a minor position among the uses for this coal, if for no other reason than that they are a substitute, which is valued by the producers at their plants in Pennsylvania at an average of $6.75 per net ton, and costs the user in Pennsylvania an average of $8 per net ton. Comparatively No. 1 buckwheat and pea coal mixed in equal proportions can be purchased for the same price.

Economic Position of Silt Coal as Boiler Fuel

Based upon the results of investigations at many localities in Pennsylvania and New England, it may be stated that with all relative plant cost, labor costs, and combustion efficiencies accounted for on a comparative basis of plant output, anthracite silt coal refined to 15 per cent ash, and sized from $^{3}/_{16}$ in. to $^{3}/_{64}$ in. inclusive at $3.27 per gross ton compares equally with bituminous low-volatile coal at $3.92 per net ton, at the point of consumption when burned as boiler fuel on stokers.

Pulverized-anthracite silt coal used as boiler fuel in furnaces designed especially for using it indicates that it can be burned at the rate of 20,000 B.t.u. per cu. ft. of combustion space, so that in comparison with stoker-fired silt coal its cost at the point of consumption may be about $1.20 per ton more than the cost of silt coal for direct stoker firing. Under average conditions within the range of freight limitations then, the adoption of pulverized anthracite coal as boiler fuel is more advantageous to both the power producer and the coal producer.

Anthracite silt coal if divided into two grades by screening, after cleaning for reduction in ash content, can be classified as boiler-stoker fuel and boiler fuel for pulverizing. It appears from Table 2 that approximately 7,800,000 tons per year out of the total production of silt is yet to find a market. Manifestly the natural market for this fuel is in the generation of electric power at large central stations, located near the sources of production of silt coal. Assuming that the producers do classify silt coal as suggested, it would then be possible to ship via rail for comparatively long hauls for direct-stoker firing the first grade of silt-coal fuel, or about 2,300,000 tons per year. The cost of producing this grade of fuel should not exceed 35 cents per gross ton at the point of origin, and could be sold for $1 to $1.25 per gross ton at the mines in competition with bituminous low-volatile coal in localities where the differential at the point of consumption was 65 cents or less per ton.

The balance or second grade of anthracite silt coal, i.e., under $^{3}/_{64}$ in. size, constitutes 70 per cent of all silt production, and after the deduction of the groups *a*, *c*, and *d* still leaves 5,400,000 tons per year for which there is now a very small market. A satisfactory market created for this slush, now waste fuel, would to a large measure solve the general anthracite problem, and to this end the author submits the following, in the belief that if carefully and thoroughly studied and practised, it will help the economic position of the industry. It is well known that the fine sizes of anthracite alone cannot be made to pay for themselves, but the greater the yield of marketable coal the less will ultimately be the cost of each ton of production.

A Suggested Program

The great objection to the use of pulverized anthracite coal even in moderately sized boiler plants is the first cost and the operating cost of the drying and grinding machinery. In large installations the cost of these elements is also a big factor. In few cases of the installation of drying and pulverizing equipment does the load factor on the entire operating and standby units exceed 50 per cent, so that the cost of pulverizing and drying is generally abnormal when considered as an element in the cost of operating at a single plant.

It appears to be a practical and economical thing to establish at suitable geographical centers with reference to the mining fields, central-station coal-pulverizing plants for converting the slush coal into marketable pulverized coal. A concept of such a plant might comprise works capable of pulverizing 250 tons of coal per hour. Drying would be accomplished by heat furnished through the combustion of a portion of the fuel. The pulverized coal could be shipped in specially constructed multi-hopper cars of air-tight construction similar to those in use in England, and hauled long distances to points of consumption.

Considering the factors in favor of such a program it is believed that coal, so prepared for use as pulverized fuel, could command a mine price of $2.20 per ton while its cost of preparation should not exceed 60 cents per ton. Prepared pulverized coal would widen the market for its use industrially. Central power stations as well as others could contract for pulverized fuel without the investment in pulverizing plant, and its consequent operation and maintenance. This should be attractive because it would relieve the power-generating organization from the problem of fuel preparation without the loss of its benefits as a fuel.

Centralized pulverized-coal preparation plants can be operated at a higher load factor than individual pulverizing plants, so that the cost of pulverizing and preparation will be reduced below what they now are at individual preparation plants.

The cost of boiler and combustion equipment for burning prepared pulverized anthracite coal is less than for the necessary equipment to burn anthracite fuel in any other way. Such equipment would comprise a storage bin with a capacity equal to the plant consumption over a period of several days or a week, coal conveyors, feeders, and burners; all relatively inexpensive parts of the equipment for burning pulverized fuel.

Pulverized anthracite coal is not subject to spontaneous combustion in storage so that the fire hazard usually present in the pulverizing plant is absent in a boiler plant fired with prepared pulverized anthracite coal.

Considered from the coal producers' standpoint it is not unreasonable to place the burden of complete anthracite-coal preparation from the broken-coal size down to pulverized coal on the mining companies, because by so doing they can effect a higher yield per ton of mine output, stabilize their output, and reduce the burden of expense generally on sized anthracite coals.

It is believed that a product such as silt coal is so different from any of the coals now handled by the railroad companies, also since it represents an additional tonnage, that it would be reasonable to expect that an adjustment should be made in the freight charges on this type of fuel, which would widen its market.

Conclusion

This paper has not been intended to deal with either the chemistry or thermodynamics of the combustion of anthracite silt coal, but rather its purpose is to define a means of converting the present average 10 per cent waste anthracite mining into marketable fuel.

It is the author's belief that this problem is fundamentally one of coal preparation, which should properly be assumed by the coal-producing companies primarily for the benefits to be derived.

Tentative locations are given on the attached map of the anthracite coal regions for proposed central pulverizing plants, and also there are indicated locations for new central power stations owned and operated by the power-generating companies having jurisdiction in the regions, which could be economically operated on prepared pulverized anthracite coal.

Generally the process that will convert fine anthracite coal into a marketable product at the least cost to the producer will ultimately be the most profitable.

Discussion

Frederick L. Moore.[2] There is without question an increasing demand for fine-size anthracite coal, and one source of supplying this demand is from the accumulated silt and culm banks and waste accumulations from the coal fields. This demand for anthracite fine sizes is due partly to the economic aspects of a cheaper fuel. The finer sizes of anthracite originally went on the market as a by-product without preparation, whereas today all sizes are prepared with equal care, and therefore contain equal heat value per pound of product. Therefore the consumer in a sense is getting more than he is paying for as the highest price of any of the anthracite fines is below the cost of production. This demand for the smaller sizes is also based on the possibilities of better combustion control and automatic features. It is true that the operator will have to produce what the consumer demands.

Some years ago lump coal was sold. Today no one seeks lump coal and none is sold. Likewise the demand for grate size is falling off, and there is practically no market for it. Egg size will soon follow the others. It becomes necessary therefore to crush these to finer sizes and produce a larger percentage of buckwheat and silt.

There seems to be considerable education required to teach the public how to burn anthracite properly. The public today is demanding close sizing of anthracite when such is not necessary nor economical and efficient. Anthracite can be burned successfully in all sizes, and the writer does not believe that briquetting will be practiced to any marked extent. Up to today it has not reached very large proportions.

That size designated as silt between $^3/_{16}$ and $^3/_{64}$ in. is now prepared and marketed as buckwheat No. 3 and No. 4, and not strictly silt. Correctly speaking silt is that below $^3/_{64}$ in. size mesh, and is being prepared today down to 60 mesh. The oversize in the present silt banks would be due to spillage from a broken or worn jacket or screen, and in that case would be but a small percentage of the reclaim. It is likely also to be the refuse from the larger sizes, and in that case would possibly be of low heat value. The finer the size the greater is the ash content, and below 60 mesh it does not at present seem economical to attempt to reclaim such fines. The use of such fines in all probabilities should be confined to or near the field of production due to the added cost of transportation. The writer does not believe that the very fine coal will ever be transported to distant points in great amounts.

Pulverized anthracite is being successfully produced and consumed in the southern field, but there is some question as to successfully and economically pulverizing the coal in the middle and northern fields due to its harder nature.

This is an age of great changes, and great changes are facing the anthracite industry. Just what the ultimate situation will be no one can tell exactly. Some of the trends are visible today, and it is well to follow these leads and prepare for the future. He who looks the furthest ahead will be the wisest.

The tendency today is toward greater use of fine sizes both by the commercial and household user due to the economical automatic feature of combustion control.

There is a certain amount of evolutionary process involved which is slow in progress and must be allowed to take its time and course. Education can hasten or deter this action. It has even been mentioned that coal be sacked the same as ce-

[2] Scranton Coal Co., Scranton, Pa. Mem. A.S.M.E.

ment. Just how and when this will be done no one can tell.

In all probability coal will be used more at or near the mine for the generation of power, possibly along the Susquehanna and Delaware rivers, and the power transmitted to the metropolitan areas. There should be no fear of a degenerated product in reclaimed fuel from waste banks as there is practically no deterioration in stored anthracite.

In one case the reclaimed fuel from an old bank tested over 14,000 B.t.u. while the fresh mine fuel from the same mine but different veins tested but over 12,000 B.t.u. This test was checked due to its apparent contradiction.

James A. Powell.[3] Much credit is due Mr. Dechant for the keen interest that he has manifested generally in the question of waste anthracite fuel. The writer is in accord with Mr. Dechant that fine sizes of anthracite coal should be prepared at the point of shipment, but questions just how far this preparation should be carried.

It is well known that silt and culm have from 10 to 15 per cent moisture which must be driven off before pulverizing, and it is certainly uneconomical to pay freight on this amount of water. Dryers can be installed at the mine, and operated cheaper than at the power plant. The writer therefore agrees entirely that the drying should be done at the point of shipment. It is perfectly feasible to pulverize the coal after drying at the point of shipment, and transport it in special cars, but this is not the most economical method. Pulverized-fuel bunkers large enough to take care of varying-load demands and irregularities in deliveries would be very expensive.

A suggested method which appears to be more economical is: (1) To dry the coal before shipment down to $1^1/_2$ to 2 per cent moisture, and then to ship in special hopper-bottom cars with a roof for keeping out moisture. (2) Coal should be stored in closed-type conventional raw-coal bunkers with capacity large enough to take care of irregularities in shipment. (3) Mills should take coal from raw-fuel bunkers and discharge to powdered-fuel bins as desired.

The pulverized-fuel installation would be no more expensive at the point of use, and as the power cost is of considerable importance, this would favor the milling at the point of use due to cheaper power cost.

A twelve-ton mill is now in use with river anthracite coal, moisture approximately 10 per cent, sand 10 to 12 per cent, with a power consumption of 30 kw-hr. per ton, and a maintenance of approximately two cents per ton which is less than other mills in this same plant using bituminous coal. This installation has demonstrated that anthracite can be dried and milled at a cost which is not prohibitive.

In regard to combustion equipment, this is a special study, which may be summarized as follows:

Today boiler-room equipment is more expensive for anthracite fuel than for bituminous, whether fired by stokers or in a pulverized form.

If a satisfactory and economical manner of preparing pulverized refuse anthracite is available, certainly development in the art of burning with a reduction in boiler cost will follow, such as higher rates of combustion by the combination of a small stoker for ignition with variable loads with very low volatile coal, or some other method.

Mr. Dechant's paper should stir up the operators to see that the silt and culm banks are not at present satisfactory as fuel for pulverized-fuel plants, and when a finished or semi-finished prepared coal can be offered to the utility field at a known price, then the power-plant designing engineer can work out the possibilities of such a fuel.

The writer understands from Mr. Dechant's paper that there are 5,400,000 tons annually available for pulverized fuel for electric generation. Assuming that a kilowatt-hour can be generated on two pounds of coal, this would give an output of 5,400,000,000 kw-hr. yearly, and with an average load factor of 50 per cent would require an installed capacity of 1,230,000 kw. to consume this fuel.

The author has selected eight station locations to consume this coal. This would mean an average of more than 150,000 kw. capacity stations. The writer does not believe that the territory shown on Mr. Dechant's map could absorb more than 300,000 kw. capacity today, so that it would appear that it will be many years before the annual electric generation would equal the silt and culm production unless all of the mines and railroads would electrify.

It is interesting to note that the public utilities for the entire state of Pennsylvania only used the equivalent of 6,700,000 tons of anthracite coal during the year of 1927 for fuel to produce electric generation.

Assuming a station cost of $100 per kw. the utilities would have to invest more than $120,000,000, and the coal operators between $7,500,000 and $15,000,000, depending upon whether the coal is simply dried or dried and pulverized. No estimate has been made of the expense necessary for special cars for transporting either dried or pulverized fuel.

The writer hopes that Mr. Dechant's paper will be an incentive for further study and work on this important subject so as to provide an economical solution for the important subject of refuse anthracite coal.

Author's Closure

It should be understood by all readers of this paper and the comments thereon that the incentive to prepare the fine sizes of anthracite for market lies in the possibility of converting this present-day loss to the mining companies into a highly profitable product with indications that the production of pulverized fuel presents the most logical course of accomplishment.

It is interesting to note that the utility companies will apparently be interested in prepared fuel of this nature so that there is a definite market awaiting developments along the line suggested.

FIG. 1 TYPICAL RECORD BY THE LEEDS AND NORTHRUP DAYLIGHT RECORDER, USING THE CASE PHOTOELECTRIC CELL
(The record, which reads from right to left, was taken on October 25, 1928; the weather was clear until about 11:30 a.m. From 11:30 a.m. to 3 p.m. there were occasional clouds; from then until dark the sky was somewhat overcast.)

Atmospheric Pollution and Sunlight

BY PHILIP DRINKER,[1] ROBERT M. THOMSON,[1] AND SARAH P. CHOATE,[1] BOSTON, MASS.

Records of daylight taken in Boston over a period of 16 months are correlated with dust counts, wind velocity, and per cent relative humidity. Results indicate a slight inverse relationship between dust counts and daylight (coefficient = −0.1861) and dust counts and wind velocity (coefficient = −0.1501). At the recording station on the southern edge of the city 68 per cent of the maximum daylight possible was received. Although conclusive proofs are lacking it seems probable that natural causes more than smoke pollution account for this transmission figure. Measurements of solar ultraviolet light by the acetone-methylene-blue method are plotted for six stations in Massachusetts. The degree of atmospheric pollution in the vicinity of the Boston recording station is not sufficient to destroy the therapeutic value of sunshine, even during the winter months.

DURING the past two years certain of the therapeutic and physical aspects of heliotherapy have been studied by the Department of Ventilation and Illumination, Harvard School of Public Health, in cooperation with the Department of Pediatrics of the Harvard Medical School and the Children's Hospital, Boston. The authors' part in the study has consisted in securing continuous records of visible daylight, records of atmospheric dust from air samples taken on the roof of the Harvard School of Public Health, and intermittent records of solar ultra-violet light inside and outside the neighboring Children's Hospital building, and at five other stations in Massachusetts.

Both ultra-violet and visible light, whether from the sun or from artificial sources, are known to be of importance in clinical medicine. Industry has been accused of so polluting the atmosphere with smoke that an appreciable part of the solar radiation to which we are entitled by nature never reaches us. If this is true, it is an important argument in favor of smoke abatement; if it cannot be demonstrated, efforts toward smoke abatement must be based in more general terms on the greater economy, convenience, and beauty of clean cities.

RECORDS OF VISIBLE DAYLIGHT

Records of visible daylight were taken by means of a Case photoelectric cell connected to a Leeds and Northrup recording potentiometer. This daylight recorder is similar to the one used by Ives in his investigations and has been fully described by him.[2]

The spectrophotoelectric curve of the Case cell agrees closely with the visibility curve of the human eye. The manufacturer claims that the photoelectric current generated in the cell is proportional to the intensity of the light incident to the cell.

The recording potentiometer, to quote Ives, is "merely a mechanism for making a chart record of a difference of potential between two points in a current circuit." The cell was connected across the potentiometer with a variable resistance in shunt so that the magnitude of the response of the recorder might be varied as desired. Fig. 1 shows a typical record for a bright October day with occasional clouds. Records of the short days in December and the long days in June are similar in type but differ in the area enclosed by the curve. By comparing points on these records for both sunny and cloudy days with actual determinations of daylight measured by the Macbeth illuminometer, a curve such as that of Fig. 2 is obtained.

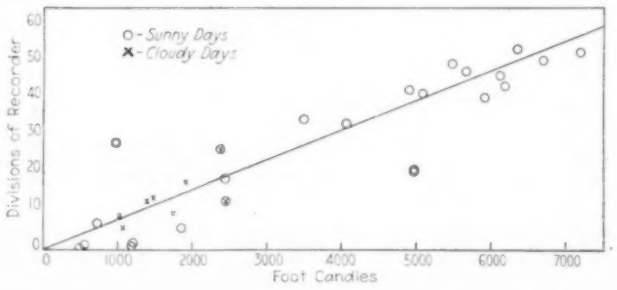

FIG. 2 RELATIONSHIP BETWEEN ACTUAL FOOT-CANDLES OF DAYLIGHT ILLUMINATION, TAKEN BY MACBETH ILLUMINOMETER WITH DAYLIGHT FILTER, AND RESPONSE OF THE DAYLIGHT RECORDER
(From the slope of the plotted line, the foot-candle-hour values of Fig. 3 were computed.)

The Leeds and Northrup recorder is driven by a very accurate constant-speed motor, so that the time intervals, abscissas in Fig. 1, are uniform and reliable. Consequently, if these records are integrated with a planimeter, the areas may be expressed in "foot-candle hours," a term devised for this particular study, whose meaning is obvious. Fig. 3 shows the results of records taken over some 16 months and calculated in this way.

The seasonal character of daylight variation is apparent on both the maximum and average curves. The maximum may be regarded as the theoretical curve obtained if precipitation (rain, snow, and fog) occurred only at night, and the days were all clear and sunny with occasional fleeting clouds and a 15- to 20-mile breeze. The average curve represents a mathematical

Presented at the Third National Fuels Meeting of the A.S.M.E. held at Philadelphia, Pa., October 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

moving average, in three-week periods, of the actual figures obtained.[3]

Atmospheric Dust Counts

By means of Owens' Jet Dust Counter[4], the dust particles in small measured volumes of air were collected twice daily on the roof of the Harvard School of Public Health, at 10:30 a.m. and 3:30 p.m., throughout the period covered by the daylight records. Owens' instrument was described at the first national meeting of the Fuels Division of this Society,[5] and is well known in this country and in England. It is especially well adapted to the estimation of particles of the order of 0.5 to 5 microns in size, particles small enough to float about in the air.

The actual points, or counts, and the three weeks' moving average values, calculated in the same way as the daylight averages in Fig. 3, are shown in Fig. 4. The seasonal character of this curve is apparent, and also certain cyclic phenomena not seen in the daylight curves. These cycles, appearing as humps in the curve, reoccur in an extension of the curve not shown in the present paper. It should be remembered that these data, also, are true only for the particular place where the observations were made.

Records of Solar Ultra-Violet Light

Solar ultra-violet radiation can be satisfactorily measured, but the methods now available are, for the most part, too elaborate and the equipment too expensive for general use.[6] There is,

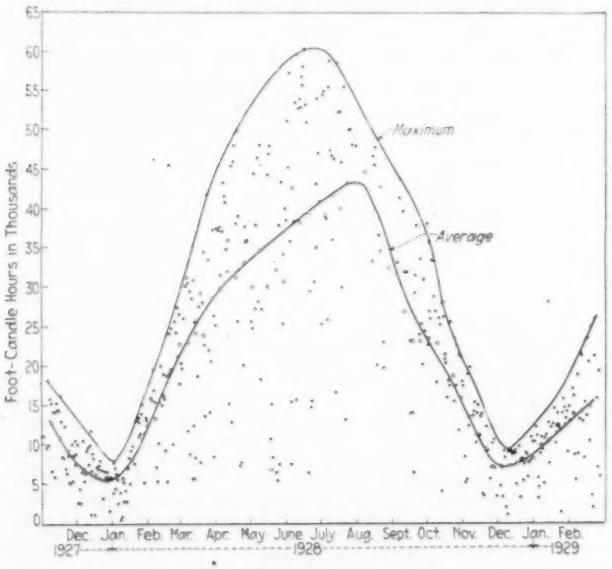

Fig. 3 Curves Showing Maximum Theoretical and Actual Average Daylight Illumination in Foot-Candle-Hours Measured From the Roof of the Harvard School of Public Health, Boston

unfortunately, no constant relationship between visible and ultra-violet solar radiation, so that ultra-violet cannot be estimated from the curves in Figs. 1 and 3. For practical reasons, therefore, a simple photochemical reaction was adopted, the bleaching of aqueous-acetone-methylene blue, suggested by Webster, Hill, and Eidinow,[7] and used by several investigators in this country.[8] A small clear quartz tube is filled with solution of methylene blue and exposed to the sun. After a suitable time interval, the tube is replaced by a fresh one, and the old tube matched against a set of fixed standards. The standards are graded in "units of methylene blue decomposed." Although this scale cannot be translated into any standard physical or

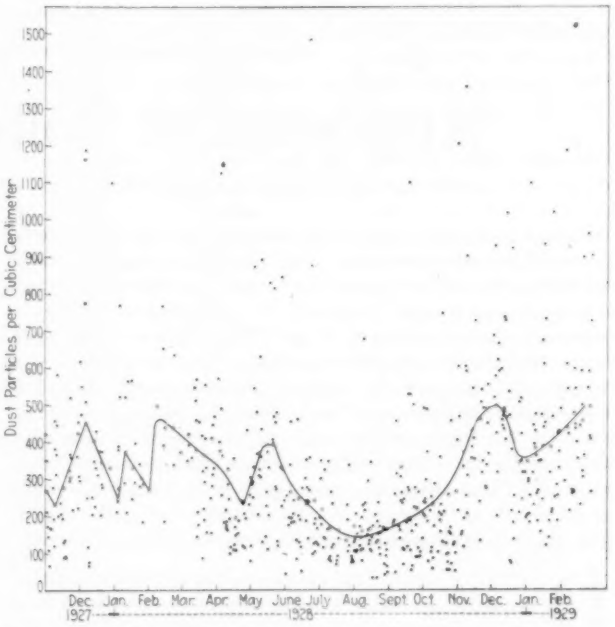

Fig. 4 Dust Particles Per Cubic Centimeter of Air as Shown by Owens' Jet Dust Counter

(Samples were taken twice daily over the periods covered from the roof of the same building in which the daylight recorder was installed.)

photometric units, it is useful in grading exposure of patients to solar ultra-violet light.

The averaged results of observations made at five stations in different parts of Massachusetts, as compared with the results from Rutland alone, are shown in Fig. 5. It would appear that Rutland, at an altitude of 1200 ft., is the station best adapted for ultra-violet treatments.

This method of estimated solar ultra-violet radiation is open to serious criticism on several grounds, chief of which is the fact that the reaction is, to some extent, caused by wave lengths other than those which are physiologically significant. The reaction, moreover, is somewhat affected by temperature. In spite of these objections it is felt that, for the purpose of the present study, the use of the method was justified.

Standard Meteorological Data

From the Boston station of the U. S. Weather Bureau, daily

[3] It would be unwarranted to assume that these figures are applicable to other cities, or even to the downtown districts of Boston. The Harvard School of Public Health is on the outskirts of Boston, and the prevailing wind is favorable to the locality.

Clark, *American Journal of Physiology*, 1924, vol. 69, p. 200; and "The Zinc-Sulphide Method of Measuring Ultra-Violet Radiation and the Results of a Year's Observations on Baltimore Sunshine," by J. H. Clark, *American Journal of Hygiene*, 1929, vol. 9, p. 646.

records were obtained of wind velocity, temperature, per cent relative humidity, and barometric pressure at times corresponding approximately to the hours when the dust counts were taken. The building where the counts were taken is about two miles southwest of the Weather Bureau station and at the same general altitude. It is reasonable to assume, therefore, that the Weather Bureau data can be applied without introducing any appreciable error.

Relation Between Daylight, Dust Counts, and Meteorological Data

Although this study was actually carried out over a two-year period, continuous data for 16 months only are used here. These data are sufficient to permit a statistical interpretation of the results and to indicate which variations are due simply to chance and which to definite physical causes.

The amount of daylight recorded depends, of course, on several factors other than dust counts. Of these, wind velocity and per cent relative humidity seem to be the most important. The effect of dust counts on daylight is of especial interest. Do these factors show a definite inverse dependence or relationship, or are other factors like relative humidity and wind velocity of greater importance?

It is possible by statistical methods[9] to determine the coefficient of partial correlation between daylight and dust counts by holding constant the variables, wind velocity and per cent relative humidity, thus eliminating the variability of wind velocity and relative humidity without actually ignoring these factors themselves. This mathematical procedure may be approximated by selecting from the tabulated data a series in which humidity and wind velocity are approximately constant, but dust counts and daylight vary. This course, however, although the more obvious one, is less accurate than the method used and equally laborious.

For daylight data the ratio of the actual values obtained on the recorder to the maximum curve of Fig. 3 was used instead of the average curve. On a bright day this ratio would be close to unity, on a dark day it would be very low regardless of the season of the year. This ratio was used in order to minimize the seasonal character of daylight variation, which otherwise might have had a quite misleading effect. The results are shown in Table 1.

TABLE 1 COEFFICIENTS OF PARTIAL CORRELATION

$r_{12.34} = -0.1861$ (count and per cent maximum daylight)
$r_{13.24} = -0.1501$ (count and wind velocity)
$r_{14.23} = -0.0357$ (count and per cent relative humidity)

The subscripts of r indicate the variable involved, those to the right of the period being held constant in accordance with the following: Count = 1, sunlight = 2, wind velocity = 3, and per cent relative humidity = 4.

According to standard statistical practice, these coefficients show a slight inverse relationship in the first two cases, whereas the relationship in the third is too low to be worth considering. Perfect correlation would, of course, give a coefficient of 1. The results indicate, therefore, that as dust counts increase daylight decreases somewhat, and that a high wind reduces dust counts to some extent.

Per Cent Transmission of Daylight

The ratio of the areas under the average and maximum curves of Fig. 3 is 0.84. Instead of using the average data, however, it is more accurate to use the summation of the ratios between the actual points and the maximum curve, as they were used in obtaining the correlation ratios. This summation gives a ratio of 0.68; that is, at this particular station, 68 per cent of the maximum daylight theoretically obtainable was reached. If a daylight recorder were installed 10 or 15 miles outside the city limits and another in the downtown section, values between the two would probably be recorded at the station where the tests were made. The differences then might be ascribed to man-made pollution and not to natural causes.

[9] An Introduction to the Theory of Statistics, by G. U. Yule. Philadelphia: J. B. Lippincott Co., 1922.

Observations

Any dense cloud of smoke, either black or white, can shut off an appreciable amount of daylight, both visible and ultra-violet radiations. Theoretically, the smaller particles (0.5μ) are the more effective in shutting off the short wave lengths of solar ultra-violet (0.35μ to 0.4μ). Particles from volcanic eruptions or explosions, like that of Krakatoa[10] in 1883, are of the order of 1.85μ, particle size being determined by the effect upon daylight.

A few years ago measurements were made by this laboratory of the size of the particles emitted from the stacks of a large power plant burning powdered coal. The samples were collected from the top of the stack at about the middle point. Under the microscope these particles were found to be approximately spherical, of glassy appearance, and somewhat pitted; among them, an occasional black particle, presumably of coke or unburned coal, occurred. These particles compared in size with the volcanic ash, most of them being less than one micron in diameter. The temperature and velocity of their carrying gases at emission from the top of the stack were, however, in no way comparable to those of a volcanic explosion. Under present methods of power-plant operation it is quite impossible for the particles to be carried for great distances.

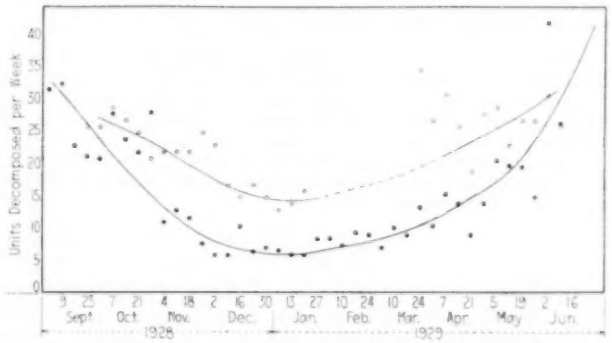

FIG. 5 RECORDS OF SOLAR ULTRA-VIOLET LIGHT BY THE METHYLENE BLUE GAGE

(Data from five stations in Massachusetts which showed values of the same order were averaged and plotted in one curve; data from Rutland, which showed consistently higher values—probably due to altitude—were plotted separately.)

Nevertheless, the ash emitted from the chimneys of some plants burning powdered coal is reaching such amounts that it must be measured in tons rather than pounds per day. The color of this ash is so light that a dense cloud of it does not necessarily appear offensive in terms of the Ringelmann chart. Obviously, then, a different method of judging atmospheric pollution from powdered-coal ash is desirable.

In a recent paper, Shrader, Coblentz, and Korff[11] state: "The belief that atmospheric pollution actually occludes ultra-violet light to a very great extent is well founded." They found that the ultra-violet transmission was greater at the tops of tall buildings than at street level, that it was greater in the country than

[10] Physics of the Air, by W. J. Humphreys, p. 572. Philadelphia: The Franklin Institute, 1920.

[11] Effect of Atmospheric Pollution Upon Incidence of Solar Ultra-Violet Light, by J. H. Shrader, M. H. Coblentz, and F. A. Korff, *American Journal of Public Health and the Nation's Health*, 1929, vol. 19, p. 717.

in the city, and that it was, of course, greater on bright sunny days than on dark cloudy days. They do not attempt to show whether health is affected by the amount of pollution observed in Baltimore.

Dr. Edwin T. Wyman[12] has demonstrated the effectiveness of applying solar ultra-violet to infants throughout the winter months in the Boston Children's Hospital. In December a much longer exposure is necessary than in September or March, but the treatment has been found to be so practical a therapeutic measure that a large solarium equipped with "Cel-O-Glass" windows[13] is being installed on the top floor of one of the new hospital buildings. The degree of atmospheric pollution occurring in this vicinity, therefore, is not sufficient to destroy the therapeutic value of sunshine. To what extent it reduces the effectiveness of sunshine and makes longer exposures necessary cannot be definitely determined from the facts now available.

Tisdall and Brown[14] believe that rickets occur rarely in localities where the height of the sun at noon exceeds 35 deg. For approximately 12 weeks, in November, December, and January, the noon sun in Boston is below 35 deg., and it is during that period that the Children's Hospital will be prepared to supplement natural with artificial solar ultra-violet radiation. Even were there no atmospheric pollution, this condition would probably not be significantly altered.

[12] The Prevention and Treatment of Rickets, by E. T. Wyman, *Boston Medical and Surgical Journal*, 1927, vol. 197, p. 376.

[13] Cel-O-Glass is cheaper than other quartz substitutes; it transmits solar ultra-violet almost as effectively (about half as well as pure quartz), and it has a low deterioration factor.

[14] Relation of the Altitude of the Sun to its Antirachitic Effect, by F. F. Tisdall and Alan Brown, *Journal of the American Medical Association*, 1928, vol. 92, p. 860.

Kimball and Hand,[15] and Owens [16] have demonstrated that an inverse relation, non-linear in character, exists between dust counts and wind velocity, the dust counts being highest on still days. The data used in both these investigations were comparatively few and represent extreme rather than routine conditions. In the present study some 550 pairs of values for dust count and wind velocity were secured. The day to day relationship is expressed by the low partial correlation coefficient, —0.1501. The difference between this value and those indicated by the previous investigators are probably explained by these differences in procedure. Had selected data been used the results given in this paper would have been more nearly like those cited.

It is clear that we suffer in this country from lack of adequate comparative data, routinely taken under similar conditions, and by similar methods in our leading cities. The Advisory Committee on Atmospheric Pollution, first organized under the Air Ministry and later under the Department of Scientific and Industrial Research, has provided an efficient service for the British Isles. The Weather Bureau would be well equipped to make similar observations at its different stations throughout the United States, and could easily undertake the work if the various groups and associations interested in atmospheric pollution would unite to initiate the necessary legislation in Congress.

The authors wish to acknowledge their obligation to Laura A. Cauble of the National Conference Board on Sanitation for her generosity in supplying the daylight recorder used in this study.

FSP-52-9

Economic Status of Anthracite and Factors Affecting Its Use as a Domestic-Heating Fuel

By A. F. DUEMLER,[1] NEW YORK, N. Y.

Pennsylvania anthracite as a smokeless fuel for domestic-heating purposes occupies an important economic position, and the producing fields are located central to the most densely populated area of the United States. The anthracite industry has for the past several years been engaged in extensive research pertaining to the utilization of this fuel for domestic heating. This work is being carried on in three stages, as follows:

1 By direct service contact with the consumer in an extensive survey to determine and classify factors affecting efficient utilization.

2 By laboratory research to determine relative efficiencies of various sizes of anthracite as one size or varying mixtures of sizes.

3 By laboratory research for the development and testing of equipment which will provide greatest convenience and efficiency in utilization.

The research work in the first stage has been particularly valuable in that it brings out the factors to be shared and considered by interests other than the anthracite industry.

TO CONVEY an idea of the important economic status of anthracite as a smokeless domestic fuel one needs only to refer to tabulations available through the U. S. Census Bureau and the U. S. Department of Commerce, which show the population of the country by states and the land area occupied by that population. This information can be reduced to density of population per square mile of land area. Then compare this information, as it applies to the eleven New England and Middle Atlantic States and District of Columbia, with the country as a whole, and then locate the geographic position of the anthracite fields in northeastern Pennsylvania.

TABLE 1—NET LAND AREAS AND POPULATION OF NEW ENGLAND AND MIDDLE ATLANTIC STATES

(U. S. Department of Commerce estimate as of July 1, 1928)

State	Rank in net land area	Net land area, square miles	Population	Population per square mile
New York	29	47,654	11,550,000	242.3
Pennsylvania	32	44,832	9,854,000	219.7
Maine	38	29,895	795,000	26.6
Maryland	41	9,941	1,616,000	162.5
Vermont	42	9,124	352,428	38.6
New Hampshire	43	9,031	456,000	50.4
Massachusetts	44	8,093	4,290,000	530.0
New Jersey	45	7,514	3,821,000	508.5
Connecticut	46	4,820	1,667,000	345.8
Delaware	47	1,965	244,000	124.1
Rhode Island	48	1,067	716,000	671.0
District of Columbia	49	62	552,000	8903.2
Total		174,037	35,913,428	

Population per square mile (35,913,428 ÷ 174,037).....206.3

Compare this figure of 206.3 persons per square mile in the district covered in Table 1 with the figure of 35.5 per square mile for the entire country.

Until five years ago anthracite as a domestic fuel in the area outlined was without competition, and the questions of smoke and air pollution due to domestic fuel consumption were negligible ones. However, the entrance of other fuels into this market during the last few years has developed a new era in the preparation, marketing, and utilization of anthracite which has proved profitable to the public as well as to the anthracite industry. The quality of the product being sent to market has been improved greatly through the extensive development of mechanical-cleaning methods.

Service to the consumer has been extended widely, not only in the Middle Atlantic and New England states, but as far west as Milwaukee, St. Paul, and Minneapolis. This service from the anthracite producers is being carried on principally through several thousand retail dealers as a part of their present merchandising methods.

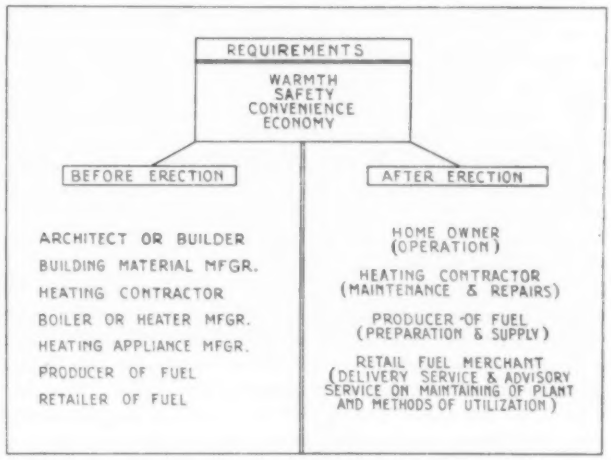

FIG. 1 FACTORS INVOLVED IN DOMESTIC-HEATING COMFORT

Utilization by the consumer has been improved greatly through this service, and other educational methods and records show that the anthracite industry was first as a fuel industry to develop a coordinated plan of operation covering the phases outlined.

Being first in planning such an operation meant that there were very few facts available to use as a guide. Therefore much had to be done in the nature of research and experiment, and the development of this work again brings to light the fact that well-prepared anthracite and a willingness to serve are not the only factors effecting efficient utilization or complete satisfaction to the home owner.

Some idea of this last statement may be gained through Fig. 1, charting the factors involved in the business of domestic-heating comfort. This indicates that the problem is not altogether unlike that encountered by the consumer of fuel for commercial purposes.

However, the consumer of fuel for commercial or industrial purposes has made it his business, through the aid of the engineering profession, to reap every possible benefit from the research and development of methods and equipment whereby the greatest return is realized for every fuel dollar expended.

Much credit is due the manufacturers of industrial boilers, furnaces, and auxiliary equipment in that every step taken by them seems to lead to higher efficiencies, resulting in conserva-

[1] Manager, Metropolitan New York District, Anthracite Coal Service.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., Oct. 7 to 10, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tion of fuel and labor. Likewise these equipment manufacturers are to be commended for their merchandising methods by which the industrial consumer, again through the services of the engineer, is able to purchase equipment of proper design and rating to perform efficiently a given duty.

On the other hand, the consumer of fuel for domestic-heating purposes is seriously handicapped in making decisions in the purchase and installation of heating equipment, a part of the home having much to do with the joy of living. It is not meant to convey the idea that the heating and ventilating business has existed without engineering research and development. Much in that respect has been done, but most of this research and development has until the past few years been largely confined to details of the heating system other than those effecting the actual burning of the fuel and utilization of heat in the combustion chamber of the boiler or heater. Also it must be discouraging to the profession to see the benefits of research and development almost entirely cancelled through misapplication due to competitive merchandising methods whereby the dollar mark of first cost very often clouds all other considerations.

Viewed strictly from an economic standpoint, the home-owner rarely is justified in going to the expense of calling in a consulting or heating engineer to solve his problem, and the result is that an ill-purchased heating plant refuses to heat the home regardless of how much or what kind of fuel is consumed. The plant might furnish heat after a fashion, but a few dollars saved in first cost generally results in what can be fairly called an annual heat tax in the form of excessive fuel requirements plus unsatisfactory operation. This condition in turn causes dissatisfaction and inconvenience, with the final result that changes to other fuels are often made in an attempt to accomplish what might well be termed the impossible.

If it is reasonable to assume that the problem is outside the range of the engineer to deal direct with the individual consumer, then it might be a reasonable suggestion that cooperative educational methods could be as successfully applied in this field as they have in other matters pertaining to the American home.

It would be rather imaginative to assume or suggest at this time that home construction, as regards weather insulation or type and size of installation of heating plants, should be regulated by municipal or state ordinances as is the case, for example, in matters of sanitation, plumbing, electrical wiring, etc. Rather, experiences in direct contact with the domestic consumer during the past few years lead to the conclusion that educational methods based on thorough research and development can be applied in making the public aware of the benefits to be enjoyed from the economical burning of fuel in well-designed and properly operated heating equipment.

As pointed out in Fig. 1, the ideal home, from the heat standpoint, involves many factors other than just fuel. While the anthracite industry has for the past few years been actively engaged in problems of service and utilization, and has only scratched the surface of possibilities, its experiences have been sufficient to prove that the consumer is willing to be advised and to make use of the advice.

Laboratory research by the anthracite industry on domestic utilization was put into operation on December 1, 1928, but in order to concentrate on the work accomplished in the field with the consumer, a summary on the work accomplished in the laboratory to date will be covered later.

Service Contact With the Consumer

In searching for a method of procedure to extend service to the consumer, it was found that all complaints from the customer to the retailer were based on quality of coal. This condition did not check with conditions at the mines where the installation of improved methods of preparation was resulting in the shipment of coal of high quality.

The retail dealer at that time was seriously handicapped in dealing with the situation because his knowledge of what constituted a good heating plant in good repair was practically nil. He generally handled such complaints with the explanation that the coal delivered was just as he had received it from the producer and he could do nothing about it. It was seen that such a condition must be corrected, and it was decided to make a very careful survey of some 5000 such complaints.

Plan of the Heating-Plant Survey

In order that the results of this survey would be of a nature permitting general application later, the following definite plan was arranged and strictly adhered to in every case investigated:

(1) The complaint must be from the consumer to the retailer delivering the coal.

(2) Investigations were not to be limited to one city or section, but carried on in all centers of the anthracite-consuming territories, as follows:

Portland, Me.	Albany, N. Y.
Boston, Mass. (Metropolitan area)	Syracuse, N. Y.
Providence, R. I.	Rochester, N. Y.
New York City (Metropolitan area)	Detroit, Mich.
Philadelphia, Pa. (Metropolitan area)	Chicago, Ill.
Baltimore, Md.	Milwaukee, Wis.
Washington, D. C.	Minneapolis, Minn.
St. Paul, Minn.	

(3) All investigations were to be made by engineers representing the anthracite producers, in the presence of the customer and retailer who delivered the coal.

(4) Investigations were to be carried on until sufficient proof and cause of trouble would be to the mutual satisfaction of the three parties.

With very few exceptions there was a cooperative spirit with the customer, and the findings shown in Table 2 formed a real basis for the work of educating the dealer to qualify himself as a source of heat service, rather than be on the obsolete basis of operating merely as a source of supply. These investigations

		Total number of occurrences	9541	100

in the field also provided an excellent laboratory in which the consumer has assisted in no small way in the development of improved methods of utilization.

Faulty Equipment

Of all the difficulties, 62 per cent was due to faulty heating equipment, 56 per cent of which was found to be caused by the condition of the chimney, flues leading from furnace to chimney, and soot lodged on the heating surfaces of the furnaces. This latter condition not only greatly reduced the thermal efficiency of the furnace but obstructed draft.

Very satisfactory progress to correct these conditions has been made all over the anthracite consuming territory. This has been accomplished largely through educational methods, first from the service department of the anthracite industry to the coal dealer, and then from the coal dealer to the consumer. From the educational state it developed into a practical working plan of service which is quickly becoming a very important and economic feature in home heating, and there are now but few sections of the territory where such service is not available.

When the tonnage sold by a dealer so warrants, the individual dealer has established his own service department, and where dealers handle comparatively smaller tonnages, they have grouped into cooperative service organizations.

A practical example of the latter plan is that covering the operation in and around Elizabeth, New Jersey, where sixty-nine dealers are carrying on this service and maintenance work through a central office and in conjunction with a registered plumbing and heating contractor.

A representative example of this service and maintenance work being done by an individual company located in Brooklyn, N. Y., can be described as follows:

All heating surfaces of the furnace are cleaned and scraped thoroughly by means of the electric vacuum machine as illustrated in Fig. 2. The flue leading from furnace to chimney is taken down, cleaned, and replaced after necessary repairs are made. The dampers are then checked over, water glass cleaned (if a steam boiler), asbestos covering repaired, and the general condition of the furnace checked over. If major repairs are necessary, an advisory report as shown in Fig. 3 is left with the customer.

The cleaning and servicing operation is completed by white painting the asbestos covering of the furnace and black painting the doors, etc. A nominal charge is made for this work, and the net result has been valuable. After finding thousands of furnaces uncleaned for several years and in bad state of repair, the consumer has not only taken a new interest in the heating plant, but utilization is on a more efficient basis.

Until this class of work was first taken up by the coal dealer, it was always the heating contractor who was called in for such cleaning work, and there was some question about the coal dealer annexing this work. However, much cooperative work has been done in this respect, and the heating contractor now finds the coal dealer a source of maintenance and repair work which greatly overbalances any other prejudice.

Overloaded Furnaces

Next in order causing operating difficulties is that of overloaded furnaces or boilers. In drawing conclusions in any investigation it is the practice to see that all other conditions are right before stating that the boiler was of inadequate capacity. Too many overloaded boilers are in operation today, and as a matter of fact are still being installed. This is particularly true in connection with houses on large contract operations built largely for speculation, and where a few dollars saved in first cost is important to the contractor but very unfortunate for the ultimate purchaser. How to solve this problem completely is always one that promotes ready discussion.

It is at this point, as referred to before, that boiler-rating codes drawn up and adopted by the various societies and manufacturers associations become ineffective, and lead to the belief that a full realization of properly selected equipment will not be present until the ultimate consumer is given more light on the subject.

An outstanding example of this was in connection with a group of 200 two-family houses involving the operation of 400 steam-heating boilers. The occupants of these houses had gone through two heating seasons under most unsatisfactory conditions when at a meeting of the owners they were told something about heating their homes. The meeting was arranged through a coal dealer supplying a majority of the fuel, and the facts given at the meeting were based on surveys made of a number of

Fig. 2 The Electric Vacuum Machine Provides a Convenient Means for Cleaning Furnaces

the heating plants which were installed uniformly in all the houses.

There were 320 sq. ft. of standing direct radiation, and an indirect hot-water supply coil which, with allowances for lines and risers, showed a total net load of 450 sq. ft. connected to a boiler which, under accepted codes, would not be installed to carry more than a 290 sq. ft. net load. With hot-water supply included, the annual anthracite requirements should not have been over $11\frac{1}{2}$ net tons, but a survey showed an average of 14 net tons per boiler, representing an average excessive cost of $35 annually. To make matters worse, all of these boilers were connected to a 6 in. × 6 in. × 28 ft. chimney whereas the manufacturer specified a 10 in. × 10 in. × 35 ft. chimney.

First cost was undoubtedly responsible for this combination of conditions. The present owners were not in position to scrutinize the plans before erection, but it is reasonable to assume that fitting publicity and educational methods would show some way for a prospective purchaser of a home to know more about the heating plant he is about to acquire. When this is done one great handicap will be removed in that the speculative builder will be forced to give proper consideration to a very important part of the home.

Work has been done with some 6000 anthracite retail dealers, giving them facts on this phase of house heating, and also urging them to make contact with prospective builders or owners of homes, giving them information on the subject. The rating code adopted by the American Society of Heating and Venti-

lating Engineers and the National Boiler and Radiator Manufacturers' code in boiler testing are fully subscribed to. Effective work is expected to be done by the Heating and Piping Contractors National Association with its certified heating campaign.

FIG. 3 FORM FOR RECOMMENDED REPAIRS

ARRANGEMENT OF DAMPERS AND THEIR CONTROL

From Table 2 it will be seen that 36 per cent of the causes of unsatisfactory results was due to methods of firing and general operation. Damper control offered the most opportunities for observation and suggestions to consumers. In checking over damper arrangements offered by the numerous boiler manufacturers, a rather wide variance of ideas is found. Those engaging greatest attention during the survey are outlined in diagrams A and B in Fig. 4.

Diagram A shows a counterweighted combination check and flue damper which, while entirely safe from a gassing standpoint, is inefficient as a means to regulate draft. When the check damper is closed the fire is subjected to a full chimney draft regardless of the size of anthracite being burned. In many instances this condition causes unnecessarily overheated fuel beds, resulting in preventable chimney losses and clinkering.

Diagram B shows an arrangement which is not only inefficient but decidedly unsafe, and it was usually encountered when customers were complaining about "coal gas," especially at night after the fire had been banked. First, it is inefficient, as regulation or setting of the flue turn damper in any position other than wide open reduces the efficiency of the check damper in checking the rate of combustion when there is no demand for heat. Secondly, when the fire is banked at night it was found to be the rule to close the flue turn damper as well as opening the check damper, and this permitted the gases to pass from the fuel bed up through the furnace and then out into the basement through the open check damper. In all cases of this kind encountered it was urged that the check damper be sealed closed permanently and a new check damper installed between the flue turn damper and the chimney, as shown in diagram C.

Diagram D outlines a damper arrangement which is efficient and safe, but is found in the minority. This gives independent flue turn damper control, and the check damper is in the correct relative location for efficient and safe checking of the fire.

It would be undoubtedly another step in the right direction if this principle of operation would act as a guide to a uniform type of damper gear furnished by boiler manufacturers. It lends itself to various adaptations, and should be considered as an integral part of the boiler or furnace as furnished by the manufacturer. All check dampers should provide a free opening of not less than 80 per cent of the area of the flue leading from the boiler to the chimney. Check and turn dampers should not be designed to operate in tandem when a change of draft condition is required. This does not permit the regulation which is desirable for different sizes of anthracite.

It was found that better results were the rule where damper

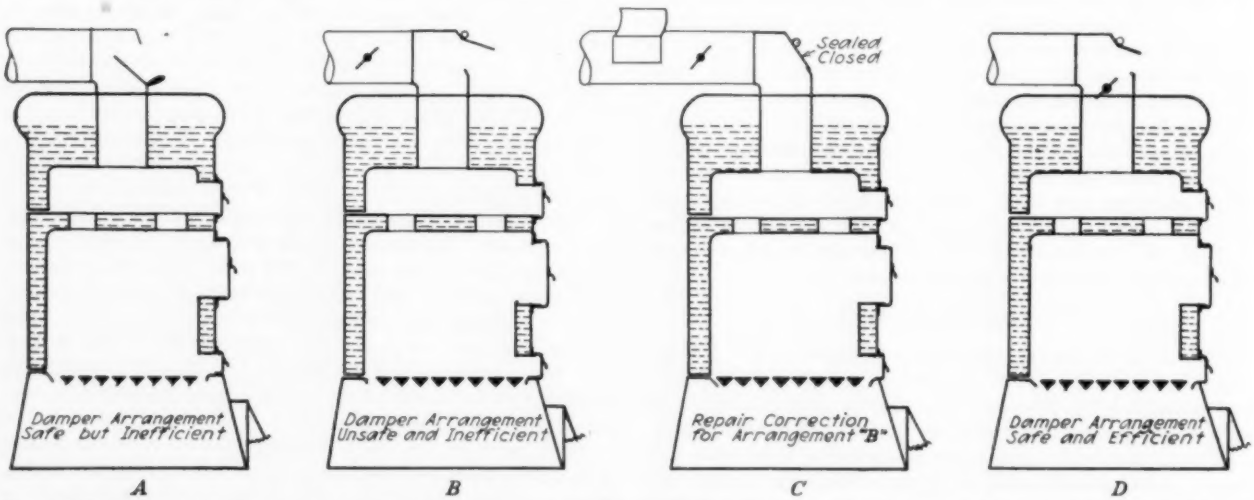

FIG. 4 DAMPER ARRANGEMENTS. A—COUNTERWEIGHTED COMBINATION CHECK AND FLUE DAMPER. B—INEFFICIENT AND UNSAFE ARRANGEMENT. C—CHECK DAMPER INSTALLED BETWEEN FLUE TURN DAMPER AND CHIMNEY. D—FLUE DAMPER INDEPENDENT OF CHECK DAMPER

arrangements, as shown in diagram D, permitted operation of the flue turn damper independent from the check damper. The flue turn damper should be set to meet the draft requirements of the particular size of anthracite being used. The check damper should be used to start or to check the draft to the furnace.

The Ashpit Draft Door

Practically all steam and hot-water heating boilers are fitted with diaphragm or sylphon damper regulators which operate the check dampers in combination with the ashpit draft door; that is, when the regulator operates to check the fire, the ashpit draft door is closed and the check damper in the flue is opened.

Compare this plan of operation with that practiced in large steam boilers where natural-draft control is not obtained by opening or closing of ashpit doors. This point should be given consideration. To date, this has not been investigated in the laboratory, but experiments in the field give considerable encouragement to the idea that improved and uniform damper arrangements between furnace and chimney, as shown in diagram D, would permit operation without the ashpit draft door and result in improved furnace operation.

This method of control is particularly beneficial when overloaded boilers are encountered in conjunction with clinker trouble. Forcing of the fire causes overheated fuel beds, and when the dampers finally operate, a sudden shutting off of air to the ashpit invariably results in ash fusion at the fuel and ash line. This formation of clinkers was practically eliminated by leaving the ashpit draft door open and limiting control to the other two dampers.

Selection of Size of Anthracite for Use

In treating this item it will be of interest to outline the standard sizing, also the yield of the various commercial sizes, as an average for the entire region based on 70,000,000 gross tons annual production, as given in Table 3.

TABLE 3 SIZING AND AVERAGE YIELD OF SIZES

Classification	Standard round-mesh sizes Through, in.	Over, in.	Yield Gross tons	Per cent of total
Broken	4 7/16	3 7/16	455,000	0.65
Egg	3 7/16	2 9/16	7,875,000	11.25
Stove	2 9/16	1 9/16	17,535,000	25.05
Chestnut	1 9/16	11/16	17,318,000	24.76
Pea	11/16	9/16	5,453,000	7.79
Buckwheat No. 1	9/16	5/16	9,240,000	13.20
Buckwheat No. 2	5/16	3/16	5,670,000	8.10
Buckwheat No. 3	3/16	3/32	5,530,000	7.90
Smaller	..	..	924,000	1.30
Total			70,000,000	100.00

Of these nine sizes, egg, stove, chestnut, and pea are classed as domestic sizes, in addition to which No. 1 buckwheat is gaining in popularity due to the development of automatic stoking equipment.

Some people are accustomed to burning a particular size of anthracite, and they are reluctant to be shown the advantages of using a size or combination of sizes which would result in better operation or greater convenience. There are others, however, who are anxious to know which will best suit the purpose.

In all the work of research and survey it has been found rather difficult to formulate a specific set of rules to govern the selection of size or combination of sizes, except that in the case of egg coal its use without combination with smaller sizes should be limited to furnaces where the depth from firedoor level to grate level is 14 in. or more and where the diameter of the grate is 22 in. or more. This is necessary in order to get volume to maintain ignition, but when furnaces not meeting these requirements are encountered it is good practice to use the egg size in combination with pea or buckwheat. The admixture of these smaller sizes acts as a baffle against excess air and "snuffing out" conditions encountered due to the low draft resistance of straight egg used in small volumes. Other than this the determination of size or combination of sizes to use is largely a matter of what is best adapted to the local conditions as regards draft available and design of the equipment to control the draft.

In connection with this question of selection of sizes probably no more interesting data could be presented than those compiled and recorded for the Anthracite Operators Conference in 1925–26 by R. H. Fernald, director, Mechanical Engineering Department, Towne Scientific School, University of Pennsylvania, Philadelphia, Pa. A great number of tests were made to determine the relative economic values of the several sizes of anthracite with the mixture of two or more sizes in varying percentages. Among the most important conclusions resulting from this series of studies were the following:

(*a*) From the standpoint of excellence of general performance, uniformity of combustion, ease of fire control, freedom from clinkering, ease of fire cleaning, and general high efficiency, the anthracite mixture of 80 per cent chestnut and 20 per cent pea took first rank of the solid fuels tested.

(*b*) The operating characteristics of the mixture of 40 per cent egg and 60 per cent stove were similar to those of the chestnut-pea mixture, thus giving it a high rating from the standpoint of operation performance.

(*c*) The excellent operating behavior and high efficiencies secured from the mixture of chestnut and pea and the corresponding ease of handling the mixture of egg and stove fully warranted further investigations of the exact proportions that will result in the highest efficiencies for mixtures of these sizes.

It was decided to devote the year 1926–27 to a careful investigation of the efficiencies and economics of different sizes and mixtures of sizes of anthracite for house heating. The tests were made in three series based on present-day commercial anthracite sizes, as shown in Table 4.

As this investigation was a study of the relative economic values of different mixture proportions of anthracite sizes and not a test of equipment, no effort was made to determine the relative efficiencies of the different heaters or the variation in efficiency of the individual heater under different load conditions. The efficiencies shown are based on the amount of heat transferred to the water.

While similar tests were conducted on various sizes of equipment the data for this discussion will be limited to that giving relative efficiencies in connection with a house-heating boiler

TABLE 4 SIZES OF EGG, CHESTNUT, AND PEA COAL

1 Egg Series

	Per cent oversize	Per cent egg	Per cent stove	Per cent chestnut	Per cent pea	Per cent slate	Per cent bone
(a)	5	80.0	15.0	0.0	0.0	1.50	3.00

2 Chestnut Series

	Per cent oversize	Per cent chestnut	Per cent pea	Per cent undersize buckwheat	Per cent slate	Per cent bone
(a)	5	80.0	10.0	5.0	4.5	2.0
(b)	5	75.0	15.0	5.0	4.5	2.0
(c)	5	65.0	25.0	5.0	4.5	2.0
(d)	5	60.0	30.0	5.0	4.5	2.0
(e)	5	55.0	35.0	5.0	4.5	2.0
(f)	5	45.0	45.0	5.0	4.5	2.0
(g)	5	40.0	45.0	10.0	4.5	2.0
(h)	5	35.0	45.0	15.0	4.5	2.0
(i)	5	30.0	45.0	20.0	4.5	2.0
(j)	5	45.0	20.0	30.0	4.5	2.0

3 Pea Series

	Per cent oversize	Per cent pea	Per cent undersize buckwheat	Per cent slate
(a)	0	85.0	15.0	7.0
(b)	0	70.0	30.0	7.0
(c)	0	55.0	45.0	7.0
(d)	0	40.0	60.0	7.0

having a manufacturer's rating of 1025 sq. ft. steam radiation with 3.53 sq. ft. grate area. Tests on each mixture were run for seven consecutive days, and for 15 hours out of each 24 the boiler was required to maintain a uniform load equivalent to 60 per cent of the manufacturer's rated capacity. For the other 9 hours out of each day the boiler was operated under banked conditions with a load equivalent to 25 per cent of the manufacturer's rating.

The operation at 60 per cent of manufacturer's rating was chosen because such heaters maintained at rating would mean flue-gas temperatures in the neighborhood of 1000 deg. fahr. or higher. This condition would of course destroy the object of the tests. The relative efficiencies of the sizes tested in the boiler described are shown graphically in Figs. 5, 6, and 7.

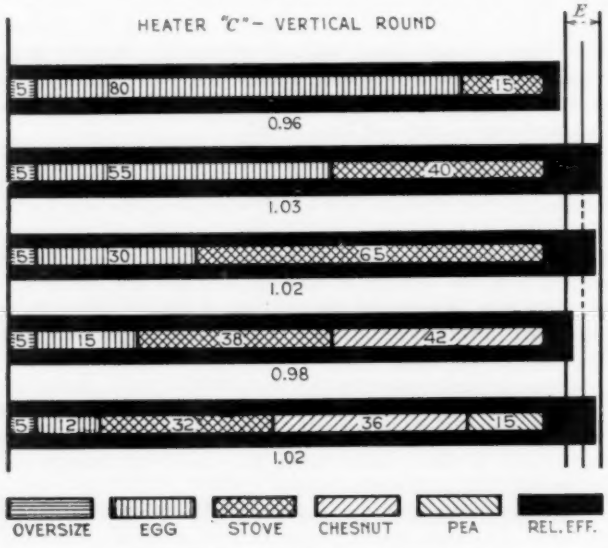

FIG. 5 RELATIVE EFFICIENCIES OF EGG SERIES

GENERAL CONCLUSIONS FROM TESTS

In connection with the vertical round boiler specified, the ease of fire control and excellence of general performance were less satisfactory with standard commercial egg coal (carrying 5 per cent oversize and 15 per cent undersize) than with any of the mixtures of egg, stove, chestnut, and pea, that is to say, egg coal carrying from 40 to 83 per cent undersize.

The average efficiency for the same boiler with egg coal carrying from 40 to 83 per cent undersize was higher than the corresponding average efficiency with standard commercial egg (carrying 5 per cent oversize and 15 per cent undersize). The average efficiency was practically constant for the egg mixtures carrying from 40 to 83 per cent undersize.

RESEARCH COVERING ANTHRACITE-BURNING EQUIPMENT

The third phase of the anthracite industry's research work is that started in December, 1928, for the purpose of developing and testing equipment which will provide the greatest convenience in utilization. This work is being carried on at the Frost research laboratory, at Norristown, Pennsylvania, under the direction of R. V. Frost, and for the present special attention is being given to the testing and development of thermostatic controls and automatic stokers for the burning of anthracite. As this development progresses and tests show that necessary requirements of convenience and economy have been met, the results will be published in bulletin form.

Fig. 8 shows a typical arrangement of a domestic-heating stoker for the burning of No. 1 buckwheat or No. 2 buckwheat anthracite under a round cast-iron boiler. This particular arrangement provides also for the continuous removal of ashes to a receptacle outside of the furnace. Fig. 9 shows a phantom view

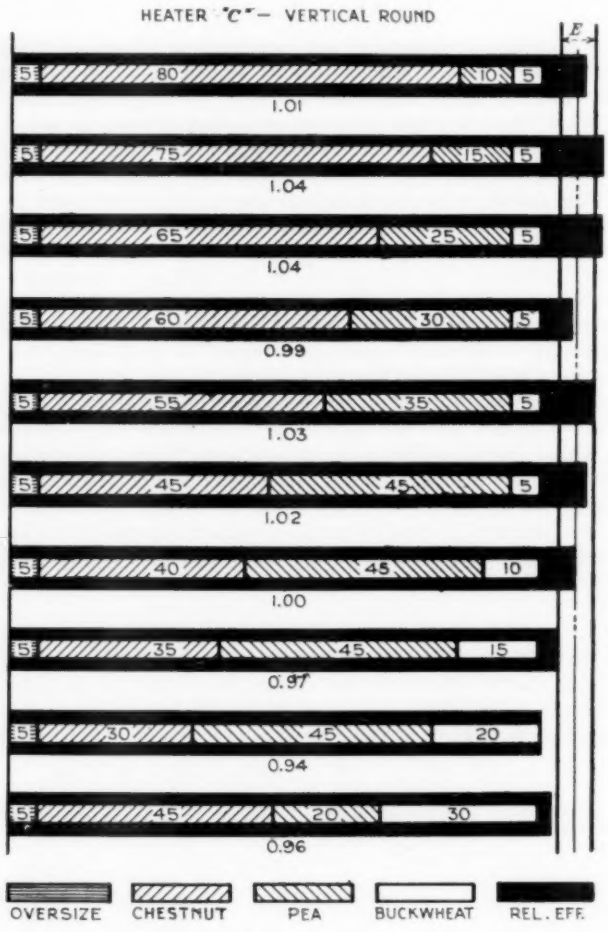

FIG. 6 RELATIVE EFFICIENCIES OF CHESTNUT SERIES

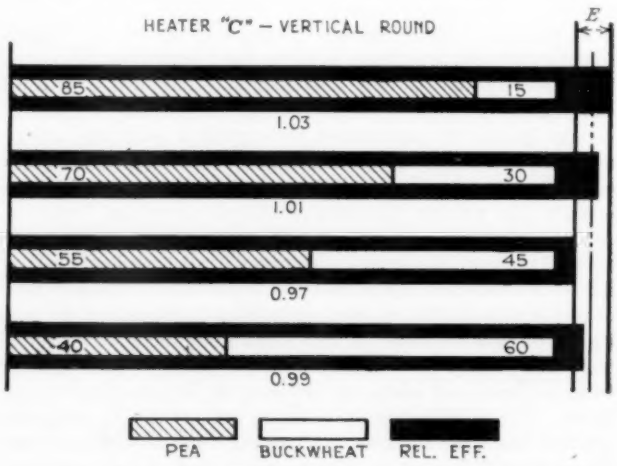

FIG. 7 RELATIVE EFFICIENCIES OF PEA SERIES

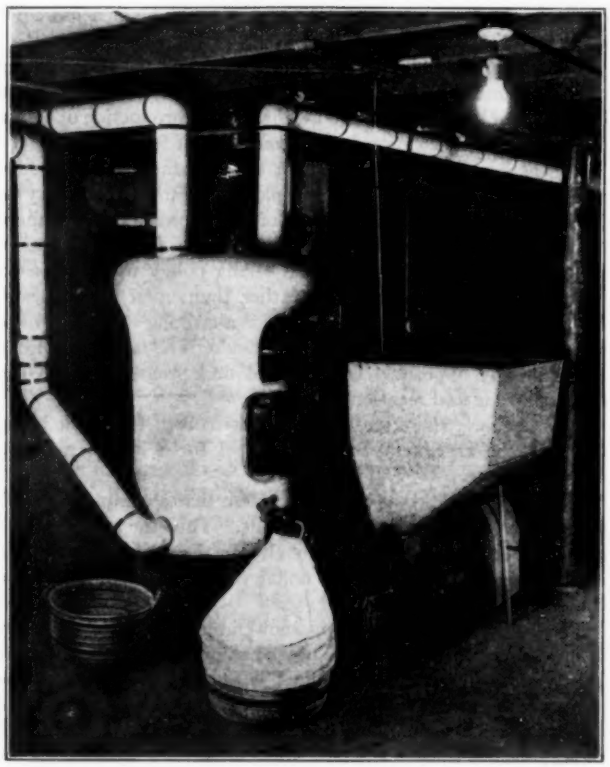

FIG. 8 DOMESTIC-HEATING STOKER ARRANGEMENT

of the same stoker applied to a sectional cast-iron boiler. That increased efficiencies may be expected from this type of equipment is brought out in Table 5, which gives results in tests where hourly coal consumption rates were 2.83, 5.93, 9.71, 16.6, and 21.4 lb.

THERMOSTATIC CONTROL OF DRAFTS

Much attention will be given to perfecting the utility of automatic draft controls which in turn will add greatly to convenience in the use of the larger sizes of anthracite in surface-fired boilers and furnaces. Investigations to date, however, indicate that damper design and arrangement will play an important part in this work. It is understood that one large producer of thermostatic controls finds it necessary to make many changes of dampers when installations are made. This is particularly true where arrangements outlined in diagrams *A* and *B* in Fig. 6 are encountered. The usual correction is outlined in diagram *C*.

ASH REMOVAL

Development of equipment or systems to reduce to a minimum or to eliminate completely the necessity of ash removal by the householder is receiving serious attention. Devices on the order of that shown in Fig. 7 are steps in the right direction, but the goal is a practical system that will go further in that the ash and refuse will be removed from the premises without any labor whatsoever on the part of the consumer.

Vacuum ash removal bids fair to meet this requirement and progress is being made. Such a system for removing ashes from the boiler operating in a large apartment house was inspected recently. This equipment is really a portable adaptation of the standard vacuum ash-removal idea, being entirely self-contained on a large motor truck chassis fitted with pneumatic tires. A gas-electric set provides power for the operation of the exhauster blower, also for the belt conveyor which discharges the ashes from the truck hopper to the standard ash truck. An 8-in. universal-joint fitting connects the blower intake line to a standard 8-in. pipe running from sidewalk level to the boiler room. The advantages of such a system are readily appreciated when compared with the common present-day procedure requiring ashcans, ash hoists, general upkeep, and the attendant noise and dust.

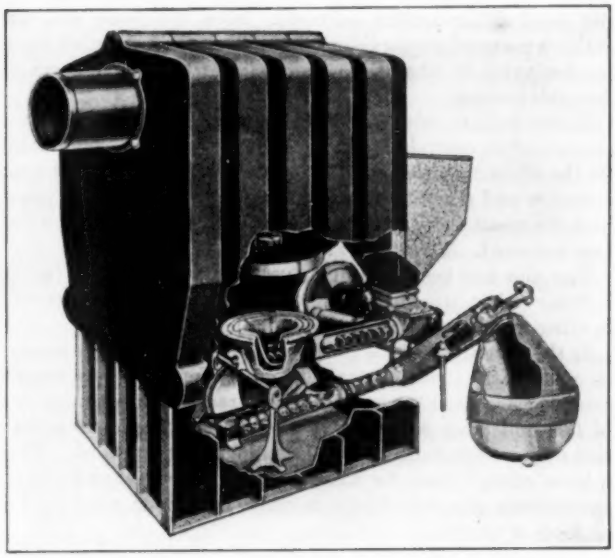

FIG. 9 PHANTOM VIEW OF STOKER APPLIED TO SECTIONAL CAST-IRON BOILER

It is proposed to design smaller units of this system which will make it adaptable for service to the domestic consumer. This is an excellent prospect to make manual ash removal a thing of the past in that it will be entirely practical to have ashes removed directly from the ashpit of the furnace to the service truck. Although the plans for de-

signing this apparatus are under way, it is not yet known to how small a size heating plant it may be applied.

Heat balances on some of these tests have been computed to check up the reliability of the results obtained. They show that the results are entirely reasonable. A typical heat balance (referring to test No. 168) is as follows:

	Per cent
Loss due to combustible in refuse in ashpit	5.3
Loss due to heat carried away in dry chimney gases	8.0
Loss due to moisture in coal and moisture formed by burning hydrogen	3.1
Loss due to radiation and unaccounted for	5.0
Total losses	21.4
Possible efficiency (by difference, 100 — 21.4)	78.6

Discussion

DAVID MOFFAT MYERS.[2] The paper is a worthy contribution in the field of fuel engineering, as pertaining specifically to anthracite for building-heating purposes. Both the paper and the author's personal accomplishment as a leader and organizer mark the beginning of what the writer believes to be a new era in domestic heating.

In the field of relatively large units, as in industrial power plants and in central stations, the art of economic combustion for the efficient generation of heat has been undergoing the most intensive and scientific development for the last fifteen years, with the result that today practically the utmost attainable has been achieved.

The aim has been maximum useful heat per dollar (which is first cousin to thermal efficiency) and reduced labor required; in other words, a minimum in fuel and labor.

In the domestic field the aim is exactly the same. If we assume as granted the items of "warmth" and "safety," there remain "convenience" and "economy" which translate into a minimum of fuel and labor costs. It is true that in the domestic field cost may include more than dollars apparently expended. Thus a home owner's time, for which he does not pay himself wages, nevertheless counts decidedly as cost. So also do soiled clothes and loss of temper.

Now when it comes to a question of reducing fuel and labor costs in domestic heating as compared to the same question in the power field, we have two sets of conditions so different as to be comparable chiefly by contrast. To be sure, fuel is fuel and combustion is combustion, but there the similarity pretty much ends.

The present state of the art in domestic heating may be said to exist chiefly in the pioneer stage, and the most hopeful sign for its future development is the fact that it is being dealt with by trained engineers.

One of the principal jobs of these engineers is to educate the public, i.e., that particular public which will benefit the most by increased convenience and economy. For it is necessary to create a desire and demand for better things and to disseminate information as to how these better things are obtainable.

The various channels through which this public may be reached effectively must be utilized. There appear to be three commercial agencies which must come in contact with the ultimate consumer more or less directly—the heater companies, the fuel producers, and the specialty companies.

Without the services of the first two, no heating plant exists or operates. The specialty companies engage in much advertising and publicity concerning their temperature-control systems and patent furnaces, combustion devices, and ash-handling methods. But their contact is not so sure as that of the first two groups. And while it is true that each group is endeavoring to sell its product, their efforts do positively assist in creating a desire for better convenience and economy. This is a most desirable result.

The fuel producers (i.e., the anthracite group), as stated in the paper, are making the most advanced and effective efforts thus far exhibited by any of the groups toward the production of better convenience and economy for the consumer of fuel.

The heater companies, although their contact with the consumer is more sure and more completely organized than any of the three, are doing the least of all of them toward real advancement in economy and convenience in the use of fuel. The reason for this appears to be an adopted selling policy which is based primarily on reduced first cost rather than upon reduced cost of operation and convenience. This is a striking contrast to the way business is handled in the power field. The two conceptions are strikingly opposite. One is right and progressive and the other is wrong and reactionary.

All the more, therefore, should be welcomed the work being done by the anthracite industry as set forth in the author's excellent survey.

It may be set down as a modern axiom that a commodity with service is worth more than one without. Thus the service which has been organized largely through Mr. Duemler's efforts has already added real thermal and dollar value to a ton of anthracite coal.

The author discusses the apparent clinker-producing tendency of checking a hot fire by closing the ashpit door. Probably at least one chief cause of this effect is the sudden raising of the temperature in the fuel bed by the quick and drastic reduction of air flow when the ashpit door is closed. The CO_2 would mount rapidly with a consequent temperature rise to a point probably above the fusion point of the ash in the fuel, whereas control by check damper would still permit a moderate air flow through the fuel, thus tending to avoid the clinkering effect.

The tests conducted by Prof. R. H. Fernald on the relative efficiency of various mixtures of different sizes of anthracite constitute a fine and constructive contribution to the art. It is easy to imagine why it is that in general the results are as they are. But the writer should like to check his imagination to the extent of knowing definitely whether the better results in each case were accompanied by a higher percentage of CO_2 in the flue gases.

Also it would be interesting, if possible, to translate the thermal-efficiency results into commercial-efficiency results by introducing the element of comparative fuel cost of the various mixtures used. In other words, which mixture is the cheapest to burn?

In closing, the writer wishes to express the satisfaction of one keenly interested in fuels and their economic application in witnessing the beginning of a movement to improve domestic heating as evidenced by the author's excellent paper.

LESTER C. BOSLER.[3] The most striking thought brought out in the paper, and it is hoped that the anthracite-consuming public will appreciate it, is the fact that a mixture of the different sizes of anthracite is a more efficient fuel than any one size alone.

Fig. 5 shows that a mixture of 40 per cent of stove size with 55 per cent of egg size with a 5 per cent of allowable oversize gives a greater efficiency than a standard egg coal. In Fig. 6 it again is shown that a 15 to 25 per cent mixture of undersize to chestnut gives better results than a standard straight chestnut coal.

This information should be very valuable to the consuming public because it represents the work of Dr. Fernald's tests made at the University of Pennsylvania a year or so ago. The time will come when the producer will make just two sizes of anthracite

[2] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[3] Mechanical Engineer, Maderia, Hill & Co., Philadelphia, Pa. Mem. A.S.M.E.

for domestic use. One will be for the warm-air furnaces and large steam boilers and the other for the smaller heating devices and kitchen ranges. They will then burn a more efficient fuel, but one that will not look so good in the coal bin.

To those wanting cleanliness and safety and at the same time the convenience given by the liquid and gaseous fuels, the steam sizes of anthracite can now be burned automatically and mechanically by stokers in such a way that the so-called hard work of shoveling the coal and ashes is entirely eliminated. By this method the yearly heating cost is the lowest and the convenience is equal to any other type of fuel.

NOEL CUNNINGHAM.[4] The author should be congratulated on the thoughtful and constructive character of his paper and particularly on having confined himself to present-day means for meeting present-day heating needs.

My own work as well as that of Mr. Duemler's organization brings me into contact with groups of merchandisers of fuel and heating equipment as well as hundreds of householders throughout the Northeast, and discussion with them of house heating and house-heating ways and means. The merchandisers are chiefly of three general classes: (1) Coal merchants who are thinking of the future of the coal business, (2) plumbing and heating people who have superposed present-day merchandising on the traditional conservatism of prewar days, and (3) young men who have incorporated businesses purely for modern merchandising to the new home demands. The householder contacts are almost exclusively with the middle and upper middle class having incomes of $5000 up.

People are educated through reiteration in advertising and propaganda articles in the home-phase magazines, to the conclusion that house heating can be dissociated from actual physical discomfort, mess, and all work of an arduous nature. The features which a very great number of anthracite users are intent upon avoiding are uncertainty of getting heat as and when required and dirtiness. Mr. Duemler has indicated that automatic control and stoker firing with synchronized coal feed and ash removal overcome these difficulties, and I can say from personal experience that he is right.

At the present time approximately five million households are being heated with anthracite. Some speakers have left the impression that this is all to be changed. I will say to those who believe that the American householder and his wife do not count the cost of home fixtures and go rushing into debt to satisfy any happy little whim, that they greatly underrate the canny thriftiness of their fellow countrymen. Normally every dollar of household expenditure is very thoroughly scrutinized; this applies to all classes, but becomes progressively more pronounced as real wealth increases. Those who casually drop into a show room and sign on the dotted line are almost invariably people of small means.

Two things will maintain anthracite in use: first, the investment which individual anthracite users have in good anthracite-burning equipment, and, secondly, the available accessories which fulfil their requirement that mess, arduous effort and uncertainty shall be eliminated, with the very important proviso that there must be proved savings which will largely or entirely repay the investment in added plant. There appears to be no foundation for an anticipation that any large proportion of householders will spend money for non-income bearing household features as long as the objections evident to their own common sense can be overcome at practically no expense.

CHARLES C. TRUMP.[5] The paper shows the importance of chimney draft for anthracite. It is equally important to regulate draft on domestic heaters with any fuel.

In fact, the difference between uncontrolled draft and properly balanced draft may mean as much as 30 per cent fuel economy.

A cold chimney does not draw. A hot one draws too much. Draft is also affected by wind and other atmospheric conditions.

Every heater using fuel therefore should be equipped with a simple but effective automatic draft control. A simple draft gage is also an advantage to show results of control.

A balanced check damper does more to give heater fuel satisfaction than any other one thing. Let us use more of them.

F. C. RUSSELL.[6] The entire question of home insulation and domestic-fuel conservation has been receiving much more attention recently than it ever has in the past, and home owners, as well as architects and builders, have shown keen interest in the application of insulation to the domestic heating plant.

The primary interest of course centers in the almost incredible economies which real insulation gives. Heating plants, in years past, have been well designed, and for the most part well installed, but the responsibility for insulation was not directly felt by the furnace manufacturer nor by the heating contractor who installed it. The result has been that the splendid results which were possible with these heating plants have been defeated by neglecting this extremely important point.

It is hardly conceivable that the home owner with his limited knowledge of heating and the complicated questions of fuel conservation would directly demand insulation, as he was ignorant of the real value and of the losses that follow the absence of efficient insulation.

But rising fuel costs have brought the possible economies of home heating to the attention of the home owners, and competition has stimulated the heating contractor and the furnace manufacturer. So today the owner of the house is insisting upon economy, and the furnace contractor is offering economy in his solicitation for business.

A great many different kinds and grades of fuel are being used today in the American home, and for the most part all of them will provide satisfactory heat if given a fair opportunity to do so. The fuel dealer is often unjustly blamed and accused of selling an inferior quality of fuel, whereas actually the cause for the dissatisfaction is due to heat losses from the boiler and piping through lack of adequate insulation. It therefore appears that it is well worth the while for the fuel dealers to recommend insulation whenever possible, as a close survey of the conditions existing in 75 per cent of the homes will show that most of the complaints will be overcome after the heating plant has been insulated.

There are a great many different insulating materials available, and while many of them are not without value, there are but few that are sufficiently efficient to produce the desired results. The thermal efficiency tests made by the U. S. Bureau of Standards may be helpful to those who desire to know the relative value of the most commonly used insulating materials. The comparisons show the heat loss in B.t.u. through various materials, and are as follows:

Air (if convection currents could be prevented), 4.2; mineral felt (mineral wool felted in blocks), 6.9; 85 per cent magnesia (magnesia and asbestos), 12.2; fire felt, 14.0; asbestos air cell, (corrugated asbestos paper), 12.2; asbestos cement (very hard and rigid), 40.0. The heat loss is the thermal conductivity expressed in B.t.u. per day per degree fahrenheit temperature difference per square foot per inch thickness.

D. H. FAULKNER.[7] One cannot help being impressed by the vision of the author of this paper. Every one in the heating industry that knows Mr. Duemler and is familiar with the good work that he has accomplished in the past few years will realize that there is food for thought in this survey.

Table 2 is of special interest and might well serve as a page for a service manual in the heating industry. There is one item that might be included in this table, namely, lack of air in boiler rooms. Many times the writer has made a long trip to survey a faulty heating job only to find that lack of proper air supply for combustion was the trouble and that merely opening a window was the remedy. This is especially important on larger work.

The paragraph on overloaded furnaces is something of vital importance to any one in the heating industry. We have been faced with a confusion in boiler ratings for years. The efforts being made by the A.S.H.&V.E., National Boiler and Radiator Manufacturers organization, etc., are steps in the right direction. This, however, is going to take time, and anything that will serve as a yardstick for boiler comparison is worth considering.

If a boiler is considered as a unit, so much in the form of iron or weight is required for the base, grates, and other accessories, and the balance in the form of weight goes into heating surface. By this token weight is a pretty fair measure of boiler capacities.

In a table here listing sectional boilers, it will be noticed that they all weigh about the same, and it so happens that they all sell at the same trade price, within $20. Boiler *C*, put in on the basis of 50 per cent allowance for piping losses, starting load, etc., will give a good job. If this is so, there is something radically wrong about the other ratings. Of course, there will be some variation in the efficiency of these boilers, depending on the way the heating surfaces are exposed to the fire, but by and large they are of equal capacity.

This makes a pretty fair method of comparing boilers, especially in competitive work, as data on weights are published by all manufacturers.

Another important point that the author stresses is the matter of adequate flues. This problem is serious, especially in suburban development work where operations involving 500 houses are not uncommon. If the mortgage and loan engineers were approached on this subject, they would realize the importance of good flues and would compel the contractors to install them.

The table listing sectional boilers is as follows:

Boiler	Rating	Weight
A	5480	6680
B	5750	6940
C	3800	6920
D	5500	6670
E	5200	6440

HORACE C. PORTER.[8] The author has given an excellent presentation of the very helpful and effective service that is now rendered to the domestic consumer by the Anthracite Service Bureau in many of the large consuming centers.

The title of his paper, however, would lead one to hope that he would present the "economic status of anthracite" more in the light of its future possibilities as a competitor with other fuels, the markets it can be expected to retain, and the basis of relative price, quality, and service that will be required to insure its success in competition with other fuels. It is true, as he says, that the quality of the product has been greatly improved of late, through development of mechanical cleaning methods, but these operations add to the cost and they tend also to add to the amount of coal discarded with the slate and other impurities on the waste piles.

The anthracite industry is confronted with serious economic difficulty in putting out a product clean enough to meet present-day demands at a cost enabling it to compete with other clean and more convenient fuels. Unless a broad research program is undertaken looking toward more advantageous use of the very fine sizes, including those not now marketed at all, so as to develop applications bringing higher returns on them and thus permitting lower prices on the domestic sizes, the prospect is not a promising one for successful competition in the domestic field.

Research should be started looking toward a growing application of more and more of the finer sizes of anthracite (and, in fact, of all solid fuel including coke and bituminous coal) for the manufacture of gas for public distribution. It may be a considerable number of years before any large proportion of the anthracite production is devoted to the making of gas, but the industry, it is believed, will show a short-sighted policy if it does not see the certain future growth of gas utilization in domestic heating to the replacement of solid fuel, and take steps accordingly to enter the field even in apparent competition with its own principal product.

Mr. Nicholls' paper on coke, following Mr. Duemler's, put in convincing fashion the excellent results that can be obtained with well-prepared and well-sized coke in domestic furnaces, when properly controlled. The Bureau of Mines in its tests has made it clear that coke can be used successfully in household furnaces and requires no very troublesome attention or control. The great drawback lies in its bulk and the extra storage and handling required, and the somewhat finer control of the fire that is necessary. In making these tests of domestic fuels, such as the bureau has many times reported, it would seem that certain optimum conditions might be chosen in each case, suited especially to the fuel under test, and a valuable practical comparison thus made.

The important factors, however, in the whole matter of domestic-heating fuels are those of cost, convenience, and cleanliness. In considering cost, also, the relative fixed charges on the investment enter, often, as a deciding factor. Both anthracite and coke are clean, smokeless, and efficient, but there will come a day not far distant when both are looked upon as old-fashioned by reason of the cumbersome handling required the dust and dirt of the ashes, the labor and attention, and the lesser degree of adaptability that they offer to automatic control.

Relative prices and the ability of the purchaser to pay for added convenience and comfort will be the principal factors in the domestic-fuel situation for many years to come.

Mechanical and Human Elements in Smoke Abatement

By GEORGE C. FISHER,[1] NASHVILLE, TENN.

A brief description is given of the history of the work of smoke abatement in Nashville, with the local conditions and the technical details and the general policies followed. The greater part of the paper deals with the human elements that entered into the problem of enforcement and the educational features that were planned and carried out to put smoke abatement into effect.

THE statement often is made by those connected with smoke-abatement that the work consists of 20 per cent mechanical engineering and 80 per cent of what one of our past-presidents calls human engineering.

While many engineering problems arise in promoting the work which, when judged apart, may appear difficult, yet when compared with the tremendous task of leading a city into new channels of thought and action, their solution seems comparatively easy. If smoke abatement were only an engineering problem with one visit sufficing to convince the smoke offender that he ought to follow out the proffered recommendations, one might go up one street and down another abating smoke with the greatest dispatch, and in most cases with a financial benefit to the individual owner of the stack. However, because of human frailty, prejudice, habit, inertia, and distrust, such occurrences are rare, and often many visits must be made, not to check the accuracy of the original investigations, but patiently to lead the mind of the offender through the gradual evolution of ideas to the acceptance of these first recommendations. The greatest hindrance to smoke abatement does not lie in its economics and its engineering but in the minds and the customs of the people.

In this paper some space will be given to the history of the work in Nashville and to the local conditions, the technical details, and the general policies in connection with the work. The remainder of the paper will deal with the human elements and the educational features relating to smoke abatement.

Referring to the history of smoke abatement in Nashville it is found that a municipal smoke department existed for a few years previous to the World War. Some constructive work was accomplished during this period, but due to the war and to other contingencies the department was abolished. Because of the fact that the organization was broken up many people gained the impression that this constituted a failure and that smoke abatement was hopeless. This served as a most noticeable handicap in the most recent smoke-abatement campaign.

The present Smoke Department had its origin in 1926. On June 16, of that year, a new smoke-abatement ordinance was adopted by the city. A short time later a Smoke Abatement Commission, composed of representative business men, was appointed. The commission felt the need of a competent and forceful man to organize the work and arouse the interest of the people. The services of John Hunter, of St. Louis, were enlisted, and he started a smoke-abatement campaign on July 1, 1926, and remained with the city for a year. On November 8, 1926, the author began his work as smoke inspector. During this year Mr. Hunter accomplished a great amount of work in the way of mechanical alterations to existing equipment and in instructing the smoke inspector in the proper methods of procedure. It is quite probable that his greatest accomplishment was in the molding of the minds of the public through various means of publicity and through his many practical applications made in the boiler room to a recognition of the fact that it could be done and that it was worth while. His policies of attacking the problem have been consistently followed out.

[1] Chief Smoke Inspector, City of Nashville. Assoc-Mem. A.S.M.E.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., October 7 to 10, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Topography Made City a Smoke Trap

The local conditions found in Nashville at the beginning of the campaign will be briefly noted.

The coal used is all high-volatile, averaging close to 40 per cent. No low-volatile coal is used, for the very good reason that none is to be had at a competitively marketable price.

The topography of the city is concave, every road out of town leading up a hill. This bowl tends to trap the smoke and hold it for long periods of time. Fogs are prevalent throughout the heating season, being especially heavy from the middle of November to the first of February. Low wind velocities are the rule during the winter.

A great conglomeration of combustion equipment was found, and it was apparent that in most cases cheapness had been the prime requisite for its purchase. Low settings, insufficient draft, run-down plants, boiler rooms lacking light and ventilation and overflowing with dirt and discarded material were the rule rather than the exception.

The A.S.M.E. Boiler Code had been in operation in the city for some time and was having an indirect bearing for good in smoke abatement.

There was no license law for engineers or firemen and no active organization for their educational and social betterment. A local chapter of the National Association of Power Engineers has since been revived and is proving to be of great benefit. Capable and alert engineers and firemen were to be found, but were not in the majority.

Managers, as a rule, took very little interest in their boiler rooms, but considered them merely as necessary nuisances and sources of expense.

The heating season has a few days comparable to a Northern winter, thus requiring plenty of capacity. On the other hand, many of the days are typically Southern, which means low ratings, low furnace temperatures, and incomplete combustion.

There was too much of a tendency among architects to lean heavily on sales advice for their heating layouts.

There was no local chapter of the Heating and Piping Contractors National Association. In the author's opinion this fact, along with the lack of "certified heating," has subjected smoke abatement, the heating trade, and the public in general to many ills.

A strong, fighting minority of the populace were confident that smoke could be abated and were insisting that it should be done, while a majority of the people were indifferent, dubious as to the value of the work, or outrightly opposed to its institution.

The local skirmish between coal and other fuels existed.

The preceding statements may give the appearance of a very dismal outlook for smoke abatement, but special stress has been given to the hazards that had to be overcome, and it is supposed that most of them are not confined to Nashville. Many favorable items might be mentioned, such as an excellent and unusual response from managers down to firemen to alter equipment and improve conditions when requested to do so.

The general policy in carrying on the work, as adopted by Mr. Hunter, was to unite an extensive program of educational publicity with a great deal of individual inspection, instruction, and recommendations.

As the work was begun in the summer time, attention was given first to the manufacturing plants. Being aware of the fact that the average owner or manager is giving most attention to his production and sales and knows very little about his steam plant, a great effort was made to impress on him the value of smoke abatement and the possible savings that could be made in connection therewith. Inspections were made of each individual plant, and in most cases recommendations were made for a complete overhauling. Engineers and firemen were instructed in the best methods of abating smoke and saving fuel. Besides general repairs and alterations to existing equipment, suggestions were made as to specific apparatus that might be added to improve conditions and lessen the smoke. Where at all practicable underfeed stokers were recommended.

Air Jets and Underfeed Stokers Were Put In

At first, managers of the plants considered the prices of stokers prohibitive and they could not be interested. However, they would give consideration to air jets, including a special type of jet designed by Mr. Hunter, and 131 sets of these were installed the first year. After two or three months several underfeed stoker installations were made, and from that time the number of stoker installations has rapidly increased, until now there are 80 new underfeed stokers in the city.

During the following heating season time was given to the inspection of heating plants. Fully a thousand plants were visited, minor changes and repairs to boilers were advocated, recommendations were made as to the best fuel to use, and instructions were given to firemen and janitors. Near the end of the heating season the motor-driven underfeed stoker was introduced and the use since that time has become general. In many of the older types of boilers there was but one solution and that was the use of a smokeless fuel such as coke. Among all the various designs of the hand-fired heating boilers there was only one that was considered, under average conditions, to be an inherently smokeless boiler and that was the downdraft.

Railroads Made Many Helpful Changes

The railroads came in for their share of consideration. Conferences were held with the officials of the three railroads entering Nashville. As a result schools were organized for the instruction of engineers and firemen for smokeless operation of their engines; the number of traveling engineers and firemen was increased; completion of the installation of ring blowers and arches was accomplished; many improvements were made in the roundhouses; and the equipment of all yard engines with air-induction tubes was undertaken, this being now nearing completion.

There is a collection of miscellaneous fuel-burning equipment such as small vertical boilers, foundries, type furnaces, tar kettles, excavating and road-building machinery, and locomotive cranes. Of these the small vertical boilers, used for a great variety of purposes, are the most numerous. These boilers have many attractive features for the purchaser, and in the smaller sizes no very practical substitute is available. We require the burning of coke in these boilers, but are recommending in sizes of 15 hp. and over that they install either horizontal downdraft boilers or updraft boilers with small mechanical stokers. Coke, oil, gas, or electricity has been used in solving the problem with many of the other types of miscellaneous equipment. Gasoline drive is proving an excellent remedy in construction equipment.

Owing to lack of funds and personnel, the residence problem can only be taken up in a general way. Coke, oil, and domestic stokers are very gradually improving this condition.

Another important phase of the work that needs to be mentioned is the issuance of permits on new installations. The ordinance requires that smokeless equipment be installed, but does not go into detail as to what constitutes smokeless equipment. This left the decision in the matter to be made by the Smoke Department. Upon investigation of the problem it was soon apparent that the extreme smoke condition would require a radical procedure. Much of the so-called "smokeless" equipment sold would hinder rather than help smoke abatement. There would not only be the work of correcting old equipment, and there was enough of it to keep the department busy for several years, but there would be also the added burden and responsibility of inventing a collection of accessories, such as jets and combustion arches, to make a smokeless installation out of the equipment that was being advertised and installed as smokeless, and then in addition be required to follow it up with constant policing. The market was littered with "pain killers" when what was needed was a cure. If there is anything that makes smoke abatement ridiculous and hopeless in the eyes of a none too optimistic or favorable public it is the permission of new installations that are chronic smokers. Quack remedies invite lack of confidence, breed discontent, depress and discourage smoke-abatement officials, and lead to ultimate disaster.

Specific Types of Equipment Described

A little space will now be given to the discussion of specific types of equipment.

The Scotch marine boiler is considered by the author the least desirable of all. It generally comes in sizes too large to induce the owner to burn coke without continuous pressure, and as a rule it is used in sizes too small for the insertion of an underfeed stoker. A Dutch oven and stoker can be used in conjunction with it, but the first cost and maintenance do not warrant it. Jets help some, but that means another stack that requires continuous observation.

The so-called "smokeless" updraft heating boilers of the drop-arch type have been a constant source of trouble. Under ideal laboratory conditions these boilers approach smokeless combustion, but any equipment will do that; and, besides, the smoke inspector has to deal with average conditions and not ideal ones. Where possible it often has been suggested to the fireman that he knock the arch out so that he could see what he was doing. The words of an old engineer and fireman come to mind; he said that you cannot handle a fire when you cannot see it.

Overfeed stokers of the various designs, both automatic and hand-operated, have subjected the Smoke Department to many additional worries. They belong to the classes of equipment previously mentioned in that if all the conditions, including stack, setting, fuel, rating, and the many human qualifications of a good fireman, are just right, reasonably smokeless operation may be expected. However, these conditions seldom exist.

The underfeed stoker and the downdraft boiler have been found uniformly good. This does not imply that they are always smokeless, but it does mean that they require a minimum of policing.

The thought that presented itself to the author was that if they are the best, why not use them. Energy that is being spent to make other equipment smokeless might be spent in

keeping it out of the city and in promoting the installation of underfeed stokers and downdraft boilers. Needless to say this proved a difficult undertaking. Besides, it worked a hardship on the local representative of other equipment and to a lesser extent on the manufacturer. However, the fact remains that the first duty of a smoke inspector is to abate smoke.

The law was not used, but an appeal to the public was made, and the response was excellent. Unsatisfactory equipment was gradually reduced, until this year there has not been a single coal-burning installation above 1200 sq. ft. of radiation other than underfeed stoker or down-draft boiler.

The severe criticism and the opposition induced have been balanced by the simplification of permits and the calculation of construction dimensions and the relief from smoke violation that only these two types of equipment can give.

Human Element Has Vital Effect

In the remainder of the paper the human elements underlying smoke abatement will be discussed.

The human problem connected with smoke abatement involves an enormous task. The large number of difficult and varied duties to be performed and the many qualifications required of a smoke inspector to successfully perform them would warrant the employment of much higher salaried men than is usually the case. Many problems which arise might tax to the limit even the well-developed ingenuity, diplomacy, courage, and all-around leadership of a ten to twenty thousand dollar a year man.

Progress in general has that difficult task of overcoming the inertia of long-established custom and of controverting reactionary policies and misinformation. To the author the most interesting fact learned in connection with this work has been the realization of the intricacies of human nature and complexities of the human mind. To most of us, habit, whether good or bad, is an all-powerful taskmaster. Some one has said that the customs of a people are much more powerful, being the habits of the individual reenforced to utter complacency and self-satisfaction by knowledge of the fact that all around him are confirmed addicts of the same habits. The individual or the firm that undertakes to sell something new to the public which will radically alter the customs of many years' standing has a problem to meet. Stimulating the demand of the public for something new requires patience and resourcefulness. However, it is being constantly done in business and commerce.

In the work accomplished in Nashville, smoke abatement has been considered as a business and has been taken up in a business and engineering manner.

As in any business that is likely to succeed, honesty and sincerity of purpose have been outstanding factors. It is needless to emphasize that political methods are not used. No favors are accepted from any one. The weak and lowly are not oppressed nor the wealthy and influential sidestepped. Everything which aids smoke abatement is actively and openly favored, and everything which hinders smoke abatement is vigorously opposed. Particular makes of equipment are not recommended, but types are.

As in any business, smoke abatement must be built on a solid foundation. Foolish expenditure of money is not recommended and, in the case of many cure-alls, is not permitted. An unsatisfactory installation based on the recommendation of the Smoke Department does more damage than good.

Smoke abatement is sold on its merits. An attempt is made to engender among the people confidence in the work being done and in the recommendations offered. A firm belief is held that smoke abatement does not generally bring oppression; it renders cheap and valuable aid. Money spent on abating smoke is not charity, but a wise investment. A smokeless stack denotes an economical plant and an enterprising owner. Smoke abatement is an asset to a community, not a liability.

In making many contacts with the public the smoke inspector has much in common with the salesman in that he is selling his product, in this case smokeless combustion, to the people. One important difference is that he has the law behind him and is always assured an entrance and hearing. Besides, the threat of prosecution always lies in the background. In other respects he meets resistance in the way of prejudice, objections, alibis, faithless promises, procrastination, suspicion, inertia, pretended or actual financial difficulties, etc. This opposition takes on many forms, but a few are predominant and ever-recurring and will be mentioned.

The most common form of resistance is the pair of violators living close together who may be called Mr. A and Mr. B. It is quite a human tendency of the individual to be intolerant of the faults of others and entirely oblivious to his own. It is also a mathematical axiom that a business man sitting in his office with a large flat roof over his head and the top of his stack above it cannot see his own smoke, while the smoking stack of his neighbor is very often at such an angle that it can be constantly observed from his office window and serves as an ever-present annoyance. When Mr. A is interviewed, the most prolific advice is forthcoming from Mr. A as to the severe tactics that the smoke inspector should adopt toward Mr. B. This is followed by a multitude of reasons why he himself should be left alone. The same dialogue occurs when interviewing Mr. B. This attitude has been dispelled with good results by ridicule through the press and other means of publicity.

A variation of the previous condition is a group of several smoking plants in the same neighborhood with the owner of each one objecting to all the others. In meeting this situation the best results have been obtained by concentrating on the weakest party and breaking him down and then using that as a leverage on the next.

Difficulties in Securing Proper Equipment

Another well-defined custom of the people is the almost universal tendency to install the cheapest equipment that can be found on the market. They may be lavish in spending money on other things that they know something about, but seldom on combustion equipment. Where there is no municipal supervision the cheap-equipment representative is assuredly resting in clover. Due to severe competition the architect and heating contractor often have been found to accentuate this condition. It is being continuously called to the attention of prospective builders that the size of the boilers should not be determined by the proposed dimensions of the boiler room, but that the dimensions of the boiler room should be determined by the size of the equipment necessary to heat the building. The cost, quality, and capacity of the boilers should not be determined by the subtraction of the money spent on other parts of the building from the money available, but by their economy of operation and the service they render. In purchasing combustion equipment first cost should receive least consideration, while operating cost and relative service should receive the most.

Another condition closely related to that just mentioned concerns those who build to sell or build to rent. These prove difficult cases to handle as they are naturally confirmed buyers of cheap equipment. The best method to deal with this type of builder has been to strike at his weakest point, hinder the sale or rental. In one particular case the sale of a property was delayed for several months, numerous legal difficulties, extra expense, and no end of trouble being encountered. Warnings have been given through the press to prospective purchasers

or renters of property to get in touch with the Smoke Department and investigate the smoke situation of their heating plant the same as they would inquire into the title of the property. If the stack is a smoke violator, have it stated in the contract that the recommendations of the smoke inspector be carried out before the sale or rental is completed. These methods have brought results.

In view of the many philanthropies and other signs of a progressive age of civilization it may appear irrelevant to say that the most attractive inducement that can be made to the smoke violator is the dollar appeal, but such is the case. Work in this city has been based on the theory that everybody loves money. The savings possible from following the recommendations of the Smoke Department have always been kept in the foreground and the pleas for smoke abatement kept in the background. It is fortunate that mechanical and economic conditions today make this possible in practically all cases. Civilization has not reached the point where indefinite and long-postponed promises of group benefits strike a very responsive chord; the average individual is much more interested in himself and his own business. The average business establishment is overrun with people inspecting this and that, asking for donations, and selling tickets for everything under the sun. The business man has his own worries and is weary of all this. He wants a breathing spell by having some one come in to help him instead of asking for help. For this reason it has been customary with the author to emphasize personal savings on investment and not charity or civic duty.

The dollar appeal is most successful, but is not always effective. In cases where it fails the next best plan has been found to be the pressure of public opinion, and particularly so in a city of this size. Public opinion is a powerful leverage. Most individuals want to be well thought of by their fellow men. Most of us will do things or fail to do things when we think nobody will find us out that we would reverse if we thought the general public would be let in on it. Advantage is taken of this human weakness always to let the sunlight in, open it up to everybody, and give the individual unfavorable publicity. If a man is a leader in church or civic activities, and orating from the platform on moral obligations, law observance, and civic pride and then failing in the practical details, it has been customary to broadcast the facts. He is sure to have plenty of acquaintances who will enjoy hearing the news. This system has been used with many variations.

Prosecution has not been used as yet. Although the author is heartily in favor of it, the work is so new in this city that the methods previously mentioned are bringing the necessary changes as fast as they can be disposed of.

Methods of Handling the Violator

A few miscellaneous items in connection with human relations will be noted. It has been found that it never pays to stoop to bitter fighting and personalities. The best method is to use the qualities of a high-grade salesman. Courtesy and respect should be rendered every one and demanded in return. If the man is really busy or worried over other matters, it pays to excuse yourself and see him at another time. If he receives you, he should give you his undivided attention, and any effort on his part to do other work such as opening mail should not be permitted.

Criticism comes from all sources. If sincere and not too malignant, no attention is paid to it. Where underhanded methods are used and great enmity shown, especially by influential people, an immediate demand is made for a "showdown." The idea is always given that they are out of step, not the Smoke Department.

Ridicule, disparagement, and disrespect are sometimes shown. Many have the idea that politics plays a big part in the work. These are best overcome by keeping steadily at the work before you and refusing either to talk or to listen to politics.

There is a very natural opposition among equipment and fuel men who may nurse real or imaginary injuries. It is frankly admitted by the author that some damage has been done them, and also for the most part their opposition has been very fair and aboveboard. It is believed that no great personal enmity exists between them and the Smoke Department. Many of these have taken plausible steps toward meeting the requirements of smoke abatement. One thing that it is well to bear in mind in this respect is that, however much it might be desired to believe the contrary, the fact remains that they are in business to make profits and not to abate smoke. The only time that they will try to aid smoke abatement is when they think it will pay them to do it. It would be foolish to expect anything else.

One of the greatest factors for success is a force of salesmen with strong personalities and unlimited energy selling smokeless equipment. They tend to minimize the efforts of those desiring to sell unsatisfactory equipment. Often where the personality of the smoke inspector will make no impression in holding off opposition a good salesman of smokeless equipment will walk away with the order. Great interest is taken in encouraging local connections of smokeless-equipment manufacturers with powerful sales representatives. Nashville is full of underfeed-stoker and downdraft-boiler salesmen.

In order to meet and overcome the many obstacles, some of which have been mentioned, it was perfectly apparent that there would have to be a pooling of resources and that all that would aid the work would have to be gathered together and organized. Disorganized effort and lack of harmony would mean defeat. Those forces which were unfavorable could get around and tear down faster than the Smoke Department could build up. A tip was taken from successful business men. After assembling a good product their next step is to let the public know about it. Mass action is employed through publicity and advertising to educate the public to its many advantages. Due to the many hazards in the path it was deemed perfectly ethical to adopt the methods of a showman and "ballyhoo" smoke abatement. "Grandstand plays" were intentionally made. An example of this was to pick out occasional bad offenders who, due to their location, were prominently known. As soon as an underfeed stoker was purchased the fireman was induced to make all the smoke possible till the stoker was installed. This would invite complaints and attract interest and often ridicule, and then when the stoker was installed the change was so noticeable that it gave everybody a thrill.

Channels of Altering Public Opinion

The methods that have been used to change public sentiment will now be discussed. It is worthy of note that the public soon gets tired of one method and wants a change, so that something new must always be devised for them. It often pays to appeal to the feelings and imagination rather than to reason.

The press forms the foundation of all educational work. Without its complete support smoke abatement would be a failure. The inseparable twin pictures of stacks before and after with explanatory articles were used till they grew old. Photographs of smokeless equipment were inserted. Articles on the savings produced and copies of testimonial letters were printed. Communications, whether favorable or unfavorable, were encouraged. Cartoons proved very effective. A photograph of the first domestic stoker installed, with the owner's baby sitting on the hopper cover, had a human appeal. A news photographer took

a picture of a noted grand-opera star as she stepped off the train. A note under the picture said that she was holding her furs close around her neck to protect her million-dollar throat from the smoke of a shifting locomotive. A clipping of this was sent to the president of the railroad and it had a good effect. The effect of smoke on aviation was emphasized. Headlines such as, "Mail Ship Gropes in City's Smoke and Lands Over River" helped the work along. Rotogravure advertisements of smokeless equipment going into new hotels and office buildings proved quite a benefit. The papers have been good to give us many editorials. This will give an idea of the aid given by the press.

The Smoke Abatement Commission is considered indispensable to the unhampered progress of the work. The members have always been willing and ready to make visits with the smoke inspector, talk over the radio in the interest of the work, write personal letters asking for support and cooperation, give addresses before clubs, and in many other ways lend their support.

The radio has assisted us greatly each winter. Station WLAC donated sixteen five-minute periods to the Smoke Department last winter. Prominent citizens from different professions and callings, such as a lawyer, nose and throat specialist, architect, engineer, women's club members, life insurance official, business man, and a manufacturer, were called upon. In the case of business men and manufacturers care was taken to pick men who had followed recommendations offered by installing equipment and who had made appreciable savings. These radio talks, coming from men viewing the smoke nuisance from different angles, aroused much interest, and favorable comment and many letters and telegrams were received.

Instruction cards for domestic use were printed and about 20,000 were distributed. On one side the approved method of firing coal in a residence furnace, together with an explanatory diagram, was printed; on the other side similar information was given concerning coke.

Booklets were printed describing the care and operation of the domestic furnace and the necessary steps to take to decrease the smoke nuisance. About 12,000 of these were distributed among home owners.

Domestic Firing Influenced by Cards

Instruction cards for the firemen of industrial plants were printed and tacked up in all boiler rooms.

Large equipment posters, 24 by 36 in., were printed. These were set up on the premises of new buildings and called the attention of the public to the fact that the owner had cooperated, the Smoke Department was on the job, and a type of smokeless equipment such as an underfeed stoker had been installed. These cards have given excellent publicity to the work. Many persons, out of interest and a desire to learn something new, inspect new construction work, and when they would see this card their curiosity would lead them to the boiler room to see what the equipment was like. This left a definite impression on their mind. Others who would merely pass by would know that something was done.

The theaters were put to work. Actors coming to the city always complained about the smoke. They were given encouragement to work some jokes about Nashville smoke into their act.

A number of articles on smoke and its abatement were written for trade magazines, local and otherwise.

Many addresses were made before clubs and organizations of all kinds. Literature relative to the smoke nuisance would be distributed among them at these times. Requests were made for their cooperation and support, and invitations were offered to any one particularly interested to visit the Smoke Department offices.

Direct Letters Form Part of the Plan

Correspondence has played a big part in promoting smoke abatement. Letters of recommendation constantly are being sent out. The most important item in connection with the work is considered the care taken in obtaining smokeless equipment in new installations. It seems illogical and useless to run one's legs off stopping old leaks and then allow new ones to appear. An individual case is made of every proposed new installation, and letters of recommendation are sent to architect, owner, contractor, and every person interested. Letters of appreciation are sent to all those who have followed our recommendations. This tends to make permanent their support and cooperation and puts them in a happy frame of mind regarding the work.

Articles are printed in the newspapers describing some new installation of smokeless equipment and containing testimonial letters from the owners regarding the large savings and satisfactory service that resulted. A number of these papers will be purchased and the clippings of this article along with an introductory letter sent to about fifty of the livest prospects. These few examples give an idea of what may be accomplished through the mail.

Encouragement on a small scale has been given to civic clubs and various other organizations to appoint committees to aid in the work. As the men appointed on these committees are generally leaders and successful business men who know nothing about smoke abatement but who have decisive views and dominating personalities, there always is danger of a top-heavy organization and of pulling in different directions. Although this method has been used very conservatively and with great success so far, the fact is appreciated that there always is danger lurking around. So long as they can be kept from taking the bit in their mouth and jumping over the traces their customary boundless energy can be used to wonderful advantage.

A number of coke-burning displays have been held in downtown office buildings and at the Tennessee State Fair. Literature on the good qualities of coke and the proper methods of burning it was distributed. These displays were not sponsored by the Smoke Department, but great interest was taken in them.

One of the best ideas on publicity was the promotion of window displays about smoke and its abatement. The displays were placed for two weeks at a time in three locations, a show window of a downtown department store, and in the central public library, and in the show window of a downtown hardware store. Each location was admirable so far as attracting the attention of the maximum number of people. Articles on and photographs of the displays were printed in the newspapers. The center of the display was composed of a large chart of coal and its by-products. About ninety samples of coal by-products were placed in front of the chart, and colored ribbon streamers were run from the name on the chart to the sample. An electric light was placed behind the samples so that the many beautiful colored dyes were shown up to the best advantage. At either side were photographs, literature, and drawings showing the implements to combat smoke. These displays proved an unusual attraction and great crowds collected. It was most interesting to mix in unknown to the crowd and listen to their comments. Their expressions were most informative and showed to an alarming extent the gross ignorance and hazy ideas that the average individual had as to what smoke abatement was all about. This was not confined to the lower classes, but was almost as common among the intelligent and

educated classes. The idea which presented itself most prominently to the author's mind was that what these people needed most was education and not prosecution.

Booth Displays at Local Fairs

Another attractive feature that was promoted by the Smoke Department was a smoke-abatement booth at the Nashville Pure Food and Better Homes Show. The center attraction in this case was a human lung, black with soot, preserved in a jar of alcohol, and resting on a high stand with a light behind it to show it up. On a placard it was called to the public's attention that the natural color of a lung taken from a person in a country district was pink. One man asked why the lung of a farmer was not placed beside it for comparison. A friend with him said the answer to that was easy. The air in the country was so pure and as a result the farmers were so healthy that they never died to furnish a sample. A local aviation official, very bitter against the smoke clouds, offered the suggestion that a handle be attached to the jar and that it be carried through the city by the smoke inspector on his visits as a practical and conclusive argument for smoke abatement. Behind this portion of the display was a table containing baskets of coke samples and jars of fuel oil. On the walls were tacked photographs and literature of smokeless equipment. Near the top of the rear wall a skyline of smoking stacks was painted. Booths containing domestic stokers, oil burners, and coke-burning displays were grouped around the smoke-abatement booth. One unusual display was an open grate, without flue or chimney, burning coke. It was a good lesson on smokeless combustion. During the afternoons and evenings three persons were kept busy at the smoke-abatement booth handing out literature and explaining the details.

An excellent means of educating the public has been through the schools. These classes were carried on under the auspices of the Nashville public schools. A night school for engineers with a professor of mechanical engineering for instructor accomplished excellent results. There is a night school for white firemen and another for colored firemen during each winter. A night school for home owners on firing domestic furnaces smokelessly has been held in school buildings in different parts of the city. It is believed that Nashville is the first public-school system in the country to include a short course in its curriculum on firing and taking care of domestic furnaces. There are only four recitation hours during the term for the eighth grade boys, but it gets them at an impressionable age and has proved of great benefit. Some of these boys have come to the smoke inspector for further information.

From the experience gained in educating the public to the value of smoke abatement the author has come to the conclusion that educational publicity is one of the most important factors in the work. The idea has been formulating for some time that the individual efforts that are being made along this line might be organized, unified, and grouped to a certain extent into a general program of national publicity and education.

A prosperous business in these progressive times is usually one that has such confidence in its product that it pays large amounts in national advertising to get it before the people and to stimulate demand. To a certain extent smoke abatement is a product to be sold to the public, and if it is worth promoting at all and engineers have confidence in its possibilities, why should not the tactics of the successful business man be employed in putting it across.

From the convincing results that quite a number of cities are now getting in smoke abatement by merely local and disunited efforts, it seems possible that the time is almost at hand when such a procedure might solve the smoke problem for good.

Discussion

George W. Bach.[2] The paper is a complete treatment of the subject of smoke abatement, from the smoke inspector's point of view. While it does not deal with deep theories and Ringelmann chart application, it covers the subject completely. The paper brings out the most important phase of smoke abatement clearly, and that is the education of the public to smoke-abatement work. His use of the radio, illustration booths at expositions, and other intelligent propaganda are the most important steps in the studies of any smoke department.

In only one thing does the writer disagree with Mr. Fisher, and that is in the matter of down-draft furnaces. In the early days of that furnace the writer was thoroughly sold on them, but in the last ten or fifteen years he has reached the conclusion that the down-draft furnace is not a practical means of firing a boiler, and prevents smoke only at one particular rating, smoking badly and operating inefficiently at all other ratings. The writer feels that Mr. Fisher will agree with him as time goes on and he gets more down-draft furnaces in use.

By far a better installation is to eliminate hand-firing entirely and use either underfeed or proper overfeed stokers wherever possible. In the smaller boilers now fired by coke or high fixed-carbon coals, the use of natural gas and oil with proper furnaces is an improvement on hand-firing.

H. E. Fishbough.[3] The paper mentions the Scotch marine boiler as one type the least desirable of all. The best-designed boiler or boiler-room equipment will not operate efficiently if the fireman does not have the proper fuel and instructions for its operation.

Fig. 1 shows a correctly designed and installed Scotch marine boiler that incorporates the fundamental principles of the modern

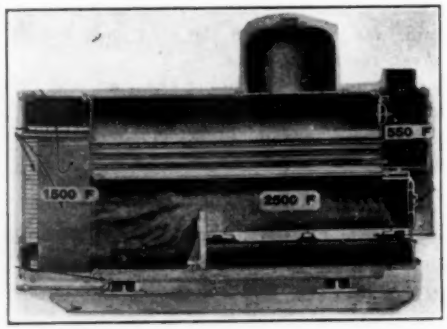

Fig. 1

high-class power unit. The furnace is completely surrounded with water walls. There are no furnace-radiation losses and no furnace refractories to be replaced from time to time. A refractory-lined combustion chamber insures complete combustion of all gases.

From many exhaustive tests the temperature of the gases, taken with electrical and optical pyrometers in passing through the boiler, was 2500 deg. fahr. furnace temperature, 1500 deg. fahr. in the combustion chamber, and 550 deg. fahr. in the flue gas passing to the stack. The flue gases averaged from 10 to 12 per cent CO_2 hand-fired.

Fuel is the next consideration. It is necessary to select the proper size of coal for stoker equipment, and it is just as important to select the proper size of coal for a hand-fired boiler if one expects to eliminate the smoke.

[2] Vice-President and General Manager, Union Iron Works, Erie, Pa. Mem. A.S.M.E.

[3] James Leffel & Co., Springfield, Ohio. Mem. A.S.M.E.

Fig. 2 represents a 3-in., a 2-in., and a 1-in. cube of coal drawn to relative scale and surrounded with a cube of air necessary to produce combustion at 12 per cent CO_2. The 3-in. cube requires approximately 309,500 cu. in. of air; the 2-in. cube requires approximately 91,800 cu. in. of air; and the 1-in. cube requires approximately 11,500 cu. in. of air.

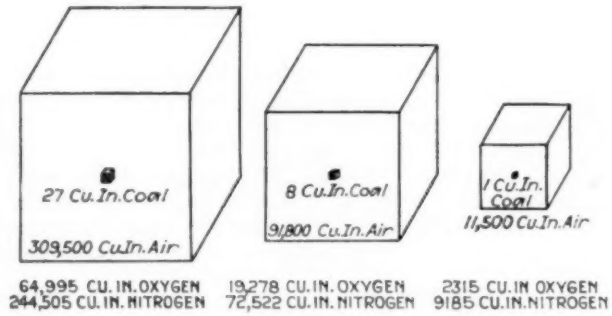

FIG. 2

From this it is apparent that it will be much less difficult to bring to the 1-in. cube of coal the 11,500 cu. in. of air required for its efficient combustion than it will be to supply the 3-in. cube of coal with 309,500 cu. in. of air and secure the intimate contact necessary for efficient and smokeless results. This conclusion has been confirmed by the results obtained on many trial runs made on the Scotch marine boilers.

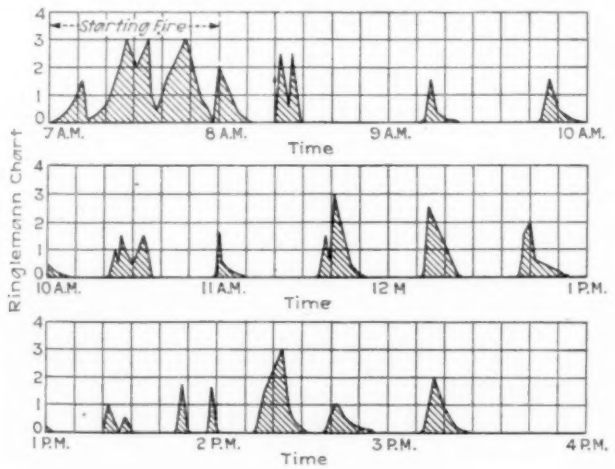

FIG. 3

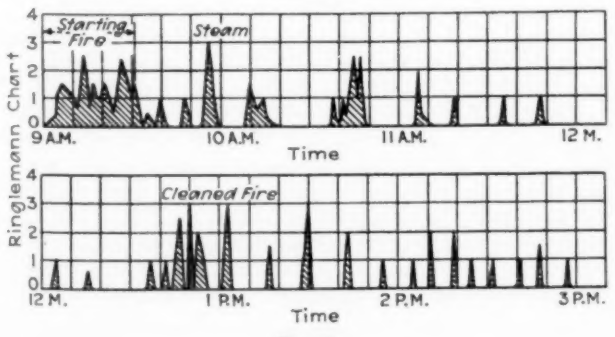

FIG. 4

Ringelmann's charts were used in recording the smoke densities for the charts shown in Figs. 3 and 4.

Fig. 3 shows the observations taken from a 30-hp. Scotch marine boiler with very poor stack conditions. The observations were without the fireman's having any knowledge of being observed. This plant uses egg-size coal consisting of the 2- and 3-in. cubes. The analysis was as follows: Fixed carbon, 47.14 per cent; volatile, 38 per cent; ash, 14.86 per cent. The period from 7 to 8 a.m. was used in starting and raising steam.

Fig. 4 gives the observations from a 40-hp. Scotch marine boiler with good stack conditions. This plant uses nut-size coal of 1-in. cube or less, having an analysis as follows: Fixed carbon, 54.88 per cent; volatile, 36.54 per cent; ash, 7.28 per cent. The period from 9 to 9:30 a.m. was used in starting fire and raising steam.

The writer draws the following conclusions: (1) The equipment must be designed and installed properly; (2) the fuel must be of a size adaptable to the furnace; (3) many stoker-fired plants are found smoking as well as hand-fired plants, and the smoke problem can be reduced only by the careful cooperation of the fireman and the smoke inspector.

AUTHOR'S CLOSURE

It is gratifying to note that the views of Mr. Bach in regard to smoke abatement are in such close accordance with those of the author.

In the matter of down-draft boilers, although no such definite statement was made in his discussion, the author has taken the liberty of believing that Mr. Bach was making special reference to power boilers 100 hp. and over and with relatively high and variable ratings. With such equipment the author agrees with Mr. Bach that the down-draft boilers are a poor substitute for underfeed stokers.

The author will go even farther in saying that he is more than favorable toward the use of underfeed stokers in heating boilers from 10,000 sq. ft. of radiation down to the small residence boiler. It is an accepted fact that average hand firing on any type of furnace is much inferior to stoker firing. Smoke-abatement officials are very fortunate in the fact that the trend of combustion equipment is toward stokers even down to the smallest sizes. Notwithstanding the great increase in stoker sales, their use in the smaller plants is comparatively new, and a recommendation to a prospective purchaser that he not only buy a good boiler but that it would be a paying investment for him to also make an additional outlay of capital for a stoker which will cost more than the boiler itself often serves as a severe shock to his sense of money values. The tendency of the average builder is to decrease the original apportionment for a heating plant as made by the architect and transfer the money thus obtained to the purchase of other things for the building rather than to increase the original cost of the heating plant for better service and economy. It is often difficult to persuade him to buy a serviceable boiler of sufficient capacity. In such cases the logical procedure is to promote the purchase of the most satisfactory hand-fired boiler, which, in the author's mind, is the down-draft.

Regarding the discussion presented by Mr. Fishbough, the author wishes to say that it will be necessary, in view of more recent information, to retract that reference to the Scotch marine boiler which states that "as a rule it is used in sizes too small for the insertion of an underfeed stoker."

The author was recently apprised of the fact that at least two manufacturers of the Scotch marine boiler are considering the adaptation of underfeed stokers to the smaller sizes of this particular boiler. Their efforts in this direction are most commendable, and a satisfactory combination of these two types of equipment will form a basis for agreement among all parties concerned.

FSP-52-11

Relative Economy of Pulverized Coal, Oil, and Gas as Boiler-Plant Fuels

By MARTIN FRISCH,[1] NEW YORK, N. Y.

Where plants are so located that several fuels are available, the management must determine which fuel is most economical. An analysis of the cost of making steam with each of the available fuels is necessary. The various commonly used fuels are compared as to their relative economy. The influence of each fuel on overall plant performance and economy is considered. The paper sums up the relative plant efficiency and the relative plant economy to be expected of the various fuels.

MOST steam plants are restricted in their choice of fuels by their location and by other considerations. But some plants are so located that several fuels of the same type or even of different types become interesting as fuel possibilities. The managers of such plants have to determine which of the available fuels will be most economical to use. The answer to this question is not necessarily the name of the fuel which may be delivered to the plant at the lowest cost per heat unit. This is a well-understood fact, and a careful and complete analysis of the final cost of making steam with each of the available fuels is necessary. But these analyses are too laborious to be made often. For that reason it is of interest to examine the various commonly used fuels and to compare their relative economy for steam making. The purpose of this paper is to present the results of such a comparison.

The ten fuels whose compositions and other properties are given in Table 1 are typical of fuels commonly employed for steam making, and they have been used as the basis of the comparison.

The fuel analysis is only a partial guide to the dollar value of a fuel, and a knowledge of physical characteristics determinable by laboratory tests only incompletely supplements the story told by the analysis. In order to evaluate the relative economy of various fuels it is necessary to consider the influence of each fuel on overall plant performance and economy, preferably on the basis of actual plant experience with each fuel. This necessarily also forces an investigation of the influence of each fuel on plant design and plant cost.

This paper will consider, first, the relative plant efficiency and, second, the relative plant economy to be expected with the various fuels.

Comparative Boiler-Plant Efficiency With Various Fuel

It is a matter of common knowledge among power-plant engineers that a given boiler plant cannot burn with equal efficiency all fuels to which the plant may be readily adaptable. The maximum efficiency attainable with any given fuel in a given plant depends on the character of the fuel. Not only the furnace efficiency, but also the boiler heat-absorbing capacity, the flue-gas temperature, and the draft loss depend on the character of the fuel. The boiler has an uncanny way of guessing changes in its furnace diet, as will be shown.

The influence of each of the ten fuels of Table 1 on the performance of a certain boiler was investigated, and the maximum efficiencies attainable with furnaces and firing equipment most suitable to develop the highest efficiency possible with each fuel were determined.

Since all of the fuels considered may be burned in suspension and some of them cannot be burned any other way, it will be understood readily that for the purpose of this investigation, embracing solid, liquid, and gaseous fuels, pulverized-fuel firing was considered only, in order to simplify the comparison. The conclusions of the investigation, which were checked against the results of comparable actual boiler tests, confirm the value of an index of boiler performance already suggested by others. This is the amount of sensible heat imparted to the products of

[1] Engineer in Charge of Development, Combustion Engineering Corporation.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., October 7 to 10, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

combustion per pound passed through the boiler. The magnitude of this index depends on (1) the heat value of the fuel, (2) the weight of gas and vapor formed in the combustion of the fuel, and (3) amount of heat made unavailable by the incomplete combustion of the fuel and the evaporation of moisture and the formation of water vapor by the burning of hydrogen in the fuel.

The effect of incomplete combustion losses on the index is small because the reduction in available heat due to this cause is compensated for by the reduction in the total amount of gas formed per pound of fuel by a quantity proportional to the amount of unburned fuel.

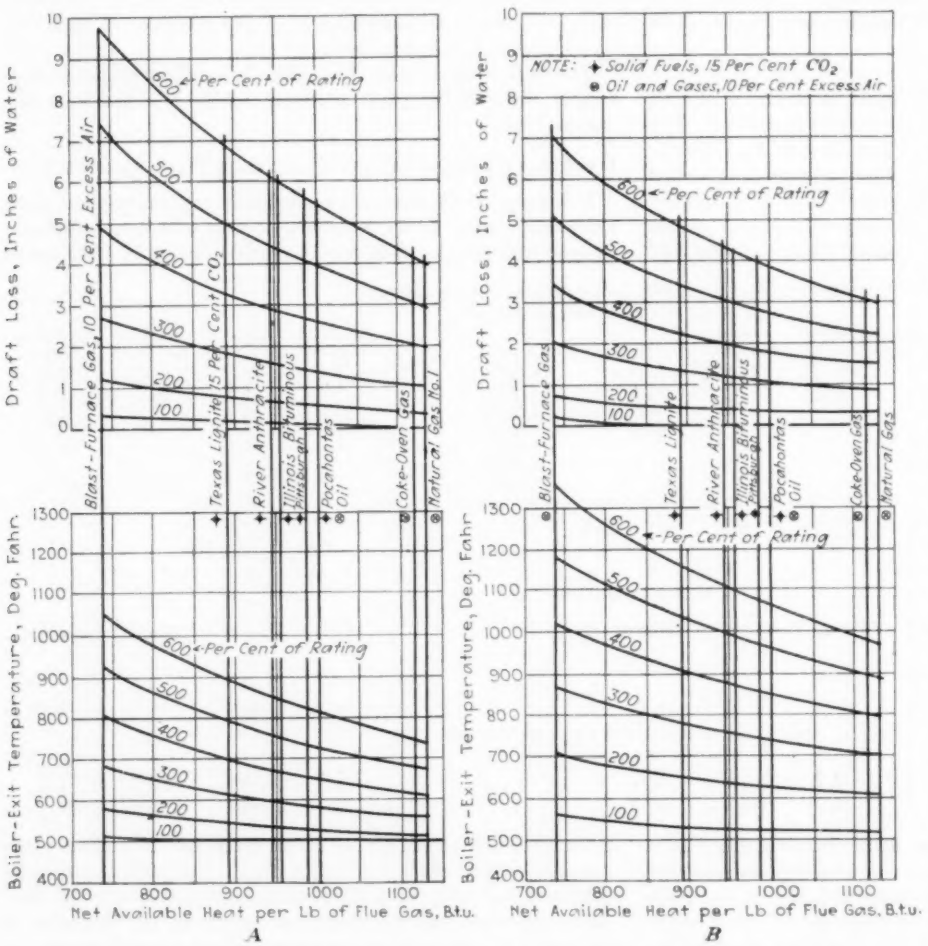

FIG. 1 SENSIBLE HEAT IN FURNACE GASES IS A GOOD INDEX OF BOILER PERFORMANCE
(*A*, typical straight-tube boiler; *B*, typical bent-tube boiler.)

The amount of excess air used influences the magnitude of the index by its effect on the total quantity of gas formed per available heat unit.

The moisture in the fuel and the vapor formed by the burning of the hydrogen have the greatest effect on the magnitude of the index, because the effect is twofold. First, the total quantity of gas formed per available heat unit varies with the amount of vapor formed, and second, the latent heat absorbed in the formation of vapor reduces the amount of sensible heat available. The index evidently depends greatly on the fuel characteristics.

Fig. 1 summarizes the relationships existing between the index (the available sensible heat) and the three factors which measure boiler performance; namely, capacity, draft loss, and exit temperature. A typical sectional header and a typical bent-tube boiler are compared in Fig. 1.

The greater the available sensible heat per pound of gas passed through the boiler the greater the capacity developed with a given draft loss. This can be pictured another way, as in Fig. 2, where the decrease in the temperature of identical weights of the products of combustion of natural gas and blast-furnace gas as more and more heating surface is passed over is shown. Each fuel was burned with 10 per cent excess air. Although the combustion temperature of the natural gas was almost 1000 deg. fahr. higher than that of the blast-furnace gas, the boiler-exit temperatures were within 35 deg. of each other. The heat given up to the boiler by the products of the natural gas and the capacity developed were 55 per cent greater, but the draft loss was very nearly the same in the two cases. An extension of such comparisons to the other fuels of Table 1 makes it possible, as shown by Fig. 1, to determine the boiler performance to be expected with each fuel, in accordance with the amount of excess air used in its combustion, and to determine the exit temperatures to be expected at any rating with the several fuels, as in Fig. 3, and the efficiencies, as in Fig. 4. It is necessary, when deriving the efficiencies peculiar to each fuel, to take into account the fact that at any rating and excess air the exit temperatures will vary with the fuel as in Fig. 3, which is based on 15 per cent CO_2 (approximately 20 per cent excess air) in the products of the solid fuels, 13 per cent CO_2 (15 per cent excess air) in the products of oil, and 10 per cent excess air in the combustion of gaseous fuels.

If the air used for combustion is preheated, the sensible heat available per pound of flue gas increases, because the heat available per pound of fuel is increased without a corresponding increase in the weight of the products of combustion. The effect of this is to increase the capacity attainable with a given weight of gas and with a given exit temperature so that at any given capacity the boiler efficiency will actually be higher than it would be with cold air and the draft loss lower. This gain, which increases with the boiler capacity, is additional to the gain which results from the actual recovery of heat in the air preheater. The effect of the use of preheated air on the boiler-exit temperature and on the efficiency is shown in Fig. 5. At 500 per cent of rating the increase in efficiency is 1 per cent and the decrease in draft loss over $^3/_4$ in.

The differences in boiler-exit temperatures at any given rating only partly account for the differences in efficiency attainable with the various fuels. There are also considerable differences in the completeness with which the various solid fuels may be

burned and in the latent heat losses (which particularly affect the oil and gaseous fuels adversely) inevitable with the various fuels. The gaseous fuels and oil may be burned with negligible incomplete combustion losses. However, this is not true of solid fuels, whether burned in suspension or on grates. Experience indicates that if the solid fuels are burned in suspension

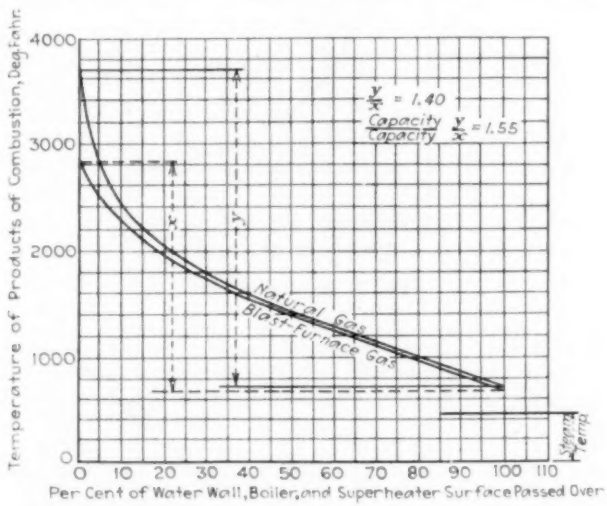

FIG. 2 FLAME TEMPERATURE HAS MORE EFFECT ON BOILER CAPACITY AND THE AMOUNT OF HEAT ABSORBED THAN ON EXIT TEMPERATURES

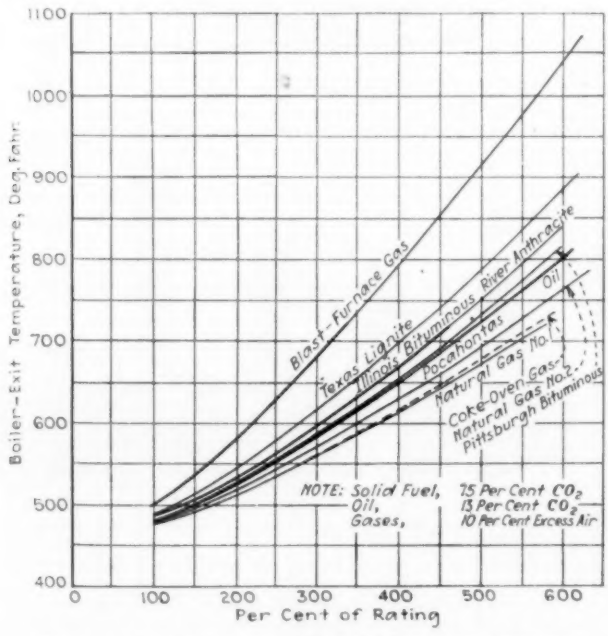

FIG. 3 AT ANY RATING THE EXIT TEMPERATURE DEPENDS ON THE FUEL

after being pulverized to the fineness customary for each fuel the losses due to incomplete combustion will be about as shown in Fig. 6. The high fixed-carbon coals are most difficult to burn completely in suspension and will suffer the greatest wastage due to incomplete combustion. As the fixed carbon decreases, the carbon loss to be expected, all other things remaining equal, also decreases.

This can be substantiated by a study of a large number of tests on pulverized-lignite fuels, Western sub-bituminous coals, Midwestern bituminous, and Eastern coals, including river anthracite. Fig. 6 is based on the conclusions of such a study.

The amount of heat lost by radiation at any capacity will be

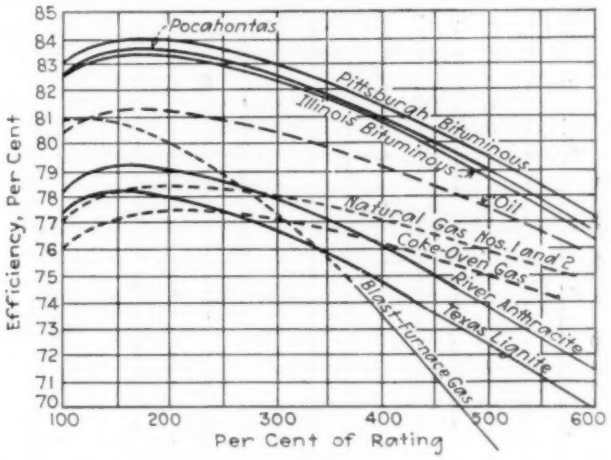

FIG. 4 THE BEST EFFICIENCIES ATTAINABLE WITH DIFFERENT FUELS VARY WIDELY
(Based on Figs. 1, 3, 6, and 7.)

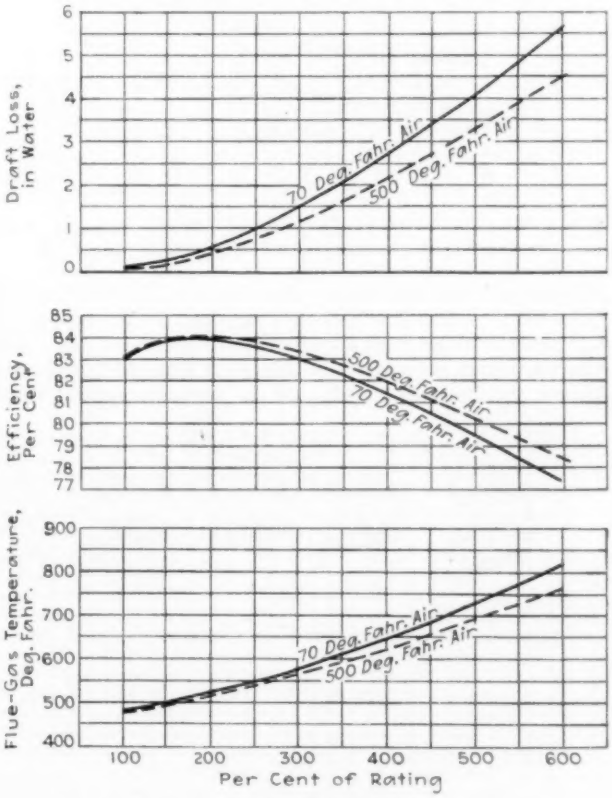

FIG. 5 PREHEATING THE COMBUSTION AIR IMPROVES BOILER PERFORMANCE

very nearly the same for all of the fuels, and no great error in the conclusions of this paper will result from assuming the radiation losses to be as shown in Fig. 7.

If the heat balances of all the fuels be compared, as in Fig. 8, the incomplete combustion will be found to increase in this order:

(1) Lignite, (2) Illinois bituminous, (3) Pittsburgh bituminous, (4) Pocahontas semi-bituminous, and (5) river anthracite. The latent heat losses due to the burning of hydrogen and the evaporation of moisture increase in the inverse order. No incomplete-

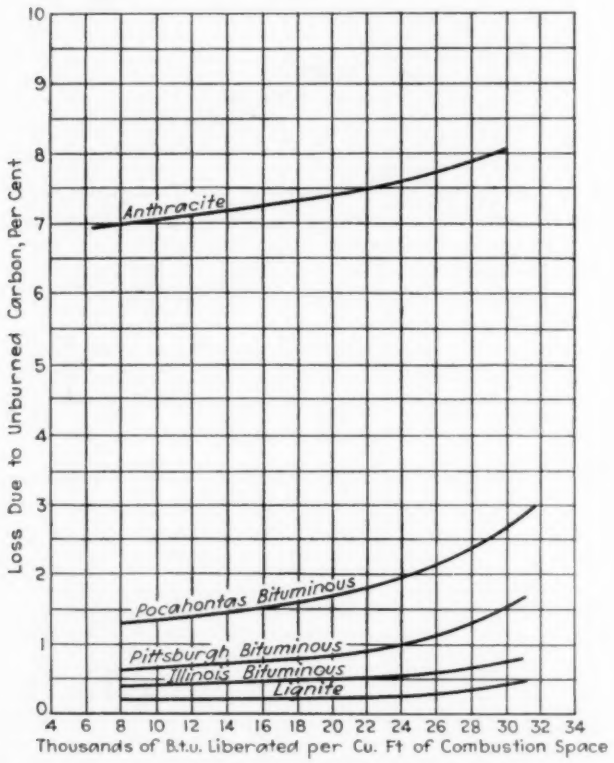

FIG. 6 INCOMPLETE COMBUSTION LOSSES WHEN BURNING PULVERIZED FUELS DEPEND ON THE HISTORY OF THE FUEL

combustion losses are expected when burning oil and the gaseous fuels, but the latent heat losses are very high for these fuels and may exceed 10 per cent for natural and coke-oven gas. The attainable efficiencies are very nearly the same for Pittsburgh, Illinois, and Pocahontas coals. Of the particular coals of Table 1, Pittsburgh coal can be burned with about $^1/_2$ per cent greater efficiency than Pocahontas coal under the assumed conditions,

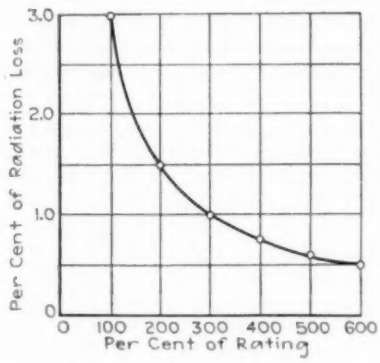

FIG. 7 RADIATION LOSS

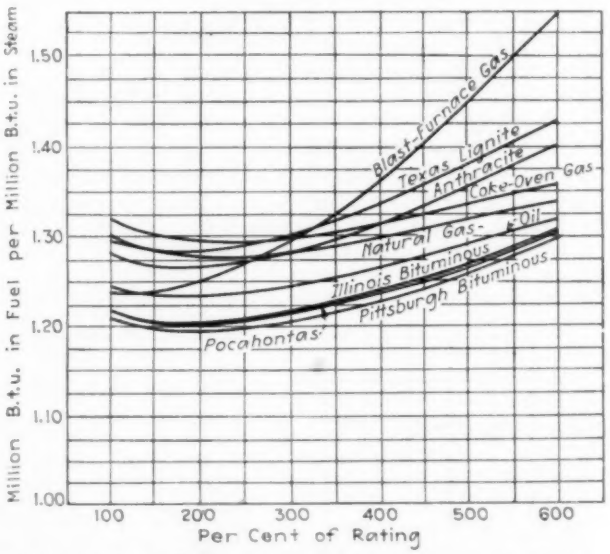

FIG. 9 HEAT UNITS REQUIRED BY FURNACE PER HEAT UNIT IN STEAM

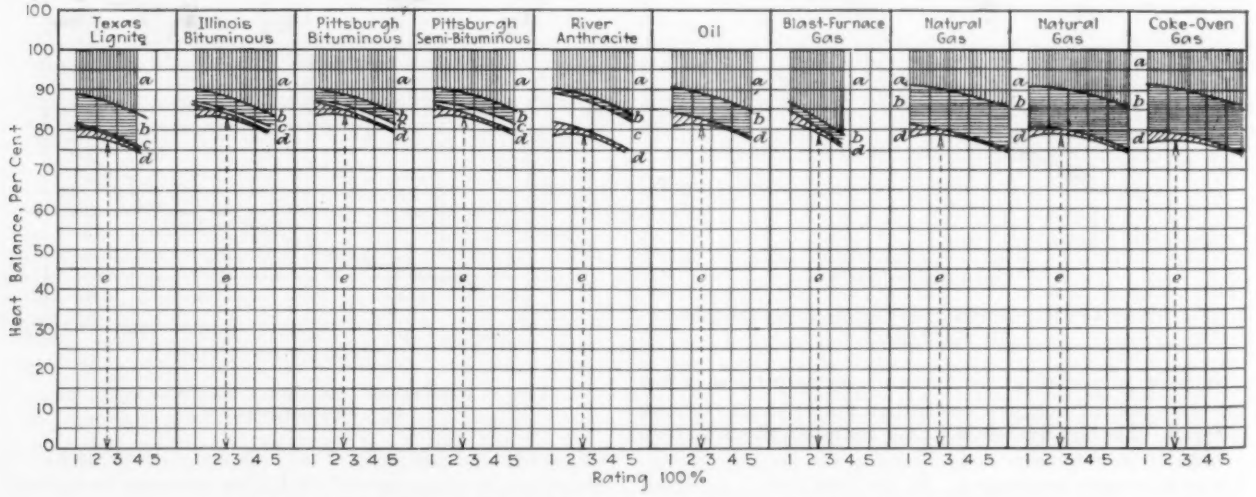

FIG. 8 HEAT BALANCE WITH A GIVEN FIRING METHOD DEPENDS ON THE FUEL

The carbon loss increases as the age of the coal increases. The latent-heat loss depends on the water and hydrogen in the fuel

(*a*, loss due to sensible heat of products of combustion (above 70 deg. fahr.); *b*, loss in latent heat of water vapor in products of combustion; *c*, loss due to incomplete combustion of carbon; *d*, radiation loss; *e*, heat absorbed, efficiency.)

chiefly because of the lower carbon losses to be expected with Pittsburgh coal, and with about ¾ per cent greater efficiency than Illinois coal, because of the somewhat higher exit temperature to be expected with Illinois coal at a given capacity and excess air. Maximum efficiencies attainable with river anthracite and Texas lignite are 5 to 6 per cent lower than with Pittsburgh coal on account of higher exit temperatures and carbon losses with river anthracite and on account of higher exit temperatures and latent heat losses with lignite at identical capacities and excess air ratios. The fact that oil and gaseous fuels can be burned with lower excess air than is the case with the solid fuels was taken into account in comparing the best efficiencies peculiar to these fuels. On this basis mechanically atomized oil can be burned with efficiencies 2 to 2¾ per cent under those to be expected with Pittsburgh coal because of the larger latent heat loss. Steam atomization will have the effect of lowering the boiler-performance index of the oil and will cause higher exit temperature and draft losses at any given capacity. Blast-furnace gas has a very steep efficiency curve on account of large sensible heat losses due to the large amount of flue gas into which the available heat must spread. Efficiencies attainable with blast-furnace gas will be 2 to 20 per cent lower than with Pittsburgh coal. Coke-oven and natural gas can be burned efficiently, but on account of latent heat losses of over 10 per cent or more, the overall efficiencies to be expected with these fuels will run 3 to 5 per cent lower than with Pittsburgh coal.

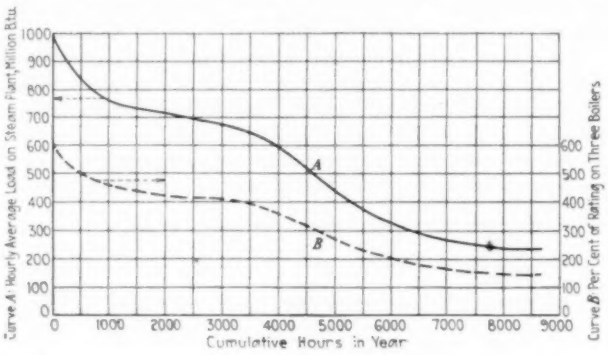

FIG. 10 BOILER-PLANT LOAD-DURATION DIAGRAM FOR COMPARING FUELS UNDER THE SAME LOAD CONDITIONS

The significance of these efficiency differences is to be found in Fig. 9, which shows the number of heat units which must be purchased in different fuels and supplied to the furnace per million B.t.u. of heat absorbed by the boiler.

COMPARATIVE BOILER-PLANT ECONOMY WITH VARIOUS FUELS

The character of the fuel affects not only the number of fuel heat units required per steam heat unit but also the amount of money that must be expended in order to properly burn each fuel. The final cost of steam will depend on the following factors, some common to all fuels and others peculiar to each fuel as shown:

Common to All Fuels.

(*a*) Fixed operating and maintenance costs on boiler plant exclusive of fuel and fan equipment.

Peculiar to Each Fuel.

(*a*) Cost of fuel.

(*b*) Fixed operating and maintenance charges on fuel storage, handling, preparation, and burning equipment.

(*c*) Fixed charges and operating charges on fans and draft equipment.

(*d*) Fixed charges on plant capacities reserved to provide peak requirements of the fuel and fan equipment.

Although a steam plant of a given capacity designed to burn some particular fuel or fuels might cost almost anything, depending on the design and on the labor and economic conditions at the time of construction, it will nevertheless be instructive to determine as accurately as possible to what extent the cost of the boiler plant and the fixed and operating and maintenance

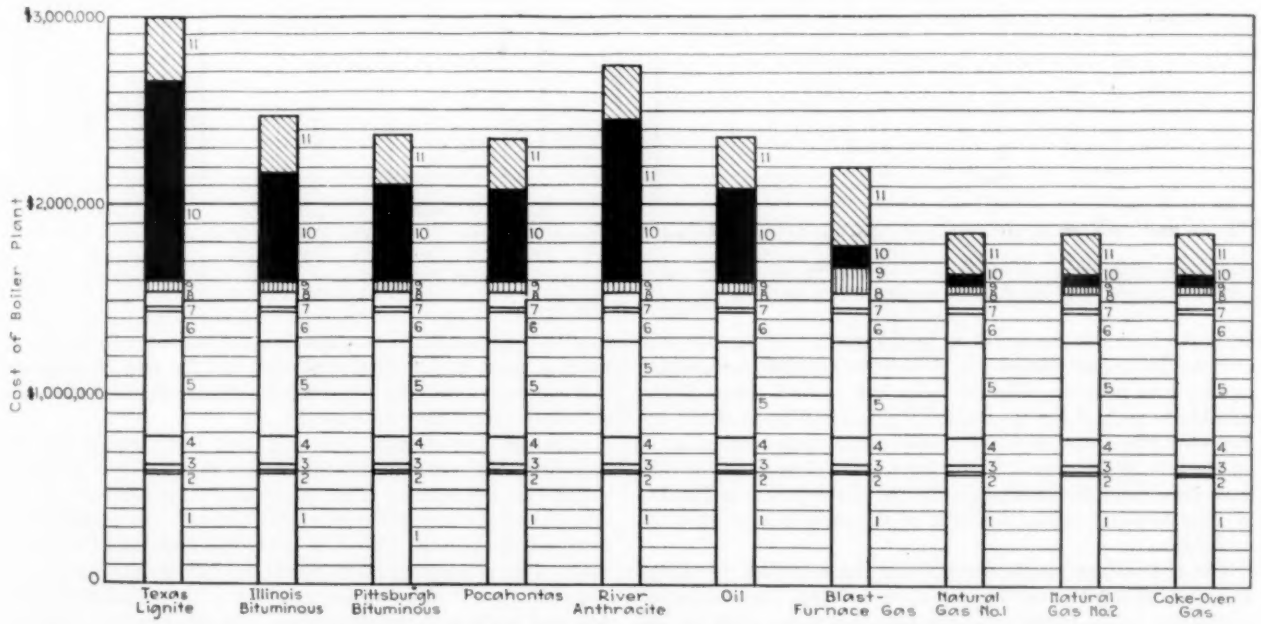

FIG. 11 COMPARATIVE COST OF BOILER PLANTS UTILIZING VARIOUS FUELS

(The figures indicate the total cost, installed, as follows: 1, boilers, superheaters, water walls, settings; 2, meters, instruments; 3, boilerfeed pumps; 4, stacks, breechings, insulation; 5, foundations, structure; 6, wiring; 7, site development; 8, engineering; 9, draft equipment, fans; 10, fuel receiving, storage, handling, preparation, firing equipment; 11, reserve-plant cost for peak-load auxiliary-power requirements of boiler plant.)

costs will depend on the fuel which the plant is intended to utilize. Data on the complete cost of building and operating steam plants were studied, and on the basis of this study the probable fixed, operating, and maintenance costs of steam plants most suitable to any one or more of the fuels of Table 1 were determined. Also, the fuels which will produce steam at the lowest price and the relative economy of all the fuels were ascertained.

The cost of building and operating steam plants best suited to meet the same annual steam-demand curve, say as of Fig. 10, and best suited to each of the ten fuels of Table 1 has been calculated in order to make a concrete comparison of the cost of steam with the various fuels. It is assumed that 1,000,000 lb. of steam per hour is the peak capacity of each plant, and for this purpose four boilers, each capable of evaporating 350,000 lb. of steam per hour at peak load, are assumed, three boilers to carry the load and the fourth to be the spare. Air heaters and economizers are not considered, in order to keep the comparison as simple as possible. The probable cost of such steam plants suitable to each of the ten fuels of Table 1 will be as shown by Fig. 11. The cost of each plant, exclusive of those costs affected by the fuel, is the same. Those costs which depend on the fuel have been carefully ascertained for the development of Fig. 11, in order to arrive at the total cost of the plant most suitable to each fuel.

The cost of equipment required for the receiving, handling, and treating of fuel from the time of its arrival at the plant until its delivery to the furnace ready to burn will vary widely for the several fuels, because of the wide differences in the character and in the quantities of the different fuels to be handled annually, in order to satisfy the load requirements of Fig. 10. Thus the quantities of the several fuels required yearly will be as follows:

Fuel	Tons
Texas lignite	440,000
Illinois bituminous	245,000
Pittsburgh bituminous	212,000
Pocahontas bituminous	196,000
River anthracite	244,000
Oil	157,500
Blast-furnace gas	2,160,000
Natural gas No. 1	195,000
Natural gas No. 2	129,000
Coke-oven gas	185,500

These weights take into account the weighted average operating efficiency over the year, which is 2 per cent lower than the weighted average of the best efficiencies attainable at each load.

The weight of lignite required is more than twice the weight of the other solid fuels. Lignite may arrive at the plant with a moisture content of 30 to 35 per cent, and this has to be reduced to about 27 or 28 per cent in order to make the lignite dry enough to pulverize and burn properly. Drying equipment to accomplish this is required. The cost of the fuel, unloading, storage, handling, preparation, and burning equipment will be about twice as great as for Pittsburgh coal, and the cost of operating this equipment will also be considerably more than for the other solid fuels except river anthracite.

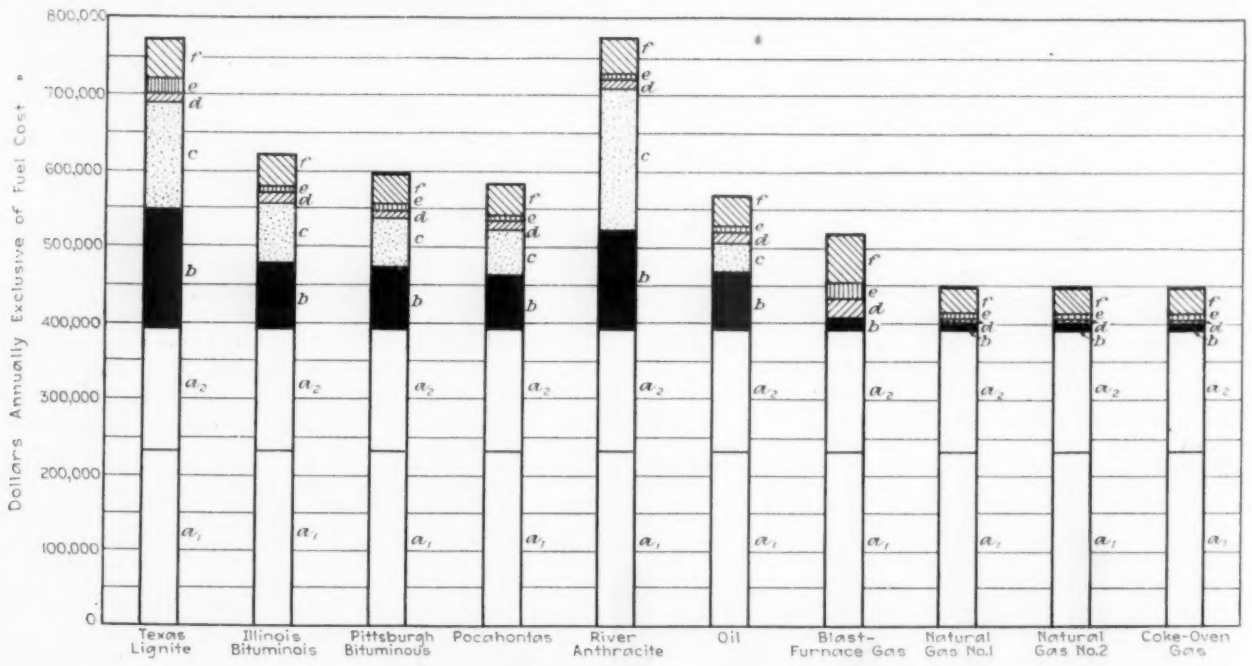

FIG. 12 YEARLY COST OF MAKING STEAM EXCLUSIVE OF FUEL COST WITH VARIOUS FUELS

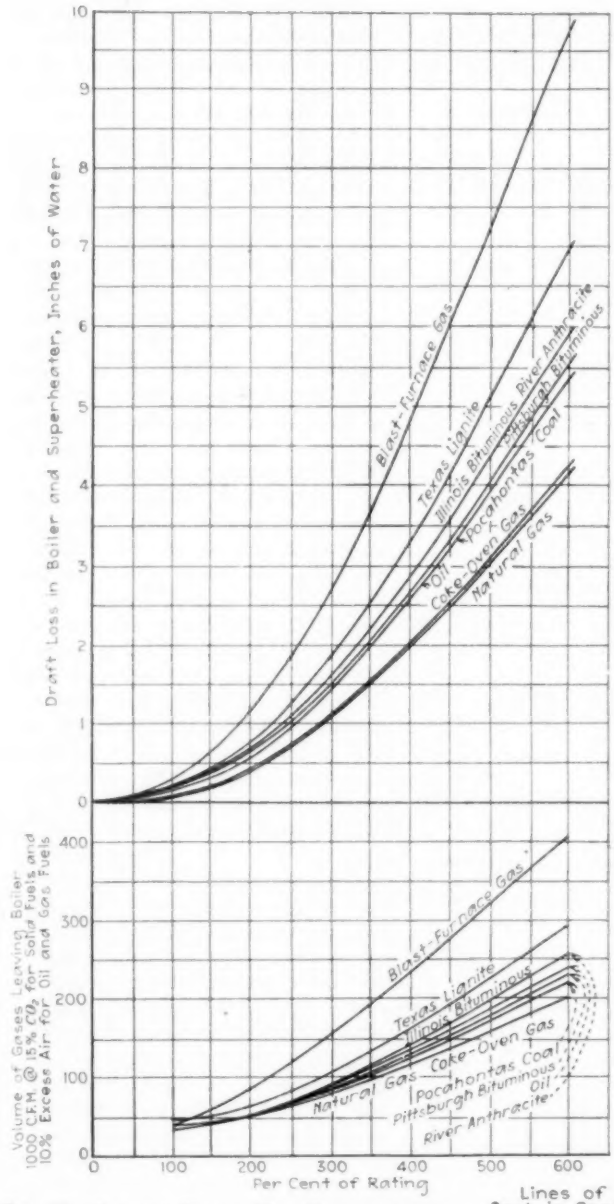
(a_1, fixed charges at 15% on boiler plant exclusive of fuel equipment $[1 + 2 + 3 + 4 + 5 + 6 + 7 + 8] \times 0.15$; b, fixed charges at 15% on fuel equipment and fans $[9 + 10] \times 0.15$; f, fixed charges at 15% on plant capacity reserved for boiler-plant peak; e, fixed charges on draft equipment; a_2, operating charges on boiler plant, not including draft and fuel equipment; c, operating charges on fuel equipment; d, operating charges on draft equipment.)

Although the storage, handling, and firing equipment for anthracite will cost but little more than that required for Pittsburgh coal, the capacity of the pulverizing plant for river anthracite coal will be at least twice as great because of its greater hardness and also because it must be pulverized finer than Pittsburgh coal. The pulverizing-plant operating and maintenance costs also will exceed those to be expected with bituminous coals, and may easily with certain types of equipment be three times as high. Pocahontas coal, on the other hand, is very easy to pulverize, and the capacity of a given grinding plant may be 30 to 50 per cent greater when handling this fuel than with Pittsburgh coal.

Oil requires heavy outlays for storage facilities, while the gaseous fuels will call for but very modest outlays for fuel handling.

All equipment and plant provisions peculiar to each fuel to be



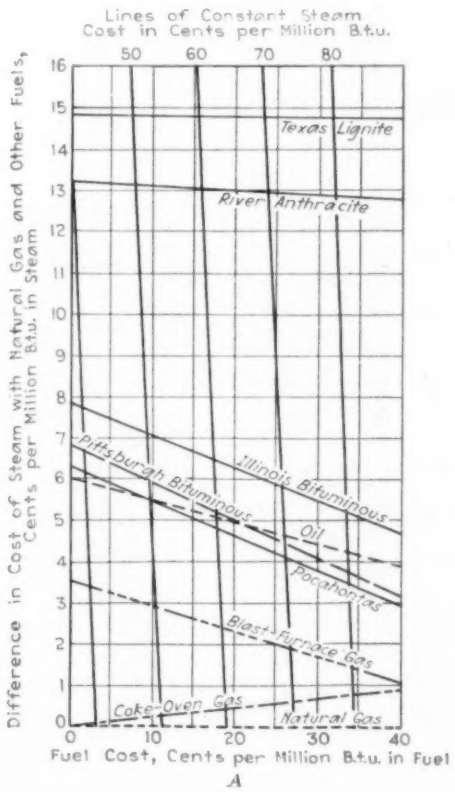


FIG. 13 INDUCED-DRAFT FAN REQUIREMENTS ALSO DEPEND ON THE FUEL

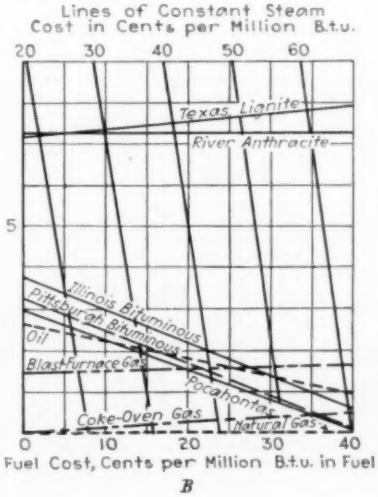

handled have been considered in computing the cost of each steam plant (as finally shown in Fig. 11) for the utilization of each fuel in accordance with the postulated load requirements. The fixed, operating, and maintenance costs peculiar to each fuel were also computed, as shown in Fig. 12.

Differences in the fixed, operating, and maintenance costs peculiar to the several fuels are not entirely accounted for by differences in the fuel equipment, but also by differences in fixed and operating costs, due to differences in the draft equipment required by the several fuels and by differences in the supplementary plant capacity that must be reserved to accommodate the peak-power requirements of the steam plant. The induced-draft fan requirements will be quite different for each fuel, as shown by Fig. 13. Furthermore, the peak-power requirements will be different for the various fuels, and reserve or supplementary plant capacity must be provided in different amounts to satisfy the peak requirements.

Fig. 12 shows the magnitude of the various items entering into the yearly cost of making steam, exclusive of the cost of fuel. The differences in the carrying and other charges which depend on the fuel are striking.

The relative economy of the several fuels on a basis which is

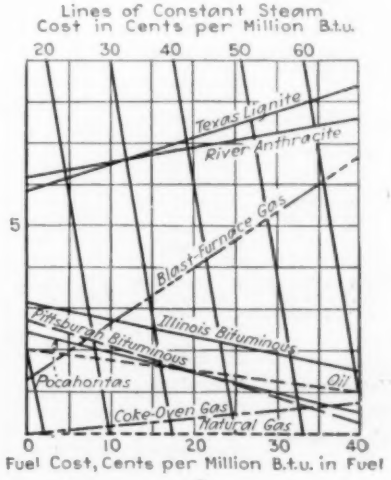

FIG. 14 (RIGHT) COMPARATIVE COST OF STEAM WITH VARIOUS FUELS

fair to each fuel can be determined by establishing the maximum price which each of the ten plants especially designed to develop the best economy with each fuel can afford to pay for fuel in order to produce steam at the same cost. This puts the fuels on a bona fide competitive basis. Or, the cost of making steam with the several fuels at a constant cost per fuel heat unit might be compared. Fig. 14 makes it possible to compare the relative economy of the ten fuels of Table 1 on either basis, at several load factors.

At a given cost per fuel heat unit, natural gas is the most economical fuel, and was therefore used as the standard for comparison. The relative economy of the several fuels is shown by the difference between the cost of making steam with natural gas and other fuels at a given fuel cost. Or, the price to be paid per fuel heat unit in order to produce steam at the same price may be determined by noting the intersections of the lines of constant steam cost with the vertical lines of constant fuel cost.

Of course, the absolute costs as established by Fig. 14 are not promiscuously applicable to any and all plants. But their relative magnitude can serve as an index of the comparative economy of certain fuel types under conditions most favorable to each.

But suppose the various plants should be confronted by the necessity of making a choice between their customary fuel and some other offerings. Some of the offerings could probably be handled without any changes in the plant. Some may require additional capital expenditures. For example, a plant designed for pulverized lignite could conveniently handle any of the other solid fuels, and by the installation of additional equipment it could also use natural gas or oil. Such a plant in Texas would probably only have the choice of lignite, natural gas, or oil.

But a lignite plant in St. Paul or Minneapolis or Duluth although primarily designed for using North Dakota lignite also might have to consider Eastern coals shipped by way of the Great Lakes, or even Midwestern coal. Fig. 15 shows the relative magnitudes of the various items entering into the cost of making steam with various fuels in plants designed primarily to handle lignite and which may or may not also have the necessary equipment to handle either natural gas or oil, or both. On the basis of such an analysis extended to the other plants also, the maximum price of each fuel which will result in the same steam cost is summarized in Table 2.

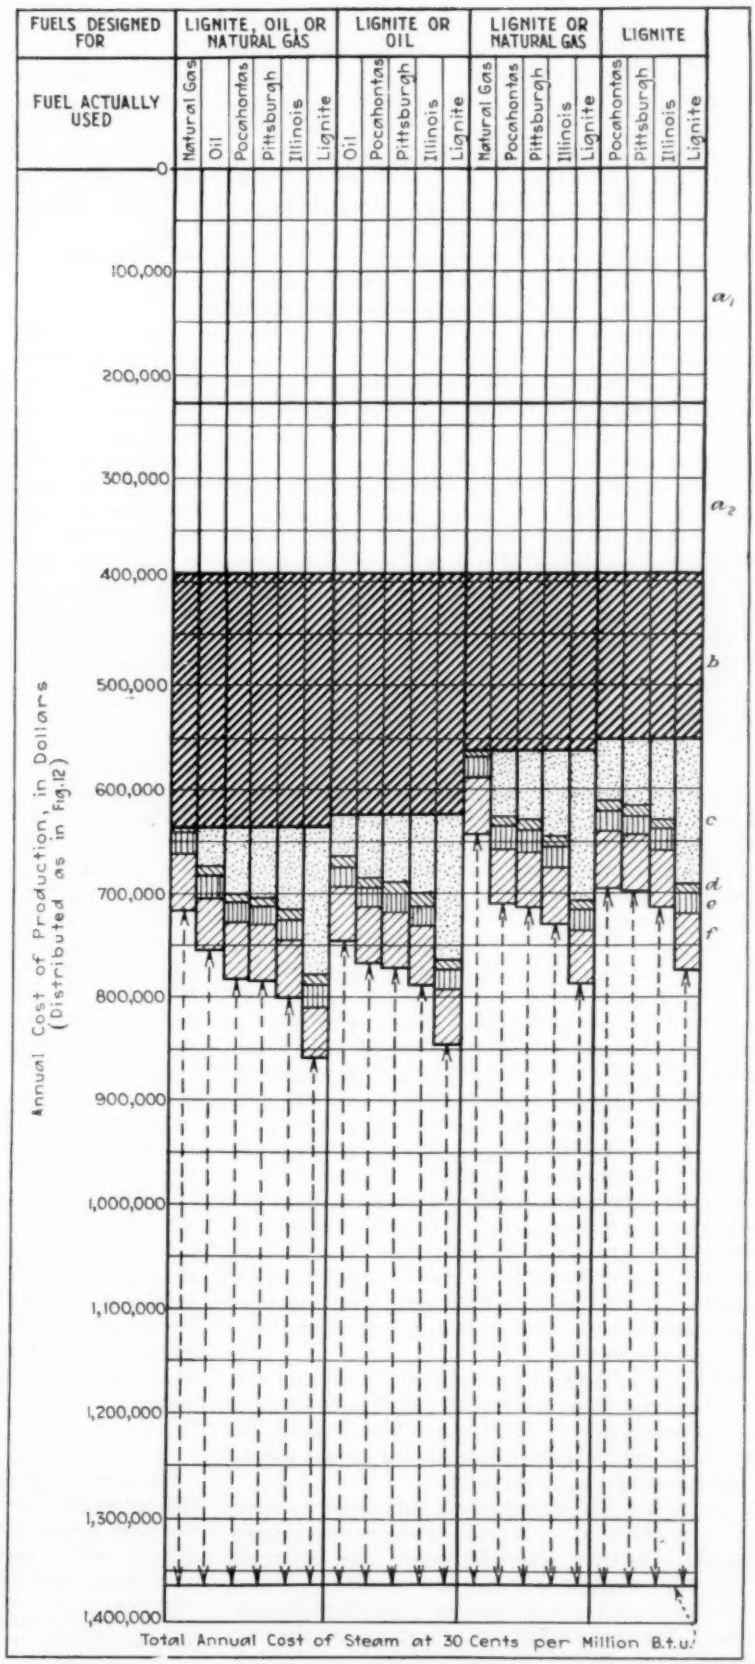

FIG. 15 EFFECT OF FUEL CHANGES ON PERMISSIBLE FUEL COST IN ORDER TO PRODUCE STEAM AT SAME COST

(a_1, fixed charges at 15% on boiler plant exclusive of fuel equipment [1 + 2 + 3½ + 4 + 5 + 6 +7 + 8] × 0.15; b, fixed charges at 15% on fuel equipment and fans [9 + 10] × 0.15; f, fixed charges at 15% on plant capacity reserved for boiler-plant peak; e, fixed charges on draft equipment; a_2, operating charges on boiler plant, not including draft and fuel equipment; c, operating charges on fuel equipment; d, operating charges on draft equipment.)

Table 2 makes it clear that a lignite plant in Texas cannot afford to burn oil. And as long as lignite may be purchased at $1.50 per ton, as is the case with several operating plants, even natural gas becomes attractive only at dump rates. A lignite plant in St. Paul, however, may not find its choice so easy with the cost of lignite from North Dakota $4 or more, laid down at the plant. Eastern coal becomes competitive under these conditions.

At present prices river anthracite would seem to merit consideration in competition with the best coals if a steady supply can be assured to the plant. Anthracite culm at prices comparable to those being obtained for river anthracite would make culm even more attractive than river anthracite. A plant suitable for culm which could be laid down at the plant at $2.50 or less for a considerable length of time could produce steam more cheaply than most plants in the East now do.

In general, it is quite safe to say that the installation of supplementary oil-burning equipment is seldom justified unless under most unusual market conditions. Even at present fuel oil prices it is difficult to do so.

In view of the many projects now under way for the more general distribution of natural gas, as for example the plans now maturing for making such gas available in the Middle West, especially in the St. Louis industrial area, it is of interest to consider the possibility of using natural gas in each of the plants considered in this paper. This is especially true because the additional capital expenditure required to adapt a pulverized coal or oil plant to the use of this fuel is small. At 20 cents per 1000 cu. ft., 1000 B.t.u. gas could compete with the usual $4.50 (delivered) Illinois coal or with $5.50 Pittsburgh coal.

Summary

The best economy attainable with various fuels at a given cost per fuel heat unit depends more on the fixed and operating costs peculiar to each fuel than on the efficiency of the plant with each fuel. In general, the greater the net available heat value of the products of combustion of the fuel as formed, the greater the economy, as shown by Fig. 14.

A plant designed for any solid fuel will generally be most economical when handling that fuel or any higher-grade fuel obtainable at the same price per heat unit which may be used without additional capital expenditures. Thus a lignite plant or a river anthracite plant can utilize any of the other solid fuels more economically than the fuels for which it was designed, if the others may be obtained at the same price per heat unit. In fact, some of them may be more economical at a higher price per heat unit. But as a rule the low-grade fuel is of local interest, and the absence of freight handicaps make it possible for it to compete with the higher-grade fuels. A plant designed for a high-grade solid fuel will generally not be able to develop its full capacity with a very much lower grade of fuel, and therefore cannot take advantage of favorable low-grade fuel prices. Thus a plant designed for Pittsburgh or Pocahontas coals could not develop its capacity without additional capital expenditures when burning river anthracite.

The solid fuels in pulverized form can generally compete with oil or even natural gas except in especially well-favored localities where gas or oil prices might be very low, or where the gas might be a waste product which has to be disposed of anyway, as for example blast-furnace gas in a steel plant.

Low-grade solid fuel, like lignite or river anthracite or anthracite culm, can be utilized in certain localities more economically than high-grade fuels handicapped by higher mine or freight charges. Oil-still residues, pitches, and petroleum cokes, although not considered in this analysis, have proved economical in many cases. The comparative economy of the various fuels considered may be approximated from Figs. 14 and 15 and Table 2.

Discussion

T. W. Harris, Jr.[2] Within the last few years, the number of pulverized-coal plants has materially increased and this undoubtedly has had an effect in increasing the demand for slack coals. This year's shipments up the lakes reflected this change in marketing conditions, and with the increase in demand for slack there is naturally an increase in price tending to bring the price of slack closer to the price of run of mine. This should be borne in mind in the drawing up of the original project covering the amortization of the plant and allowance made accordingly.

O. F. Campbell.[3] When operating cracking stills at high pressures, pulverized coal is not satisfactory due to the inability of the operators to have a clear view of the oil tubes. Hot tubes accompany coke deposits within the tubes and when hot tubes occur the still is shut down for cleaning. The operators must, therefore, be able to see the tubes clearly at all times so as to prevent tube failure and fires. When burning pulverized coal the fly ash prevents clear vision of tubes. Ash also sticks to the tubes, covering them over so as to prevent the determination of a hot tube, were such to occur.

In boiler practice, if a tube fails there is a tendency to put the fire out. In oil-still operation, when a tube fails a bad fire results, accompanied by considerable property damage and possible loss of life. Fuel for cracking stills must, therefore, be confined to liquid or gaseous fuels. Pulverized coal is used successfully on tube stills, where no cracking occurs and with comparatively low oil pressures. The use of coal, oil, or gas on this type of still is primarily one of economy, and is usually used where there is a large price differential between coal and oil or gas.

The burning of any kind of fuel in the furnace of a modern tube still presents a different problem than any discussed at this conference. The design of a modern tube still is such that the fuel must be burned in a furnace of comparatively low temperature. The furnace temperature of modern tube stills is approximately 1200 to 1500 deg. fahr. When burning pulverized coal under these low temperatures, consideration should be given to kind of coal, fineness of pulverization, burner design, use of preheated air, etc. Low volatile fuels are difficult to burn under the best of conditions on modern tube stills and the fixed carbon loss is high.

In an oil refinery it appears to be good economy to equip boilers to burn pulverized coal, pulverized coke, oil, or gas. Petroleum coke, in some cases, is a by-product and must be disposed of. Furnaces designed to burn pulverized petroleum coke can readily burn pulverized coal. Combination burners that will burn either pulverized fuel, oil, or gas appear to be the best installation. In furnaces where combination burners are not used, it is usually difficult to get proper air distribution when burning fuels in combination, or separately. Fuel-oil storage for the boiler house does not present much of a problem in an oil refinery as only small tanks are used at the boiler house into which oil is transferred from regular refinery fuel-oil storage tanks.

Author's Closure

The discussions emphasize the difficulty of making the conclusions of an economic study generally acceptable, and make it clear that specific points of view in evaluating the relative value of fuels lead to specific economic conclusions. Mr. Campbell, who speaks with the experience and point of view of the oil-

[2] Division Purchasing Agent, E. I. du Pont de Nemours and Co., Wilmington, Del.

[3] Sinclair Refining Co., East Chicago, Ind.

refinery engineer, points to factors which compel choices of fuels for certain types of refinery service so as to give but light emphasis to economic considerations.

Each of these "slants" on this wide subject helps to facilitate answers to questions as to why superficially equivalent fuels do not produce equivalent effects in a given plant.

The object of this paper is to show that even though the relative thermal value of various fuels with quite diverse properties may be readily predicted, the relative economy with which these may be utilized requires data on plant construction and operation costs not generally available. Such data were used to evaluate the relative rank of each of the fuels considered and which are representative of fuels commonly used for steam making in this country. Since the thermal rank assigned to the various fuels and the plant construction and operation costs used in this evaluation are representative of present American practice, the relative economy of the various fuels may be approximated from the charts, at least qualitatively, if not quantitatively.

Photo-Electric Smoke Recorder

By V. P. GRIFFIN[1] and J. V. BREISKY,[2] PITTSBURGH, PA.

The paper discusses the necessity of measuring smoke density in the stacks of power plants, so as to enable the operator to keep the smoke down to a minimum. Methods of smoke determination that have been available in the past are described. All of these methods depend on the human eye for judging the smoke density, and are influenced by weather conditions, being entirely inoperative at night. The necessity of a continuous and permanent record is brought out, a feature which has not been available in apparatus heretofore in use.

The photo-electric smoke recorder is then described. The scheme of operation is to project a beam of light through the stack or the breeching on a photo-electric cell. Depending on a lighter or heavier density of smoke in the stack, the photo-electric cell, popularly called the "electric eye," receives more or less light, which causes a greater or smaller current to flow through the cell. This current is then amplified so as to be sufficiently large to operate a standard indicating and a recording meter. These meters can be located at any desired point.

This device gives a continuous indication as well as a permanent record of smoke density, and also sounds an alarm or lights a lamp whenever the smoke density approaches a predetermined value. It works equally well day or night and is independent of weather conditions.

Operating results, including chart records of several installations, also are given, showing that smoke can be reduced to a minimum in a well-designed and properly operated plant.

MUCH has been said and written about smoke abatement, the evils of excessive smoke production, its deleterious effect on health and property, and the wastefulness of badly adjusted combustion.[3,4,5,6] Cities are passing ordinances and every one is interested in the problem. During recent years various efforts have been made to combat the causes of smoke. Combustion engineers have made noteworthy progress in doing away with improper combustion of fuel. Furnace designs have been improved so that greater effectiveness is secured from the fuel consumed. Experience has shown that even with the best designed boilers it is almost impossible to avoid the production of smoke under all conditions. It is, therefore, necessary to supervise the stacks in such a way as to get an immediate indication of the smoke being produced. Means for doing this have been rather crude and ineffective in the past, and those commonly used are unsatisfactory because they depend upon the fallible human eye. Such means of judging are inaccurate during the day as weather conditions vary, and altogether ineffective at night.

An eye more accurate than the human eye has been perfected by research. The photo-electric cell is an automatic device which is on duty 24 hours a day without suffering fatigue or variability such as affect the human eye. This cell has made possible the design of a reliable and accurate device which will both indicate and record smoke density.

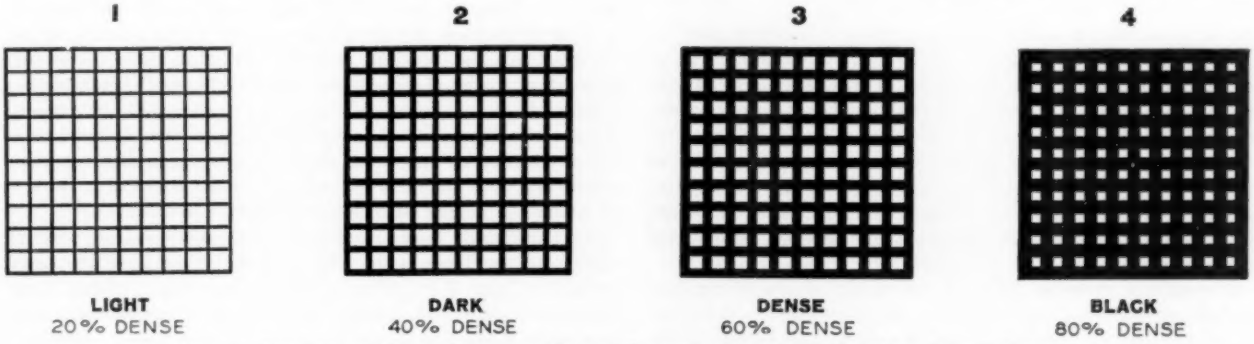

Fig. 1 Ringelmann Chart Reduced—In the Original the Charts Are Two Inches Square
(To use this a full-sized chart is set up directly in line between the observer and the stack at a distance of about fifty feet from the observer, so as to cause the lines to merge.)

Reasons for Measuring Smoke Density

Smoke is the term applied to the volatilized products of combustion of organic compounds when they are charged with finely divided particles of soot or carbon. The discoloration of the combustion gases as influenced by soot will vary with the amount present. Accordingly the color density will be an indication of the extent to which the combustion of the hydrocarbon constituent of the fuel has been completed. The slogan of former days, "where there is fire, there must be smoke," has been discarded. It is now an accepted fact that smoke is the result of poor combustion, and that its production can be attributed either to poor operation or to inherent defects in the design of the fuel-burning equipment or both.

No matter how excellent in design the equipment may be, good results can be obtained only if the equipment is correctly operated. This cannot be accomplished unless the operating personnel are supplied with the necessary instruments. In the case of boiler installations the steam-pressure and water-level gages are accepted as absolute necessities, but in addition, for economical reasons, many other instruments are required to guide the operating personnel properly. These consist of water-input or steam-output meters, temperature indicators and re-

corders, instruments to indicate the pressure throughout the air ducts, boiler setting, and flues, and some means of determining the composition of flue gases. The CO_2 meter or the air-flow steam-flow ratio meters are generally supplied to indicate the composition of the products of combustion.

There is, however, a considerable loss in furnace operation which is not directly indicated by any of the instruments mentioned, even though indirectly the air-flow steam-flow ratio or the CO_2 meters have been applied. This is the loss incident to the production of smoke. A predetermined standard CO_2 in the flue gases can be obtained with both a deficiency or an excess in air supplied. To prevent smoke there must be an excess of air, which excess, however, should be kept to a minimum so as to keep the percentage of CO_2 as high as possible. Smoke also may be produced in localized sections of the furnace, even though the CO_2 meter or the total steam-flow and air-flow ratio meter indications are correct.

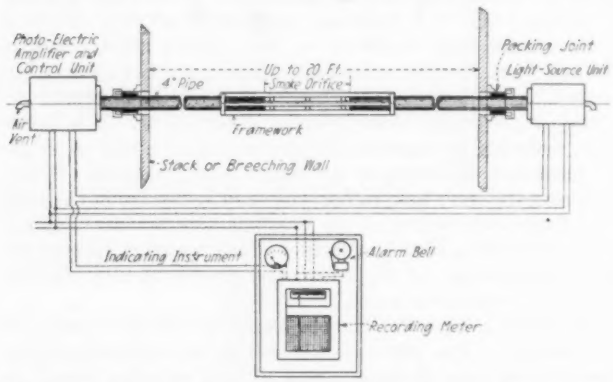

FIG. 2 SCHEMATIC VIEW OF PHOTO-ELECTRIC SMOKE RECORDER INSTALLATION

A condition entering into the operation of the steam-flow air-flow ratio meter which is not always recognized is that produced by irregular feeding of the water to the boiler, or by variations in feed-water temperature, commonly found where bleed heating is used. Instruments are now available which will proportion the rate of feeding to the steam output, and also compensate for differences in feed-water temperature. These are very beneficial, but they do not fulfil all conditions.

As a further check on furnace conditions, engineers have long recognized the desirability of determining the presence of flocculent, finely divided carbon particles in the products of combustion. Unless some reliable and convenient means of detecting the production of smoke is made available, the operator is left more or less at his own resources. Of course, ocular inspection of the furnace or stack by an experienced operator will show when smoke is produced. But such inspection, although effective, is not always practicable. There is, therefore, a demand for equipment which will give a reliable indication and record of the presence of amorphous carbon in the flue gases.

AVAILABLE METHODS OF SMOKE-DENSITY DETERMINATION

It may be well to review methods of smoke-density determination that have been available in the past.[7]

1 *The Ringelmann chart* (Fig. 1) is the method most commonly used. This system of classifying smoke densities into five grades, called No. 1, 2, 3, 4, and 5, has become quite generally adopted. Smoke ordinances in most cities are based on this method, most of them prohibiting the emission of No. 3 smoke for a period or periods aggregating more than six minutes in any one hour.

This method, of course, presupposes the ability of the human eye to judge colors correctly, and due to the fact that in practice the observations are nearly always made without the actual use of the charts, the possibilities of error become proportionately greater. Readings will vary depending on (1) whether the sky is clear or clouded, (2) the position of the sun in relation to the observer, (3) the direction in which the wind blows the smoke in relation to the observer, any satisfactory result being almost impossible of attainment if the smoke is being blown directly toward the observer, (4) on the distance of the observer from the stack, smoke appearing more dense from a distance than when close up. Inability to make any observations after dark is of course the biggest handicap in using this method.

2 *The Roberts smoke chart and the Donkin's smoke chart* are similar to the Ringelmann chart, in that they have the same gradation from 0 to 100 per cent dense smoke. Both these methods show smoke density by a definite greyness and therefore make it possible to use the charts close at hand. Observations are thus somewhat simpler than with the Ringelmann chart. In all other respects these two methods are comparable with the Ringelmann chart.

3 *The Umbrascope* consists of a cylinder containing four

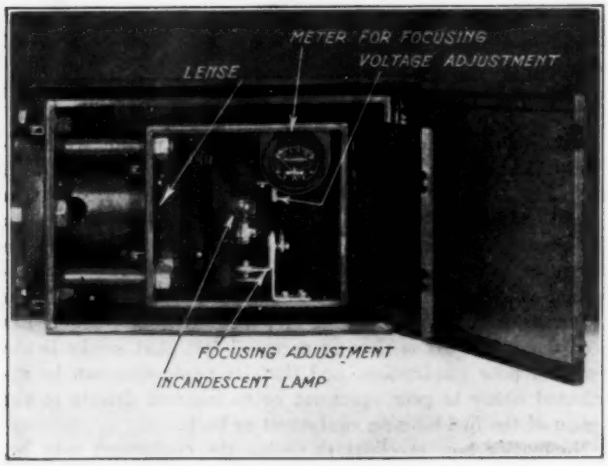

FIG. 3 LIGHT-SOURCE UNIT

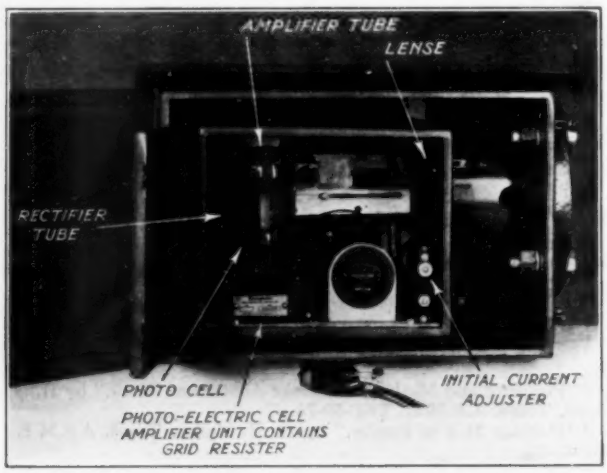

FIG. 4 PHOTO-ELECTRIC AMPLIFIER AND CONTROL UNIT

[7] Power Test Codes, A.S.M.E., Series 1923, Instruments and Apparatus, Part 20, "Smoke Determinations."

like thicknesses of glass hinged to swing in and out of the field of vision, each of them cutting off a certain percentage of light. The glasses are arranged to extend over only one-half of the field of vision, the other half of the cylinder being left open, through which the smoke may be seen. A direct comparison can therefore be made between the smoke and a standard. Thus it is easier to obtain comparative readings than by means of a chart.

To be able to use any of the above-mentioned methods, the man in the boiler room must have a clear vision of the stack from where he is working. This is usually not possible. Sometimes, however, use is made of a mirror mounted outside a window in such a position as to show the top of the stack to a person in the boiler room, so as to give at least an approximate indication of the amount of smoke emitted. This method is, of course, more subject to error than the direct use of the Ringelmann chart.

4 *Photographic Observation.* None of the methods described so far leaves a permanent record of the readings taken, except as these may be noted down by the observer. Thus it is impossible for the engineer in charge to check conditions regularly. Some plants have, therefore, adopted the scheme of automatically taking photographs of the stacks at predetermined intervals of time, so as to have a check on the fireman. This method is a step in the right direction toward automatic recording of smoke density. However, this scheme is also ineffective during the night, and the accuracy of the record obtained during the day depends greatly upon weather conditions. Besides, this record is of value only so far as a check on the operator is concerned, not being available instantaneously so as to be of use in correcting smoke conditions.

Necessity for Continuous and Permanent Record

An instrument is needed which will give an accurate continuous indication as well as a permanent record of smoke density. Such an instrument should operate during the day as well as during the night, and should be independent of weather conditions. Preferably it should also sound an alarm in the boiler room whenever the smoke density approaches a predetermined value. The indicating instrument should be located in the boiler room, while the recording instrument could be in the boiler room or in the chief engineer's office.

It is the purpose of this paper to describe the construction and operation of an instrument which was designed to fulfil the conditions outlined.

Construction and Operation of the Photo-Electric Smoke Recorder

General. The heart of this instrument is the photo-electric cell, a device which translates light impulses into electrical impulses, the amount of current flowing through the photo cell being directly proportional to the amount of light falling on it.

Talking movies, television, transmission of pictures by wire, and radio have the same photo-electric cell as their nucleus. Naturally a great deal of research work has been done in recent years on the development of this tube, and as now available it is constant in its characteristics, and has a long life.

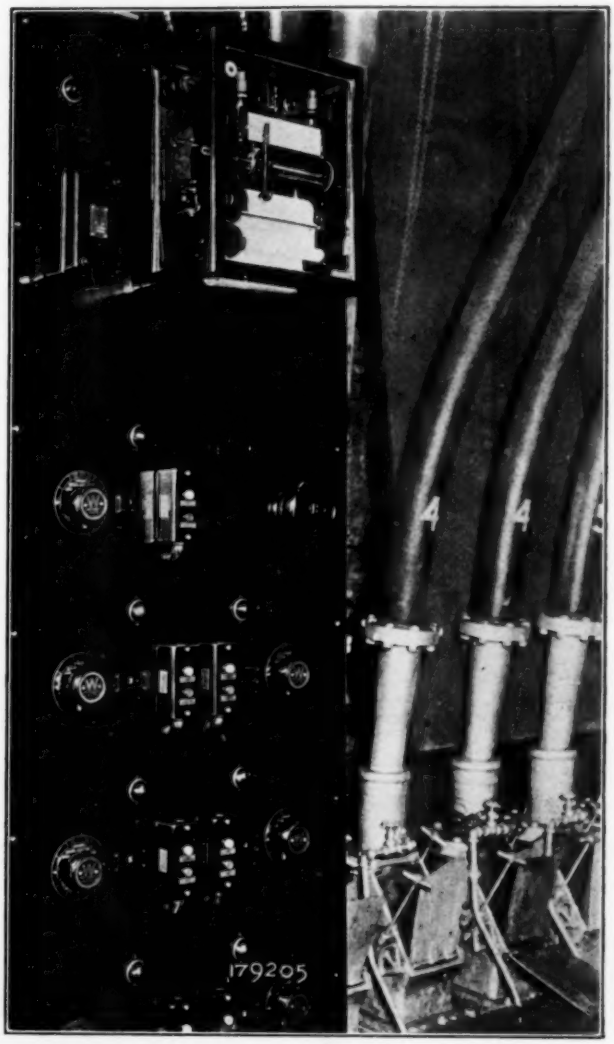

Fig. 7 Instrument Panel in Boiler Room

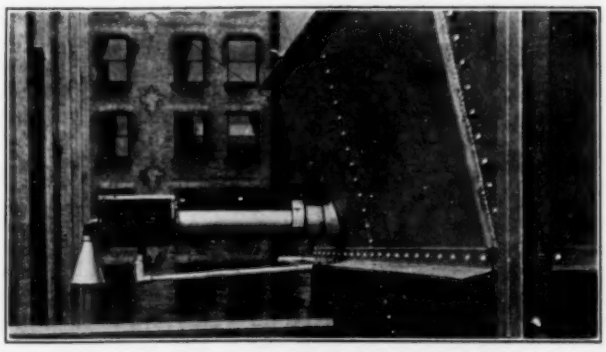

Fig. 5 Installation of Light-Source Unit

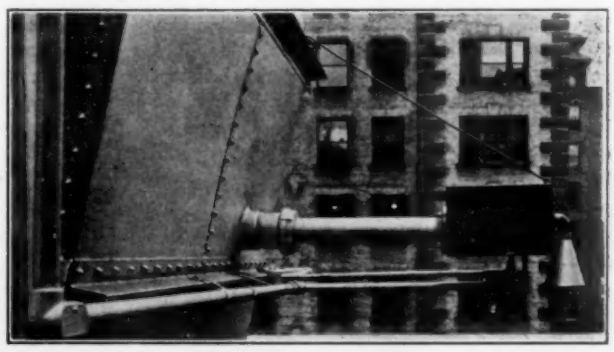

Fig. 6 Photo-Electric Amplifier and Control Unit Installed

Engineering developments have kept pace with the research work on this device, and industrial applications have been worked out.[8] The photo-electric smoke recorder is only one of the developments which make use of the photo-electric cell.

Early experiments made by Dr. Zworykin[9] showed that modern photo-electric cells were sufficiently sensitive to detect small amounts of smoke passing through a beam of light. Further laboratory tests made later on, as well as field tests, proved the practicability of designing a smoke indicator based on this principle. These experiments also caused efforts on behalf of other engineers toward the development of a smoke recorder.[10]

Description of Device. The photo-electric smoke indicator and recorder as developed by the Westinghouse Electric and Manufacturing Company[11] is shown schematically in Fig. 2.

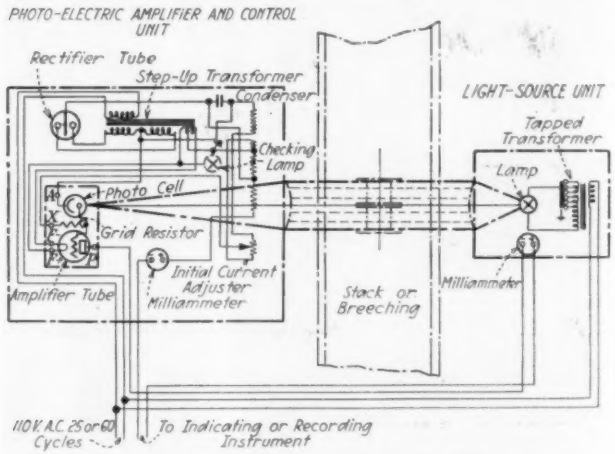

FIG. 8 WIRING DIAGRAM OF SMOKE RECORDER

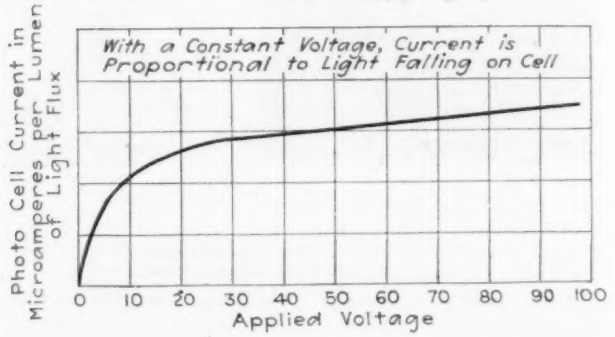

FIG. 9 CHARACTERISTIC CURVE OF PHOTO-ELECTRIC CELL

Briefly the scheme of operation is to project a beam of light through the stack or the breeching on a photo-electric cell. Depending on a smaller or greater density of smoke in the stack, the photo-electric cell receives more or less light, which causes a greater or smaller current to flow through the cell. This current is then amplified so as to be sufficiently large to operate standard instruments. The instruments are calibrated in degrees of smoke density as read on a Ringelmann chart.

[8] "Some Photo-Electric and Glow Discharge Devices and Their Application to Industry," by J. V. Breisky and E. O. Erickson; Abstract in *A.I.E.E. Journal* for April, 1929. For full article see A.I.E.E. reprint No. 28–146.

[9] *Electric Journal*, March, 1926, "The Photo-Electric Cell as a Smoke Detector," by S. H. Reynolds.

[10] "A Smoke Density Meter," by Frank Sawford, *Mechanical Engineering*, September, 1927.

[11] "A Photo-Electric Smoke Recorder," by E. H. Vedder, *Electric Journal*, May, 1929.

The device consists of two main parts: first, the light-source unit and the photo-electric amplifier and control unit, mounted on opposite sides of the stack; second, the indicating and recording instruments, as well as the bell alarm or indicating lamp, located in the boiler room or any other convenient location. Details of the stack units are shown in Figs. 3 and 4. Figs. 5, 6, and 7 show a complete smoke-recorder installation. The light-source unit consists essentially of a low-wattage incandescent lamp, a condensing lens for collecting the light rays into a parallel beam, which is projected through the stack, as well as adjustments for properly focusing this beam of light. The photo-electric amplifier and control unit contains the photo-electric cell on which, through a condensing lens, the beam of light sent out from the light-source unit is focused. It also contains the amplifier unit which requires direct current for its operation, and the necessary equipment for rectifying the alternating-current supply.

The double-box construction is used for the purpose of making the units weatherproof, so that they can be mounted either

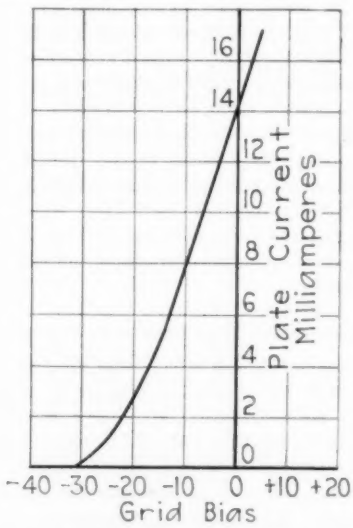

FIG. 10 CHARACTERISTIC CURVE OF THE AMPLIFIER TUBE

indoors or outdoors. Air is allowed to be drawn in at the vent at the rear of the unit and around the internal box, which is kept covered, and into the holes in the pipe connecting the internal and external boxes. The air drawn in flows through the pipe on which the units are mounted and into the stack. Thus the smoke has no chance of getting to the lens which is mounted on the front of the internal box. The flow of air through the units also prevents excessive heating of the apparatus due to the absorption of heat from the sun on particularly hot and bright days.

Installation. The construction of the mounting and the smoke orifice is shown in Fig. 2. The pipes on which the units are mounted are joined inside the stack by a framework (the smoke orifice), which forms a rigid connection between the pipes, thus assuring maintenance of alignment, but at the same time permitting the flow of smoke through the light beam which traverses the pipes and framework. The pipes pass through the walls of the smokestack in semi-flexible packing joints. This is necessary because it has been found that at high ratings, particularly in large stacks, the walls of the stack or breeching warp considerably due to the high flue-gas temperature. By using an orifice of a given length which allows a definite portion of the smoke to cross the beam of light, the total diameter of the stack has no influence on the calibration of the device.

All stack-mounting details (framework, packing joints, pipe flanges, etc.), with the exception of the 4-in. pipe, are supplied with the units. The user simply cuts two openings through the stack or breeching on opposite sides and supplies two pieces of standard 4-in. pipe cut to proper lengths depending on the width

A full-wave rectifier tube supplies direct current to the load resistor across which is a condenser to smooth out the ripple. The remainder of the apparatus is supplied with direct current from the rectifier. The characteristic of the photo-electric cell is shown in Fig. 9, and the vacuum-tube characteristic is shown

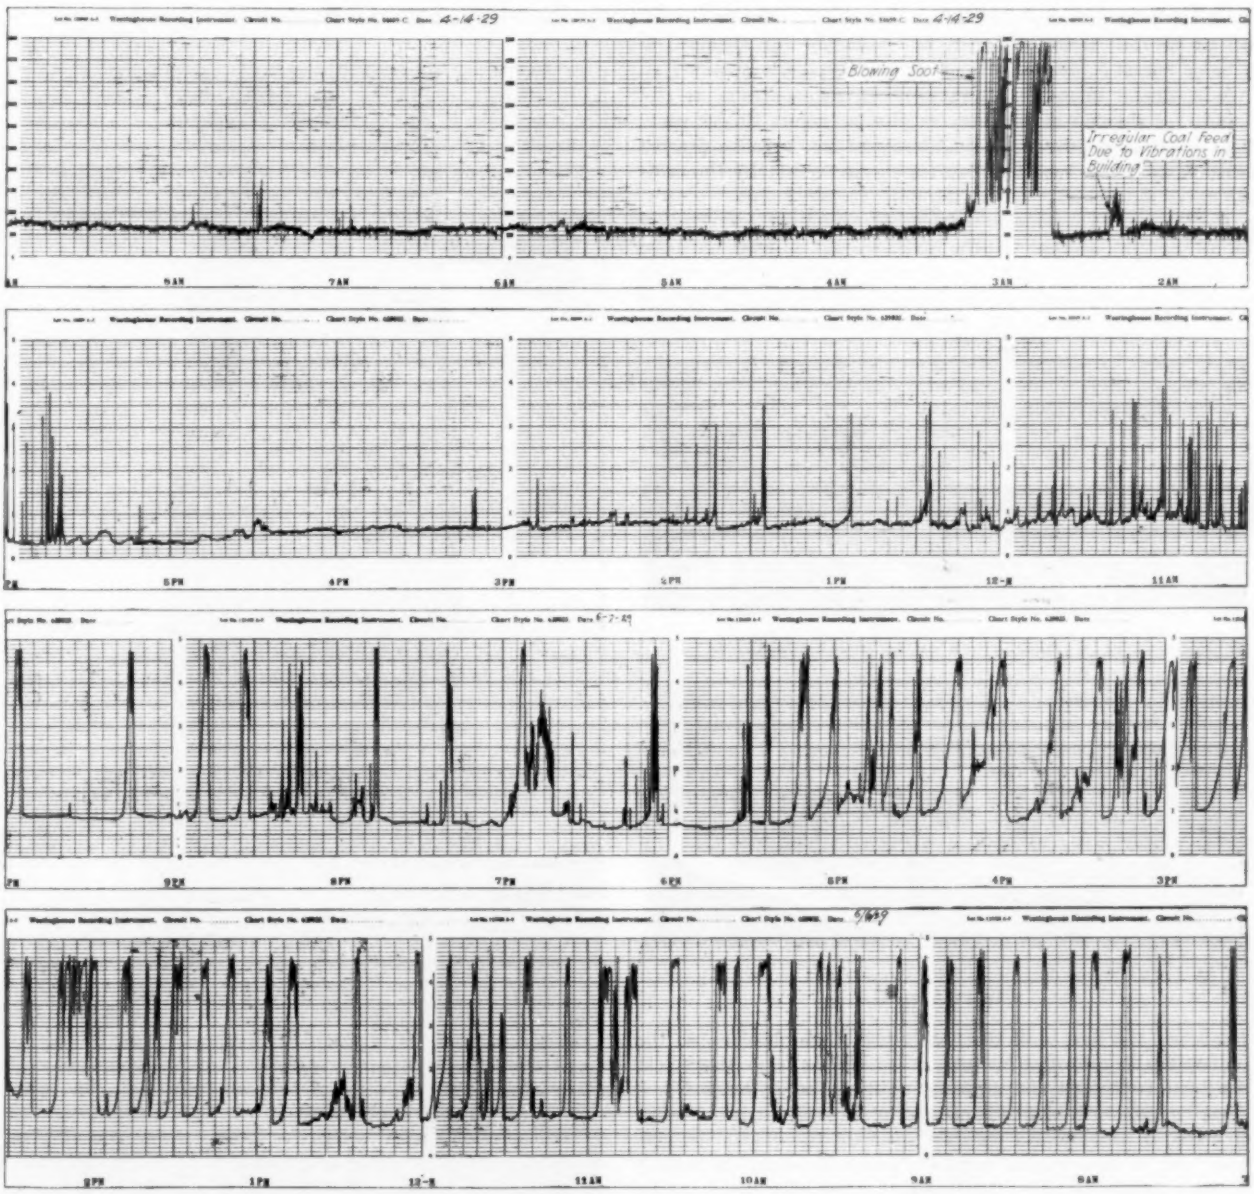

FIG. 11 SECTIONS OF SMOKE-RECORDER CHARTS OF SEVERAL INSTALLATIONS

of the stack, and then makes the assembly as shown in Fig. 2.

Electric Circuits. The electric circuit of the device is shown in Fig. 8. The units must be supplied with 110 volts, 25 to 60 cycles, no other source of electric energy being required. The circuit of the light-source unit is obvious. The electric characteristics of the photo-electric amplifier and control unit are described hereafter, in a rather sketchy manner. For a detailed description reference should be had to another article.[12]

[12] "Some Photo-Electric and Glow Discharge Devices and Their Application to Industry," by J. V. Breisky and E. O. Erickson, A.I.E.E. reprint No. 28-146.

in Fig. 10. It may be seen from the circuits in Fig. 8 that, when the photo-electric cell is dark and passes no current, the amplifier will have a negative bias on the grid, of a value determined by the setting of the initial current adjuster. If light is permitted to fall on the photo-electric cell, a current will flow from the cell to the load resistor, out of the load resistor at the initial-current adjuster, through the grid resistor, and back to the cell. This flow of current results in a potential over the grid resistor of a value determined by the quantity of light (in lumens) entering the cell, and also by the ohmic resistance of the grid resistor. If the unit is designed properly,

the amplifier tube will operate over the straight portion of its grid-voltage plate-current characteristic, and a straight line relation between smoke density as indicated and that read from a Ringelmann chart will result.

Compensation for Voltage Variation. The apparatus compensates automatically for effect of changes in line voltage. This has been accomplished in a very simple manner in the design of the circuit. Correct compensation for changes of plus or minus 5 per cent change in the voltage is obtained at No. 3 smoke density. Almost perfect compensation is obtained for changes of as much as plus or minus 10 per cent. The circuit is calibrated to compensate at No. 3 smoke density because this is the legal limit set for smoke density by the ordinances of most cities.

Calibration. The smoke recorder is calibrated by shutting off all the light, and moving the initial-current adjuster until the recording instrument reads No. 5 smoke density, corresponding to No. 5 smoke density on the Ringelmann chart. The light is then allowed to fall on the cell, and the lamp is focused with

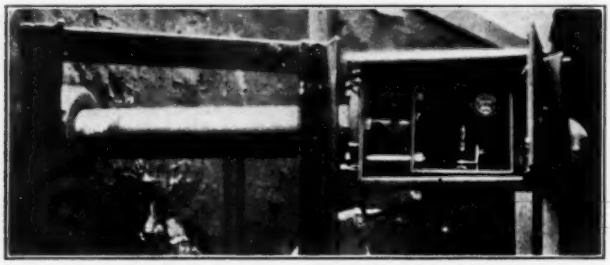

FIG. 12 INSTALLATIONS OF LIGHT-SOURCE UNIT

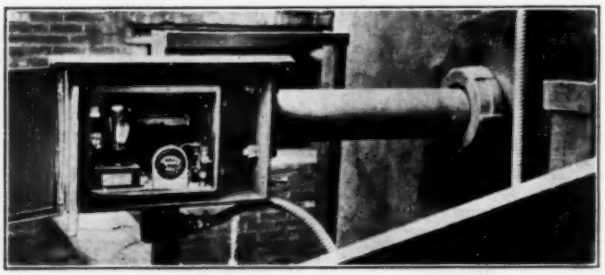

FIG. 13 PHOTO-ELECTRIC AMPLIFIER AND CONTROL UNIT INSTALLATION

respect to the lens until the proper reading is obtained on the indicating or recording meter. If no smoke is in the stack, the light is focused and adjusted until the meter reads No. 0 smoke density. If smoke is present in the stack, it is necessary to have an experienced observer estimate the smoke density. The light is then focused until the meter indicates the correct value of smoke density. The apparatus will then be in adjustment for all values of smoke density.

It should be mentioned here that all adjustments can be made at the light-source unit and the photo-electric amplifier and control unit without reading the recording meter, since each unit contains a small indicating instrument which is connected in series with the main instrument in the boiler room.

The graphic instrument (see Figs. 2 and 7) is a standard recording meter of the relay type, calibrated directly in degrees of smoke density. It is equipped with contacts which can be set too close at any desired value of smoke density. This makes it possible to ring a bell alarm or to light an indicating lamp the instant the smoke density approaches a prohibitive value. If the recording instrument is located in the boiler room, no indicating instrument is required. If, however, it is located in the engineer's office, an indicating meter must be mounted in the boiler room for the fireman.

Maintenance. After proper installation and calibration no difficulty is experienced in keeping the instrument calibrated. Changes in calibration, if any, will be caused by a change in the characteristics of the amplifier tube, photo-electric cell, lamp, dirt on lenses, etc. These parts, with the exception of the lamp, will have a life of a year or more. The lamp should be replaced once each six months. During this time its characteristics will be constant to such an extent that circuit adjustment

will have to be made only about once a month. Long life is obtained from the light source, amplifier tube, rectifier tube, and photo-electric cell by extremely conservative design of the circuit and apparatus, as well as by the use of specially designed tubes. All of these are operated considerably under their rating in order that rapid deterioration will not result. The lenses will need to be cleaned only about once each week or ten days, depending on the weather.

Operating Results

The first installation of this smoke recorder was made on a pulverized-fuel boiler. Previously to this, visional inspection of the stack by means of a mirror located outside the building had been resorted to at this plant. Shortly after the installation of the recorder, a marked improvement was evident as revealed by the chart records, in decreasing the density of the smoke produced, particularly at night, when ocular inspection of the stack was impossible.

Photographs of this installation are shown in Figs. 3 and 4. The light-source unit, photo-electric amplifier, and control unit are mounted to the breeching near the point where the latter joins the stack. The breeching is 18 ft. wide at this point. In the boiler room are located the graphic instrument, the indicating light, and the alarm relay, as shown in Fig. 7 (see top portion of panel).

A smoke density chart of the above installation is reproduced in the first chart of Fig. 11. The boiler control is very effective, and therefore there is very little increase in smoke density due to load changes. Most of the smoke shown on the chart is caused by blowing soot, and comes at relatively infrequent intervals. This chart shows how the emission of smoke can be kept to a minimum in a well-designed and properly operated plant.

The smoke-recorder installation shown in Figs. 12 and 13 was made in another plant, and is on a stack to which are connected six-600 hp. boilers equipped with underfeed stokers. The second section of the chart shown in Fig. 11 is for an average day's operation except that soot was not blown from the tubes during this period. However, the first chart in Fig. 11 shows this effect very clearly for another installation, and it would be the same here. Table 1 explains in detail what caused the various periods of high smoke density in the second chart of Fig. 11, and the cause for this smoke. Such a study should help in reducing the amount of smoke produced.

There is considerable difference between various boiler installations in the quantity and duration of smoke emitted. The first chart in Fig. 11 is taken from a plant burning pulverized fuel, and consists of a very jagged line, at low smoke density most of the time. The very jagged line is caused by slight puffs of smoke emitted by the flames in the various burners and is quite regular. The chart from the stoker-fired plant in the second section of Fig. 11 shows a more regular low limit, but shows greater tendency to smoke. The peaks as shown in the tabulation are nearly all caused by firing methods incident to stoker firing such as hooking and green coal falling down in chunks, cleaning fires, etc. Blowing soot is of course incidental to both methods of firing.

Fig. 14 shows a smoke-recorder installation in a smaller industrial power plant, using underfeed stokers. The stack is four feet in diameter. The third and fourth charts in Fig. 11 show that there are frequent peaks of long duration of dense smoke, which should call for improvements in operating methods or improvements in the boiler installation itself.

Conclusions

As mentioned previously, there is a direct loss of fuel concomitant with the coloring of the stack gases with finely divided carbon particles, the extent of the loss varying with the color density of the smoke. No specific value can be assigned to the losses encountered that will cover all conditions, but the production of smoke and loss are synonymous.

The elimination of smoke is not only conducive to economy, but also contributes to the intangible good-will of the surrounding territory. It can, and should be avoided by the use of properly designed equipment and by the adoption of satisfactory operating methods.

Discussion

P. Nicholls.[13] Measurements of the products emitted from a chimney which are based on appearance or on absorption of light are at best crude, and their numerical values are not dependable as a relative measure for different conditions of the same chimney, and still less as a true comparison of the undesirable emissions from different chimneys. To be really just, different chimneys should be compared on the basis of their area, and the length of smoke viewed, that is, the length of the slot in the pipe of the instrument, should be some fixed numerical value multiplied by the product of the area of the flue or chimney and the velocity of the gases.

An instrument such as described is, however, sufficiently satisfactory for present purposes, and the more important requirements are that it should be reliable without constant attention, and should be of reasonable price. A price that would put it within the reach of the smaller plants would make it a great boon. If there should come a day when inspectors could visit a plant periodically and inspect smoke charts in the same way as a fire-insurance inspector calls for the watchman's clock cards, then their life would be easier. It is to be hoped that this new instrument will be manufactured soon on a production basis, and simplified to reduce its cost rather than complicated for greater normal accuracy.

Everett H. Bickley.[14] While the writer believes the photo-electric smoke recorder to be the best method of recording smoke

[13] Supervising Engineer, Fuels Section, United States Department of Commerce, Bureau of Mines Experiment Station, Pittsburgh, Pa.

[14] Engineer, Bickley Manufacturing Co., Cynwyd, Pa.

at the present time, there are certain conditions under which the readings would not check with the Ringelmann density standards. White or yellow smoke, as generated by oil burners, ore smelters, or zinc roasters, would be recorded as black (as it should be), but the color would not check by visual observation.

A. S. Langsdorf.[15] This paper is of great interest since it makes use of an apparatus somewhat similar to a device that has been planned to yield measurements in a related field of smoke-abatement work. The particular instrument described in the paper is intended to produce a record of smoke issuing from an individual stack; however, in smoke-abatement work there is great need of a device which will give a more reliable indication than can now be obtained of the amount of solid material in suspension in the atmosphere over considerable areas. In measuring such suspended material, present practice has to be content with the weighing of deposits collected in containers of various types, or else with dust counts made with some such device as the Owens' dust counter. In both cases the results are subject to the errors common to all sampling, these errors being aggravated in this instance because of the fact that the samples are necessarily very minute in comparison with the total quantity to be determined. It was hoped that a new device, for the measurement of suspended material in a large area, might be ready for presentation at this meeting, but circumstances prevented the completion of the work. It may be in order at this time to report that the device makes use of a photo-electric cell upon which is projected a beam of light from a projector at a considerable distance, thereby making it possible to measure the amount of absorption of the light due to scattering caused by suspended material between the two stations. Many difficulties have been encountered, chief among which has been the elimination of the effect of daylight upon the photo-electric cell, but a way has been found to get around this difficulty. It is apparent that an observation which bears a quantitative relation to the condition of the atmosphere over a considerable distance, say a quarter of a mile, will be a measure of average conditions far more representative than that of a very small sample. It is expected that difficulties will be encountered in calibrating the device, since these readings will be dependent upon all kinds of floating particles, such as limestone dust, and not upon smoke and soot alone. In any case, the work thus briefly described will be presented for publication at a later date.

J. H. Walker.[16] This device will be welcomed by every enterprising power-plant operator. It fills a long-felt want.

[15] Dean, Washington University, St. Louis, Mo. Mem. A.S.M.E.

[16] Superintendent of Central Heating, The Detroit Edison Company, Detroit, Mich.

In Detroit at various times several devices have been experimented with for observing smoke. Periscopes and mirrors have been tried and an observer has been stationed to watch continuously the appearance of the stacks during certain periods when trouble was being experienced from excessive smoke. Now automatic cameras are trained on the stacks of central heating plants which take pictures at ten-minute intervals and record the date and time. All of these devices are more or less makeshifts. What is really needed is a continuous and instantaneous record right in front of the fireman.

Two important objections appear to the apparatus which has just been demonstrated. One is that the cost is very high. An instrument of this kind should be on each boiler if it is used at all. The purpose is not entirely accomplished if only one is installed for the entire plant, for it is necessary to know not only that there is smoke, but which boiler is the offender. If installed in this manner the total cost is a rather large figure.

The second objection that might be raised is that the instrument as now designed is hardly what one would call appropriate for a boiler room where there is exposure to coal dust. No doubt both of these objections will be remedied as the instrument becomes perfected and more of them are manufactured.

Author's Closure

The Ringelmann chart is based on the assumption that an area 60 per cent white for instance can be compared accurately with a sample of smoke in such a way that smoke which will transmit 60 per cent of the light will look the same to the eye as the mottled chart when held at a distance. The smoke recorder operates absolutely on quantity of light transmitted. The Ringelmann chart is in error, however, as soon as smoke is emitted which will reflect light, such as is the case with white smoke from various unusual fuels. The light reflected makes the smoke appear to be transmitting light even when such is not the case.

It is believed that considerable difficulty will be encountered in the development of apparatus to measure density of smoke, etc. over long distances due particularly to such things as fog, rain, etc. which it would not be desirable to measure.

The cost of the smoke recorder will decrease as the device is produced in quantities with tools, and in more or less continuous production.

The apparatus outside of the recording meter is very serviceable in any location, and is not affected by coal dust and water such as is obtained in ordinary weather outdoors. The recording meter is a standard instrument which is satisfactory in most cases for boiler-room installation. If exceptionally dirty conditions are encountered, a special case can be designed with the same meter parts which would be exceedingly rugged for severe conditions.

FSP-52-13

Stokers for Heating and Small Industrial Power-Plant Boilers

By JOSEPH HARRINGTON,[1] HARVEY, ILL.

Satisfactory small stokers for domestic or apartment-building heating are needed. The author describes the underfeed and overfeed principles of stoking and the design of the overfeed forced-blast progressive-combustion type.

IN APARTMENT buildings the boiler usually is devoted strictly to the purposes of heating. Occasionally there is a high-pressure boiler where part of the steam generated is used for cooking, laundry, or, in hospitals, for sterilization purposes. Schools, colleges, hospitals, and small hotels come into this category, the major portion being purely a heating proposition. To this large class may be added a certain limited number of small industrial plants of which the laundry is the principal exponent. Boilers used in this service are 250 hp. down to little fellows that do not exceed 10 or 15 hp. The cast-iron sectional boiler is one of the largest subdivisions of this class.

Up to the present time these have been practically all fired by hand, and the use of low-volatile or so-called smokeless coal, generally known as Pocahontas, has been the outstanding fuel, especially in the cities where smoke ordinances are enforced.

Residence heating can be divided into two broad divisions—first, that of heating the single residence building, in which the owner or occupant does the firing, and second, a class where a janitor is employed. Furnaces for the first class are usually small, one or two thousand feet of radiation being attached to them, and they are usually served by very low chimneys with very indifferent draft. These boilers are frequently round in cross-section, and some of them are hot-air furnaces. In any event they are handled by people who are in no way conversant with the principles of efficient combustion. The path must be smoothed so that the householder shall not be called upon for any technical or expert knowledge. The oil burner is filling this field with considerable satisfaction at the present time. It is probably the most difficult field for the automatic mechanical stoker.

The second class is the larger one wherein there is a janitor whose sole business is to take care of the fires. This janitor has a certain amount of expert knowledge; at least, it is his particular business to run the heating plant, even though he does it at long intervals and with indifferent care.

This class of buildings includes the multiple-resident apartments such as the hotels, hospitals, schools, and apartment buildings. Some of these jobs run into considerable size, and a mechanical stoker of large type is suitable, but there are tens of thousands of small apartment buildings in which there is need of a janitor only occasionally and wherein the firing attention is at considerable intervals.

There is very little more skilled attention in this case than in the case of the home, but at least there is one person specifically delegated to do the work. If he is supplied with reasonably efficient mechanical means which are pretty nearly fool-proof, he will get by with fairly satisfactory results. However, beyond doubt the equipment must be designed so as to withstand neglect and be capable of being operated in every possible improper manner without injury to the equipment.

The successful stoker for this service must be of such a type that it can scarcely be burned up or broken down by neglect. Coal of the wrong size will be used, ashpits will be neglected and allowed to fill up, drafts will be cut off, and all sorts of things will happen or fail to happen that ordinarily would put a stoker out of business. The nature of this service is such that the

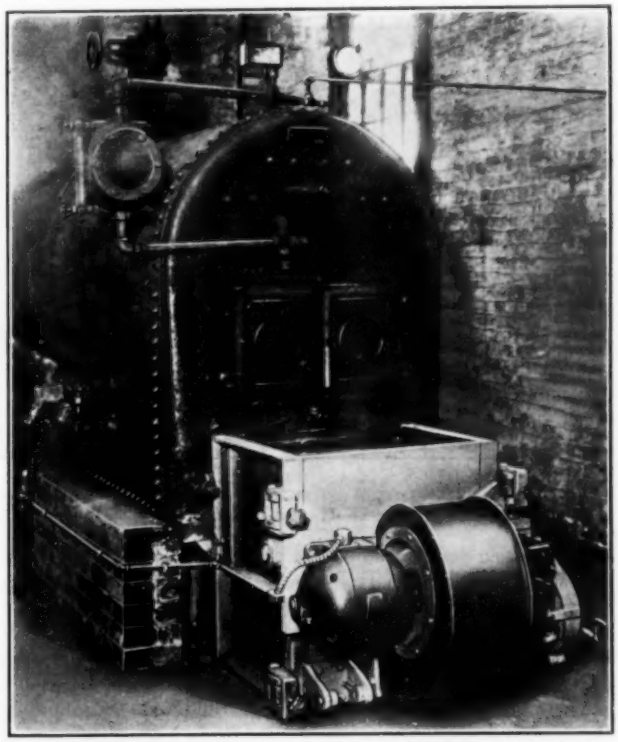

FIG. 1 INSTALLATION OF A WHITING STOKER UNDER A KEWANEE BOILER OF STANDARD HEIGHT

successful stoker in this field must be able to withstand all of these adverse circumstances. There must be some continuous removal of the ash in order to come within these specifications, inasmuch as the ash is the one element that is most likely to cause damage. It is comparatively simple to get the coal into the furnace, and comparatively simple to introduce the air, but the handling of the refuse involves the most difficult and complex part of the problem. If this is done automatically and continuously, the most prolific source of trouble is removed and there will result the necessary uniformity of conditions which are required for even control of temperature.

The average person comprehends but vaguely the tremendous magnitude of the residence-heating field. Of the half billion tons of coal consumed annually in the United States approximately one-third is consumed in the heating of buildings. Every building north of the Mason and Dixon line, with practically

Presented at the Third National Fuels Meeting of the A.S.M.E. at Philadelphia, Pa., October 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

no exception, must be heated during the greater portion of the year. The number of individual units serving this territory is almost beyond computation, and there is no branch of combustion engineering that so intimately affects the health and comfort of the people. It is a problem upon which an immense amount of thought has been expended, but up to recent months mostly in the design of the boiler itself, and upon the design of the radiation in the rooms to be heated. The purely combustion end of the business has been more or less neglected.

A firebox as commodious as could be obtained in connection with the boiler under consideration has been provided, and into this the best coal obtainable is shoveled at infrequent intervals. Provision for a little overfire air is made by placing a small grid in the firedoor, but beyond this practically nothing has been done to insure smokelessness or high efficiency in the heating furnace.

Some splendid work has been done by members of this association in improving the design of the hot-air furnace, but very

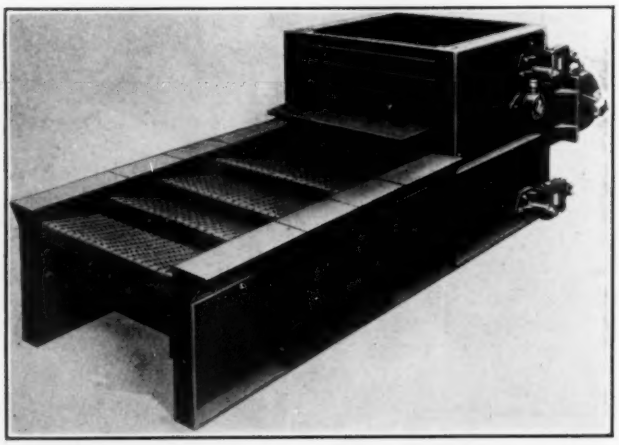

FIG. 2 REAR VIEW OF WHITING STOKER SHOWING UPWARDLY INCLINED GRATE SECTIONS

little has been done in the way of providing automatic mechanical stoking until within a comparatively short period, which may be counted in months rather than in years. In other words, up to three or four years ago, stokers for the smaller heating jobs were practically unknown, but today they are coming into use with remarkable rapidity.

There is little doubt that the conditions surrounding the usual shovel-fired domestic heating furnace are uneconomical in the extreme. Nothing much worse could be designed than the method of burning coal which is comparatively general in this service. Efficiencies down to 20 or 30 per cent are common enough in boilers of this type, whereas there is no fundamental reason why the heating boiler should not be operated at efficiencies comparable to the better class of power-plant boilers. Just because the unit is small, is no real reason why it should not be efficient. There is undoubtedly room for improvement in the boilers themselves, but there are many boilers on the market today that in themselves will take up heat in a very efficient manner, so that if this heat could be economically provided the unit would be quite an efficient one. However, the system of shovel firing does not provide the essentials of smokeless or economical combustion, and it remains for the mechanical stoker to provide these.

The oil burner is a fuel feeder that might readily be classed as a "stoker." It introduces the fuel mechanically and uniformly, and thereby provides for efficient combustion to that extent. When accompanied by proper air mixture and temperature, excellent combustion conditions are secured and fine efficiencies are obtained.

During the war the author worked on a special oil-fired boiler. Uptake temperatures, so low that the burned hydrogen condensed and ran out as water, proved that it was almost too good as a heat absorber, and it was necessary to allow it to soot up some, so as to keep the stack gases above 212 deg. fahr. A careful laboratory test gave an overall efficiency of something like 86 per cent.

This boiler is not on the market, although the author has one in the basement of his home, where it has given good service for about 12 years. It simply goes to prove that the residence heater can be just as efficient as the big power-plant boiler. It is also just as good evidence that some form of mechanical fuel feeding is at the root of such efficiency.

One-half of the fuel used in many installations can be saved by the use of efficient stokers. What this would mean to the American household can readily be calculated. In addition to the actual coal saving there must be the accompanying conditions of labor saving, cleanliness, convenience, and fully automatic operation. The day of the coal stoker embodying all of these is at hand.

The oil-burner people were the first to enter this field, beginning with the strictly single-family residence buildings, and they have, by the expenditure of large sums of money, frequent advertising, and persistency, developed the field to a point where now it is unnecessary to sell the prospective customer the idea of mechanical stoking, either for liquid or solid fuel. The large stoker in the power-plant field has reached a stage where it is a thoroughly accepted piece of equipment, and it is no longer necessary to argue with the customer the basic proposition of whether he should have stokers. It is only a question of what kind of stokers he should have.

In the new field of the small heating plant it is necessary frequently to convince the prospect that there is something better than Pocahontas coal and the shovel. There is also a human factor which one does not always meet with in the larger plants, i.e., the janitor. It is the custom for each man to have a string of buildings within walking distance, sometimes as many as 10 or 12, which he visits with a certain regularity, firing on each return trip.

It is necessary under these conditions to have a firing period long enough for the janitor to make his rounds. This frequently is of two or three hours' duration, so that when he arrives at a plant in his circuit, he shakes the fire, cleans out a few clinkers, and then puts on anywhere from 15 to 25 scoops of coal. This is supposed to last until his return trip, on which occasion it is most probable that the fire has burned pretty well down and sadly needs replenishing.

This intermittent extreme method of stoking a furnace is just about as inefficient as could possibly be devised, and without doubt the mechanical stoker has a wonderful field in which to work if only from the standpoint of uniform, continuous firing, smokeless combustion, and uniform heat evolution. Also here is a double waste, the very inefficient firing method and the expensive fuel.

The oil-burner people have certainly done a good job in preparing the public mind for some form of automatic equipment in the basement. There still remains, however, the argument that oil fuel is expensive and at times dangerous, and the field is still open for a successful automatic mechanical stoker handling raw coal or coke, in which form heat can be purchased at the lowest possible price. If this low-priced unlimited fuel source can be combined with a cleanliness that is equal to oil, and all automatically operated so as to respond readily to thermostatic control, and the absence of this disagreeable ash handling that

accompanies shovel firing, a prospect that is extremely interesting is opened up.

The very first attempt at mechanical stoking of fuel was made quite a number of years ago. It consisted of a hand-operated plunger forcing coal up through a circular duct to a vertical riser in the center of the grate. This forced the coal up into a mound-like formation, and it then burned on the grates as usual. This was first applied to hot-air furnaces, and it preferably called for anthracite buckwheat or similar non-coking coal. Today there are may be a dozen small stokers built that employ the underfeed principle.

The restricted areas available in the domestic heater are not sufficient for much of anything in the way of automatic ash removal with this type of stoker. Side dump plates such as are employed in the type E stoker are not practical, so that these stokers consist of merely a bedplate covering the entire area of the furnace with the exception of a central retort into which the fuel is screwed or pushed, and through which it flows upward into the characteristic mound of the underfeed stoker. As it passes the tuyere line it reaches the zone of ignition, ignites, and the fixed carbon burns in a layer on top of the green fuel. As the fixed-carbon combustion terminates, the ash is left at the surface of the heap, where it generally rolls down the sides on the bedplate opposite the clean-out doors. If the temperature is below the melting point of the ash, it will be loose and soft, but if the temperature exceeds the melting point, the ash melts and runs into rather generous clinkers which must be removed with the firing tools through the door. This operation is sometimes difficult and usually results in considerable disturbance to the fuel bed, production of dust in the boiler room, and possible smoke.

From the foregoing it appears highly desirable to have a coal with a high fusing point or else operated at the rate of combustion that insures a low fuel-bed temperature. Selection of the coal to be used on this stoker therefore becomes of considerable importance, and manufacturers are now classifying the coals of their district with a view to selecting those which have the least clinker-forming tendencies. This is usually a direct function of the fusing temperatures of the ash. Not all coals present the desirable characteristic of high melting temperature, and it therefore becomes a source of considerable concern to the manufacturer and also to the users of this equipment to find a coal which will operate satisfactorily.

These stokers are governed by automatic control which is always of the "stop-and-go" type. In other words, a sensitive spring or a mercury tube is connected to the boiler in such a manner as to be affected by the steam pressure. As the steam pressure goes up this closes a circuit, which, acting through a relay, shuts down the motor on the stoker and conversely starts it up again after the pressure has dropped a few ounces or a few pounds. Reasonably satisfactory pressure control can be obtained in this way. These fans are usually substantial, and it is immaterial mechanically whether they start and stop often or not. If some care is taken in adjusting the damper in the stoker and the amount of fuel feed, it can be made to develop a long "on" period, but if the load is such that the "off" period lasts for an hour or two, it is inevitable that the fire should burn down to a very small amount, so that when the stoker again starts up the fan will simply blow cold air into the furnace, and still further reduce the pressure.

Under these conditions the recovery of steam pressure is very slow as things must wait until the stoker has again filled the furnace with enough coal to cover the tuyeres. When this occurs the fire will build up and temperature or pressure can be recovered. However, this is sometimes a matter of a considerable period, possibly half an hour or so, before a good fire is again built up after a long period of idleness.

This suggests a method of control which is known as the floating control in which the controller floats with the steam, moving slightly up or down as the steam pressure varies, and correspondingly affecting the fuel feed and air supply. For high-pressure units these floating-control devices are readily enough obtainable, but for low-pressure or vapor systems they do not seem to exist. The "stop-and-go" method is therefore apparently the only one which is applicable to such installations.

An interesting contrast to the underfeed principle is afforded by a fuel feeder which feeds coal through a pipe or chute into the furnace above the fuel bed, allowing it to drop freely on the top of the pile. At the same time air is blown in directly on the surface of the fuel bed. No attempt is made to remove ash or shake the grate. It is limited in size, and is intended to serve the countless single family residence, which it is reported as doing successfully.

Outside of the boiler, there is a hopper holding a considerable quantity of coal. A small motor operates both the fan and the

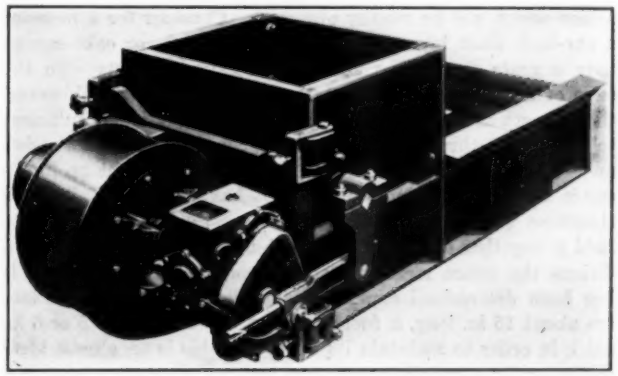

FIG. 3 FRONT VIEW OF WHITING STOKER SHOWING DRIVE AND FAN ASSEMBLY ON FRONT DOOR

means for getting the coal into the furnace. It is applicable to any of the small, round hot-water or air furnaces.

In contrast to these principles of stoking is the overfeed progressive-combustion type. The one that the author is interested in at present consists of a series of four-grate steps or sections, the first and the third section reciprocating adjustably from nothing to 4 in., and the other two steps are stationary. Each step is made up of a plurality of ventilated grate bars arranged side by side so that the air space can be adjusted from minimum to any required amount by simply wider spacing of the bars. A hopper is placed over the front of the stoker ahead of the front wall of the boiler. In front of this there is a panel or door carrying on it the blowing equipment, motor, and speed-reducing device.

There are certain novel principles of design incorporated in this stoker. It is a front-overfeed stepped grate without gravity action and without inverting the fuel bed. The fuel enters at the front under a vertically adjustable gate just the same as a chain grate. The reciprocation of the first grate section which forms the bottom of the coal hopper advances the green fuel at a thickness determined by the height of the gate. On the inward stroke of the feed plate the feed is carried in a matter of 3 or 4 in., whereas on the return or back stroke, the fuel is held in place by the vertical portion of the hopper apron and the weight of the coal in the hopper, and the plate slides under the mass of fuel, thereby advancing the fuel relative to the feed plate a certain amount. This alternate action continues until the fuel is advanced to the end of the first row of grate bars which are attached to the feed plate. At this point it falls off

over the end of the grate bars on the second or stationary step. Then immediately following the forward stroke of the plate, this coal which has fallen over on the second step is pushed along in compression, and the return stroke then causes more coal to fall over the nose of the grate into the space provided by the previous forward action. This coal is in turn then pushed along and eventually the entire grate surface is covered.

There are two very distinct actions in this motion; first, the entire fuel bed breaks down over the end of the grate section, thus breaking up any caking tendency there may be due to the cracking or breaking down of the fuel bed. Each stroke then embodies a compressive thrust causing a compacting or compression of the fuel bed to a point where all of the granulated fragments of coke are pushed together into a compact mass. This mass, of course, is not permitted to consolidate into continuous coke, because shortly afterward it is again caused to fall over the end of the succeeding step, which breaks it up and again subjects it to alternate compression and release.

There is a curious, interesting, and valuable result of this action which will be readily observed. Consider for a moment a one-inch thick layer of coal, or sand, or ash, or coke spread over a grate step. The advancing section contacts with the edge of this thin layer and starts to push it along. However, the strength in compression of the granular layer is not sufficient to transmit a thrust sufficient to overcome the frictional resistance on the grate. It therefore piles up or thickens up in advance of the advancing step until it has gradually built up a thickness wherein the weight of the layer will be sufficient to hold it together and resist further buckling. Under these conditions the entire mass will slide along the grate section. It has been determined experimentally that when these sections are about 15 in. long, a fuel bed must of necessity be 5 or 6 in. thick in order to maintain its form, and this is an almost ideal thickness for a traveling-grate fuel bed. Uniformity of fuel bed constitutes one of the essentials required of good combustion, and in this stoker the uniformity of the fuel bed is particularly marked.

Imagine a thin spot occurring in the fuel bed due to either physical disturbance or burning out of a porous section more rapidly than the surrounding area. Just as soon as this spot thins down to a point where it becomes structurally weak it will no longer sustain the thrust of the moving fuel bed, and it therefore buckles up and becomes as thick as the surrounding area. Under these conditions it can transmit the thrust and move along just the same as its neighbor particles. It is obvious from this that there cannot be a thin spot or hole in the fire, and it is due to a combination of this characteristic plus the granular porous character of the fuel bed that is responsible for the rather unusually high CO_2 that is habitually obtained.

The uniform rate of combustion indicates also a uniform termination. In other words, the coal finishes its combustion, and the ash is finally deposited in a very straight line at the extreme rear end of the stoker. At this point another one of the author's favorite principles of stoker design is brought into play, viz., the continuous and automatic discharge of the ash.

Just as the chain grate is characterized by a perfectly uniform condition of fuel bed, so is the Whiting stoker. The constant and uniform discharge of the ash as formed means, of course, that the fuel bed is always in just the same condition, and efficiency once obtained can be maintained continuously.

The mechanical features of the stoker can best be seen from the accompanying illustrations. Only the entire operating and blowing mechanism is carried in one assembly on the front door of the stoker. This is the only machine-shop part. This assemblage is carefully put together and is shipped out as a unit; it being necessary only to put the hinge pins in at the two hinges on either side of the door, and it is ready to close up and start to work.

Heating boilers which are most commonly encountered are cast-iron sectional boilers or all-steel types. In both cases they are of the water-leg type in which a water-cooled member approaches the floor to within 18 or 20 in. The grate surface of the Whiting stoker is cut down to a maximum height of 16 in. so that the entire structure can be slid under the front water leg of one of these boilers without any disturbance of the foundation or the boiler setting. In order to meet variations in these boilers, the stoker is made sectional both as to width and length in variations of a few inches. It is possible, therefore, to fit a stoker to any boiler furnace, filling it out and supplying practically as much grate area as it originally had with shaking grates. The stoker being essentially a forced-draft stoker, it is possible to secure a considerably higher rate of combustion on a slightly reduced grate surface and thereby develop much higher ratings from the boilers.

Even with the restricted furnace volume that is encountered in some of these boilers, the stoker is completely smokeless by virtue of the fact that the fuel bed is unusually uniform and the resultant penetration of oxygen very evenly divided. The flame is short, sharp, and completely smokeless. This stoker is adapted to thermostatic pressure control, and will carry steam pressures or water temperatures within a close range. The fan is perfectly silent and a hopper of several hours' capacity can be supplied.

The problem of heating residences involves a number of conditions which the steam engineer never encounters in the boiler room of the power plant. The peculiar janitor situation already referred to calls for perfectly automatic operation, and it is essential that control equipment be provided that will stop and start the stoker in accordance with steam requirements. This question of stopping and starting is all right provided the intervals are spaced so that the fire is not ruined during the off periods. The Whiting stoker is equipped with standard stop-and-go controls just like all of the other small stokers. It seems to be the most practical form of controlling equipment for low-pressure systems, and there is no reason why it should not be satisfactory provided there is within the stoker necessary controls manually adjusted so that the rate of burning or rate of steam generation can be controlled carefully. If the hand controls of the stoker are set so that the recovery is slow and the "off" periods short, then there is practically continuous operation. This is quite possible with most of the small stokers in which there is control of both the amount of air supplied and the amount of coal fed. This is in sharp contrast with certain types of oil-burning equipment used for the same service. In these burners the air is not adjusted below a certain point because of practical difficulties. The oil is cut down mechanically to a point corresponding with the steam requirements, but it is obvious that when the oil is cut down beyond the corresponding air admission there is an excess of air, and the CO_2 will drop rapidly. Under these conditions efficiency is lost, and while the steam generation is controlled, it is controlled in an expensive manner.

There is a difference, however, between the stoker firing coal and the burner using oil as a fuel. Whenever the oil burner goes off entirely, the consumption of oil absolutely stops, and the oil must be re-ignited upon resuming operation. With the coal stoker, however, there is a certain weight of incandescent fuel left on the grate surface, and this continues to produce heat and steam for quite a length of time. It is very noticeable, however, that with the forced-draft stoker the steam generation drops very rapidly the moment the blower is cut out, so that there is a very satisfactory control because of this effect. There

is not, however, the strain on the boiler and brickwork due to absolutely shutting off the heat, and upon resuming operation there is a warm furnace already there for the early stages of combustion. With the oil burner the furnace may get perfectly cold between fires, and it is quite a handicap to oil, to fire it into a cold chamber and expect it to burn without deposit of soot or the production of smoke.

With the Whiting stoker there is a double form of the so-called "stop and go." First there is the complete stoppage of everything caused by the mercoid cutting out the motor and allowing it to come to a full stop. Then there is the duplex system wherein the mercoid merely cuts in or out a certain amount of resistance, and slows the motor down a predetermined amount. This speed will produce steam at a rate somewhat lower than that required, whereas when it is going on full it produces steam at a greater rate. The operation of the stoker is therefore a short period of overproduction and a short period of underproduction, the average being suited to the requirements of the job. This, of course, means that at no time is the stoker standing still and the fuel bed without air. It is always in good condition

FSP-52-14

Coke as a Domestic Heating Fuel[1]

By P. NICHOLLS,[2] and B. A. LANDRY,[3] PITTSBURGH, PA.

This paper deals with one of several types of fuel used in heating houses. It sets forth the burning characteristics of coke when used for this purpose as shown by work done by the U. S. Bureau of Mines and others. Of the solid fuels, anthracite and coke are truly smokeless and are held in high regard for this quality. Ways are being found for making commercial coke from a wider range of coals than heretofore, and the use of coke for domestic heating is increasing.

UNTIL recently, the term "coke" has had a definite and limited meaning and has referred to "high-temperature" coke, more specifically defined as "beehive," "gas-house," and "by-product" coke; all three types having the common property of a low-volatile-matter content of about 1 to 2 per cent. Of recent years, "low-temperature" cokes have been coming on the market and have been widely discussed. These are produced at lower coking temperatures, and a smaller part of the volatile matter is driven off. Another kind of coke comes as a residue from the refining of oil, termed "petroleum coke" which is available to a limited extent in some districts, its outstanding property being its low ash content. The term "coke" unqualified as used in this paper refers to high-temperature coke, any other type being specifically defined.

Table 1 shows typical compositions of three types of coke. The per cent of ash in a low-temperature coke will be less than that in a high-temperature coke made from the same coal because less of the combustible is removed.

TABLE 1 TYPICAL COMPOSITIONS OF MOISTURE-FREE COKES

	High-temperature	Low-temperature	Petroleum
Fixed carbon, per cent	88.5	81.0	83.5
Volatile matter, per cent	1.5	10.0	9.6
Ash, per cent	10.0	9.0	1.9
Calorific value, B.t.u.	12,900	13,500	15,600

The use of coke as a domestic fuel has increased rapidly in recent years; in 1928 it was 2¼ times what it was in 1924. Table 2 shows the figures as reported by the Bureau of Mines[4] (3, 4) for the years 1923 to 1928.

TABLE 2 COKE SOLD FOR DOMESTIC USE IN THE UNITED STATES, MILLIONS OF TONS

	1924	1925	1926	1927	1928
Beehive coke	0.14	0.39	0.37	0.11	0.07
By-product coke	2.8	4.1	5.0	4.7	6.25
Gas-house coke	about 1.3 million tons per year				
Petroleum coke	0.235 million tons estimated for 1928				
Pitch coke	No data available.				

These quantities compare with 60 to 70 million tons of domestic sizes of anthracite produced per year, and 56 to 77 million tons of bituminous coal which the bureau estimates as used for domestic purposes; cokes, therefore, at present form about 6 per cent of the total of solid fuels used for domestic purposes.

Producers and distributors of fuel are offering greater service. This includes (1) advertising and sales effort; (2) inspecting the furnace of a prospective customer to see that it is suitable for burning the particular fuel and is in good repair; (3) instructing a purchaser as to firing and damper adjustments; and (4) following up sales to ensure that the users obtain satisfactory results. Improvements in quality of coke have been mainly in grading the coke by size, supplying the size well suited to the particular furnace, and in avoiding excessive dust and moisture. The chemical and burning characteristics, as affected by the coals used and the process of coking, have also been studied in the effort to produce a fuel that will be best suited to average conditions.

Quality of Coke

The reputation of coke as a domestic fuel was formerly not good. The viewpoint of householders was expressed by saying that they could not be bothered with it; that it required too much attention; that it either all burned away or the fire went out, although there was plenty of unburned coke in the furnace; and that in cold weather such bad clinkers were formed that the fire had to be rekindled after removing them. It is true that the burning characteristics of coke as compared with other fuels may have permitted such conditions, but the causes are preventable. In many districts coke was a by-product and little effort was made by the producers to supply it in the right size or to give the service needed. This was particularly the condition when it was distributed through dealers who had not the proper facilities for storing and handling it, nor sufficient interest in promoting its sale.

The qualities of a domestic fuel cannot be described in detail without associating them with the size of the pieces. This applies to coke (6, 7, 8) and to all free-burning fuels, but to a less extent to those coals which cake and coke because the pieces fuse together and tend to form a single solid mass. Coke has, however, some general characteristics which are well recognized. These are listed briefly in the following paragraphs. However, it should be recognized that there are differences even between high-temperature cokes, and that their qualities have a range of variation even though it be small.

Favorable Characteristics of Coke

1 Coke is a relatively clean fuel, although if too dry it may be dusty, and such dust is disagreeable because of its gritty nature.

2 Coke is a truly smokeless fuel and is referred to as the ideal solid fuel from that standpoint; as a consequence, the user has no trouble from soot accumulations nor from reduction of the available draft.

3 Coke gives a uniform-burning fuel bed which requires no attention between times of firing.

4 Coke requires little draft and the fire responds quickly when the dampers are opened.

5 Coke gives a high thermal efficiency. The overall efficiency based on the calorific value, obtainable with coke burned in a given boiler, is at least equal to that obtained with anthracite, as fuel-bed burning characteristics are very similar. Anthracite having 3 to 5 per cent of hydrogen against 1 to 2 for coke may have a larger loss in the latent heat of the steam carried in the flue gases, while the loss of combustible in the ashpit may be larger with the fuel having the larger percentage of ash, since small pieces of unburned fuel get smothered in the ashes. The heat obtainable per pound of each fuel will depend on the quantity of ash-free combustible, and will be proportional to the calorific

value, and it may be taken as approximately proportional to 100 minus the sum of the ash and moisture contents.

Numerous tests of coke burned in domestic furnaces have been reported; a few references are given in the bibliography (10, 11, 12). The efficiencies obtained have depended on the furnace; values of 60 to 65 per cent for warm-air furnaces and 68 to 72 for boilers have been reported. The average efficiency that a householder would obtain during a heating season would be lower than these test values; tests with coke under less careful attendance such as reported (13) by the Bureau of Mines for coals would be useful.

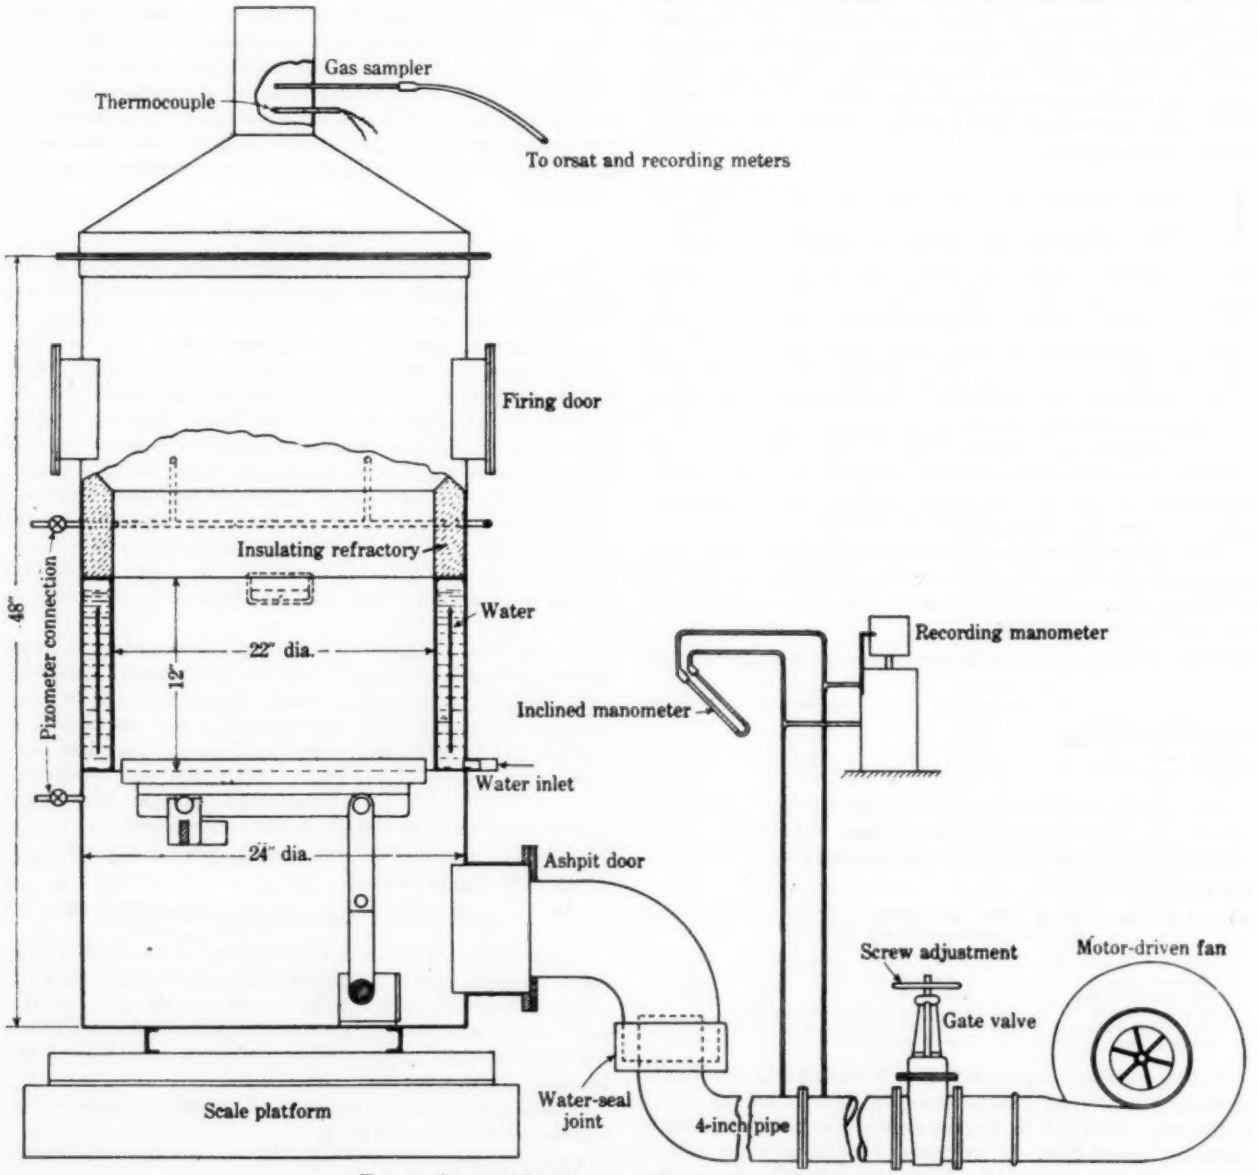

FIG. 1 SPECIAL FURNACE AND SET-UP USED IN STUDIES

COMPLAINTS REGARDING COKE

Besides the favorable qualities mentioned there may be placed complaints which vary according to the skill of the fuel user. These complaints are listed with brief comments as follows:

1 "Coke requires more frequent firings than do anthracite and bituminous coal." This, of course, is true when the comparison is based on the weights of equal volumes of the fuels. The weights per cubic foot compared on the basis of sized fuels are: Coke 20 to 28 lb., with an average of all coke as sold of probably 26 lb.; bituminous coals, 45 to 50 lb.; anthracite 50 to 56 lb. A mixture of sizes of any one of the fuels will give larger weights per cubic foot. On the basis of firing equal volumes of the fuels, the time a firing would last with equal rates of heat production would be proportional to pounds per cubic foot, times calorific value per pound, times average thermal efficiency. The relative time that equal volumes of the fuels would last can be taken in round numbers for the sake of illustration as, coke 1, bituminous coal $1^1/_4$, anthracite 2. Such a basis of comparison is not the whole story; the possibility and advisability of firing a given volume of fuel are fixed by the size of the fuel, the combustion space it leaves above the fuel in the furnace, and the draft available. Bituminous coal requires more combustion space over the fuel bed, and heavy firings in ordinary furnaces will produce excessive smoke and loss of heat value from unburned volatile

matter. There should therefore be more frequent firings for this reason. The combustion spaces required for anthracite and coke for equally good results do not differ much with equally suitable sizes of fuel, but would slightly favor the coke. The comparison between these two fuels depends more on the average requirements of householders and whether a furnace will hold sufficient coke to last for the period desired, which is usually such that the housewife will not have to add fuel during the daytime. Coke advocates have claimed that the average practice has shown that coke is fired $1^1/_2$ times as often as anthracite, but this does not disprove the 2 times possibility that anthracite has.

2 "It is difficult to start a coke fire." This again is a matter of comparison. Fuels vary considerably in their "ease of ignition" or "ignitability." A pile of wood can be ignited by starting one small portion of it, and a bituminous fire can be nursed to complete ignition if a relatively small portion of it gets a start. On the other hand, coke and anthracite must be ignited over a larger portion of the bed if they are to continue burning; the lack of flame from volatile matter must be replaced by higher surrounding temperatures. The absence of volatile matter is not, however, the only factor, as the carbon in the various types of cokes has varying ability to combine with oxygen at a given temperature. The ease of ignition depends also on the size of the coke pieces, and the quantity of wood required to start the fire increases with increase in size of coke.

3 "Coke is difficult to bank so that it will either not go out during the night or not be all burned up before morning." The ease with which a fire is maintained overnight depends on the weight of fuel that can be put in the fire pot and on the probability of guessing the correct adjustments of the dampers. Coke suffers by comparison because there is less weight in a given fire pot, and because the range of movement of the dampers required to produce rapid burning on the one hand and to extinguish the fire on the other, is often smaller than that of the fuel with which it is compared, thus increasing the probability of not setting them correctly. It is necessary that the ashpit be tight and that all the entering air be under the control of dampers. Successful banking is then a question of experience with each furnace. A fire is more likely to go out when using large coke than with small coke.

4 "In mild weather it is difficult to adjust the dampers so that the desired heating of the house is obtained, and unless the furnace is given frequent attention either the house gets too hot or the fire goes out." This complaint is more commonly heard from those who have used bituminous fuels and have been accustomed to operate the furnace in mild weather by maintaining a small bed of live coals in the center of the grate with ashes around the sides. This method cannot be used with coke, and the recommendation is always made to fill the fire pot and regulate the rate of burning by the dampers. It is not necessarily true that there is economy in having a small bed of fire as the burning is then very inefficient. However, with any fuel there is difficulty in keeping a fire all day when only a small quantity of heat is required in morning and evening.

5 "Coke makes worse clinkers than do coals, and one is likely to have to use more kindling after removing the clinkers." The latter difficulty is overcome by removing the clinker before the fuel bed gets too low. The process of coking a coal does not alter the clinkering characteristics of the ash. Tests made by the Bureau of Mines showed that with the same rate of burning the same quantities of clinker were formed by the coal and by the coke made from it. However, a user is more liable to form clinker when burning coke because he can make it burn faster than he can burn the coal, and thus get a hotter fuel bed. If this forcing of the fuel bed overheats the house, he may shut down all the dampers and stop the flow of air through the fuel bed; this allows its heat to travel down to the ash and thus increase the clinker formation. Table 3 gives the results of tests made by the bureau and shows the increase in clinkering caused by including a one-hour banking period in burning tests, each of which lasted about five hours.

TABLE 3 EFFECT OF BANKING FIRE ON CLINKER FORMATION

Fuel	Ash-softening temp., deg. fahr.	Rate of burning lb. per sq. ft. per hr.	Per cent clinker over 2 in. Not banked	Banked
Coke	2610	10	6.8	12.7
Coke	2610	20	9.3	19.0

It is to be expected that the increase in clinkering would have been greater if the ash of the coke had been more fusible.

It is desirable that coke for domestic use should be made from coals having a softening temperature of the ash of not less than 2400 deg. fahr. Coke with a lower fusion temperature can be used without trouble in furnaces which are sufficiently large to heat the house easily, but if they are small and have to be forced to the limit, troubles from clinker may result.

6 There is sometimes a belief that burning and destruction of the furnace grates accompany the use of coke. Such trouble may occur with any fuel if, to obtain a rapid rate of burning, the ashes are all shaken out so as to leave the hot fuel in contact with the grates. Especially is this true if the fire is banked when the fuel bed is at a high temperature. The damage will be more severe if molten slag drops on the bare grate when hot, because it will combine with the iron. Coke does not differ from other fuels in this respect, except that one can obtain more readily a higher rate of combustion and a hotter fire than with other fuels.

7 Complaints have been made that when coke is used in a warm-air furnace the fumes permeate the house, whereas this trouble was not experienced when burning bituminous coal. As far as this occurs it is caused by incorrect operation of the furnace, and the closing of the stack damper so far that a positive pressure is produced in the fire pot, gases being forced through the firedoor and into the warm-air ducts if the joints in the furnace are not tight. When bituminous coal is burned, the person adjusting the dampers easily recognizes when he has closed them too far because smoke will issue from the firedoor, whereas with coke, the issuing gases are invisible.

Instructions for Burning Coke

There are a few simple instructions which show how the causes for the complaints can be minimized and the good qualities emphasized. Such instructions have been given wide publicity by the Bureau or Mines (5) and others, and by the coke producers and distributors through advertisements and pamphlets. All of the instructions have been similar and are briefly as follows:

1 Before starting to use coke, the furnace should be inspected to see that it is in good repair and that the dampers will close, that the ashpit is tight and has no leaks which will admit air when its damper is closed.

2 The flues and smoke-pipe should be cleaned.

3 The size of coke recommended for the heater should be used. There is no standard scale for coke sizes and producers differ in their methods of grading, both on size and on the number of sizes carried; consequently, recommendations have varied. The effects of size are discussed later.

4 A deep fuel bed should be carried and as large a charge fired as the furnace will hold. A shallow bed should not be carried, but the fire pot filled to its capacity, even in mild weather.

5 The fire should be leveled but not poked and the ashes removed by shaking the grates, leaving a layer of ash to protect the grates and to increase the resistance of the fuel bed.

6 Dampers should be opened the minimum distance necessary to obtain the desired heat.

Such instructions can only be very general, and they leave a

lot for the user to learn from experience if he is to get the most satisfactory results. His problem with coke is, however, no worse than with other fuels, except that the adjustment of dampers may have to be finer. Success with coke does, however, call for more self-restraint than with other fuels; it is easier to obtain a fierce fire, and trouble is less likely to result if one exercises patience and gives the house time to warm up without making use of the full possibilities of the extra hot fire obtainable with coke.

Investigation on the Burning of Coke in Domestic Furnaces

The foregoing part of this paper has consisted of statements of generalities concerning the characteristics of coke as a domestic fuel. A great amount of investigative work (1, 2) has been carried out during the past eight years on the manufacture, properties, and use of cokes, both of the high- and low-temperature types. Most of this work and the causes for its being done are foreign to the purpose of this paper; it is pertinent, however, to show how far the general characteristics previously set forth

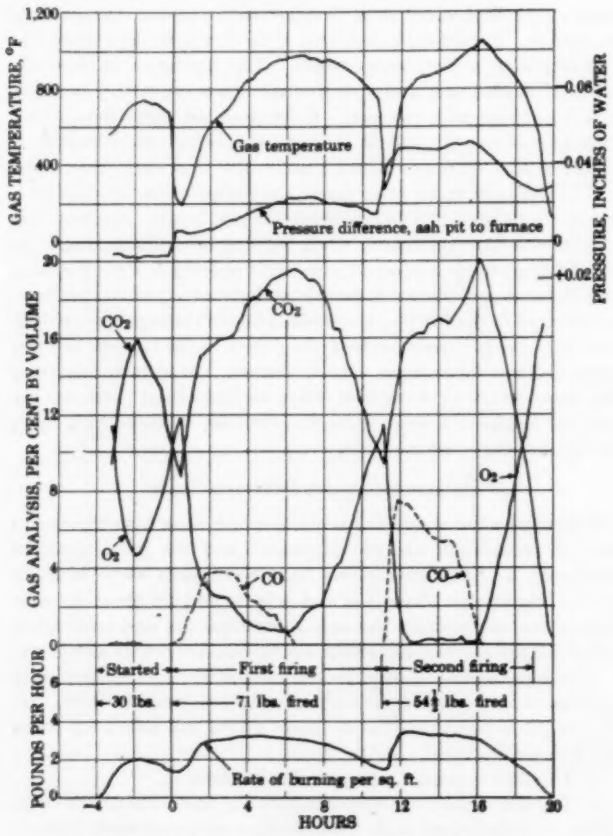

Fig. 2 Graphs of Data From a Test of Coke

can be confirmed by experimental data. The data to be given are extracted in the main from work done at the Pittsburgh Experiment Station of the U. S. Bureau of Mines; unless references are quoted the results have not previously been published. Much work has also been done in England, but it is not applicable to usual American conditions because in England domestic coke is burned mainly in open grates.

The actions involved in the operation of a heating furnace can be considered in four stages: (1) The burning of the fuel with the primary air from the ashpit, and the transfer of some heat from the fuel bed through its direct contact with the sides of the fire pot and by radiation from the top of the bed; (2) the burning of the combustible gas with the secondary air supplied through the door slots; (3) the transference of the sensible heat of the hot gases to the water or air; and (4) the exhausting of the gaseous products by the chimney action. Although the rate at which the fuel burns is dependent on the chimney action, yet the characteristics, that is, the actions in the fuel bed and the results that follow, at each rate of burning in a given furnace are dependent only on the fuel, and a study of what occurs in the fire pot should give quantities which can be compared.

Studies of the fuel-bed actions have been made by the Bureau of Mines; the tests have been conducted under strictly controllable conditions which simulated those of household use. It is not necessary for the purposes of this paper to describe the apparatus and methods of test in detail or to give the results in full. Fig. 1 shows the set-up of a special furnace having a 20-in. diameter fire pot; a similar set-up was used with a furnace having one of 28 in. Both fire pots were water-cooled so that the conditions surrounding the fuel bed corresponded to those of a steam or hot-water boiler. The furnace was mounted on scales and arranged so that accurate measures could be obtained of the weight of fuel gasified during any short period. The primary air supplied through the ashpit was measured and could be controlled closely, the air pressure in the ashpit also could be maintained at any desired amount. It was thus possible to subject each fuel tested to similar conditions, and to eliminate the variations of draft, control, and manipulation associated with tests of fuels in heating boilers which hamper close comparisons between results unless a large number of tests are made. The methods of conducting the tests were rigidly alike. The quantity of fuel fired affects results. The basis adopted for cokes was to fill the fire pot to the same depth, $16^1/_2$ in., at every firing, which corresponds to what householders are instructed to do.

Fig. 2 is a typical plotting of some of the data obtained during a complete test. It shows a log of the rate of burning, the composition and temperature of the gases above the fuel bed, and the draft above the fuel bed. It will be seen that there were three stages to the test, starting the fire with a small amount of fuel followed by two full firings.

It is rather difficult to summarize briefly the results of such tests. Each period between times of firing is a cycle in which the fuel bed is changing from moment to moment. The results will therefore be shown as average of a complete period between firing because it is the average the householder is interested in. The results will also be shown as curves without indicating the test points because this paper is only concerned with tendencies.

Effect of Size of Coke Pieces

Statements have previously been made that the size of the coke pieces materially affects the burning characteristics of coke and that for each furnace a certain range of sizes will, on the average, be found to give the best satisfaction. It is of importance to have at least a general idea why that is so, how the results obtained may depend on the size, and how the size may affect the way the furnace should be operated to obtain the best results.

The investigations on the effect of size were made for several types of high-temperature coke, but because such cokes do not differ materially the results for one only are shown. They were also made for at least three rates of burning, but because the householder would need the same rate of heat supply regardless of the size he was using, the comparisons will first be made on the basis of the same rate of burning. A rate of $3^1/_2$ lb. per hour per square foot of grate area has been chosen because it is about the average rate during cold weather. The term "rate" as used in this paper means the pounds of combustible burned, thus eliminating the effect of variations in the quantity of ash in the coke.

Four sizes were tested, 1/2 to 1 in., 1 to 1 1/2 in., 1 1/2 to 2 in., and 2 to 3 in. All were sized by square-mesh screens.

Size of Coke and Draft Required

By the draft required for a furnace is usually implied that at the smoke outlet, which includes the draft required to move the gases through the passes of the heater. However, by measuring the draft over the fuel bed the effect of the construction of the heater is eliminated and the comparisons are confined to the fuel bed. Fig. 3 shows this draft plotted against the mean screen size; both the average for the period between firings and the maximum values are shown. The curves show that the draft required decreases rapidly with increase in size of coke pieces.

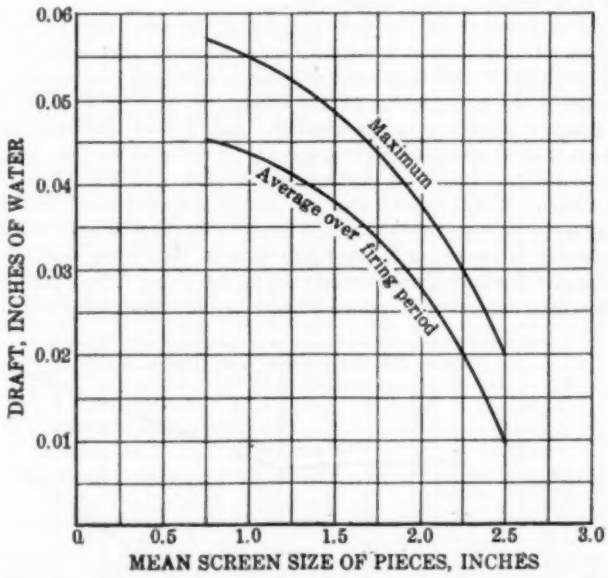

Fig. 3 Draft Required Over Fuel Bed as Related to Size of Coke for High-Temperature Coke Burning at an Average Rate of 3 1/2 Lb. per Square Foot per Hour

It is interesting to note that the draft required decreases with increase in size of coke in spite of the fact, as will be seen from Fig. 6, that the quantity of air passing through the fuel bed to obtain the same rate of combustion is greater for the larger than the smaller size. Thus the draft required for a 2 1/2-in. coke is only about one-fifth of that for a 3/4-in. coke, whereas the quantity of air through the fuel bed for the 2 1/2-in. size is more than twice that required for the 3/4-in. coke.

Fig. 4 shows the relation of the maximum draft required above the fuel bed to the rate of burning for 1- to 1 1/2-in. coke. The draft increases with the rate, but not as rapidly as one at first might expect. The primary air required to gasify a pound of fuel decreases as the rate increases, while the temperature head increases; both of these causes reduce the draft above the fuel bed.

Size of Coke and Secondary Air Required

The composition of the gases arising from the fuel bed of a domestic furnace, even when burning a uniformly sized fuel, is not the same over its entire area because of the cooling effect of the sides of the furnace which retards combustion. As a result, at the top of the bed free oxygen may be found around the sides, whereas the gases in the central portion may contain no oxygen and considerable carbon monoxide (CO); if there is good mixing of the gases after they leave the fuel bed the free oxygen may combine with the CO. The amount of air which must be supplied above the fuel bed through the firedoor slots (secondary air) will be that required in addition to that passing up the sides. It will evidently be more for a warm-air furnace in which the sides of the fire pot are much hotter than the water-cooled sides of a steam or hot-water boiler.

This occasion is taken to point out the misapplication or misuse which has often been made of the data and statements contained in Bureau of Mines Technical Papers No. 137 (1916) and 139 (1918) on the combustion in the fuel bed of hand-fired furnaces. These publications deal with furnaces in which the fuel bed is large, and its thickness kept the same by relatively short intervals between firings. These publications clearly state that some of the secondary air which the experimental tests showed to be necessary would be supplied through holes in the fuel bed, around the sides of the bed, through cracks in the wall and around the doors, and not all would have to be supplied through the door slots. Also, it was stated that all the experimental data were obtained with one size of fuel, 1 to 1 1/2 in. In spite of this, isolated statements have often been quoted, without the qualifying contexts, and applied to domestic furnaces to support some device being sold to improve their combustion efficiency.

It will be seen by an inspection of Fig. 2 that the amount of CO above the fuel bed varies during the period between firings, starting from zero, reaching a maximum, and then decreasing to zero again. Comparisons of the composition of the gases above the fuel bed as it is affected by the size of the coke can be made by taking the average of the composition over the whole period. Fig. 5 shows such averages for the carbon dioxide (CO_2) and the CO. These values are only of interest because the composition of the gases determines the secondary air required. It will be seen that the quantity of CO is high for small coke and low for large coke.

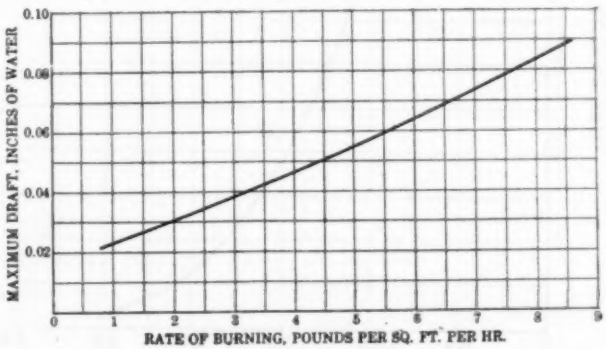

Fig. 4 Draft Above Fuel Bed as Related to Rate of Burning 1- to 1 1/2-In. High-Temperature Coke

Because the CO above the fuel bed varies in amount during a period, the quantity of secondary air supplied should also be varied if it is to be restricted to just that amount necessary to burn the CO. This, of course, is not practical and the best the householder can do is to open the slots a certain amount and leave them so; moreover, the only way he can set them, if he thinks of it at all, will be by guess, and the results obtained will be a matter of chance. However, it is logical to make comparisons on the basis that each size of coke has an equal chance. The basis adopted was that for each size the slots are opened such an amount that the average of the CO_2 over the whole firing period would be 12 per cent. The quantity of primary air necessary to burn or gasify the same weight of each size of coke in the same time was determined by the tests; the composition of the gases and the draft in the furnace were also known from the tests; the draft at each instant fixes the rate at which secondary air will be drawn into the furnace; a size of slot opening could therefore be found which would give the specified average CO_2.

Fig. 6 shows for each size of coke the weights of primary and secondary air required per square foot of grate area per hour when burning at the average rate of $3^1/_2$ lb. an hour. The $^3/_4$-in. mean screen-size coke requires about equal quantities of each, and the quantity of primary air increases and the secondary decreases as the size of coke increases.

If there were complete control over the admittance of the secondary air and no leakage around the slides of the slots and

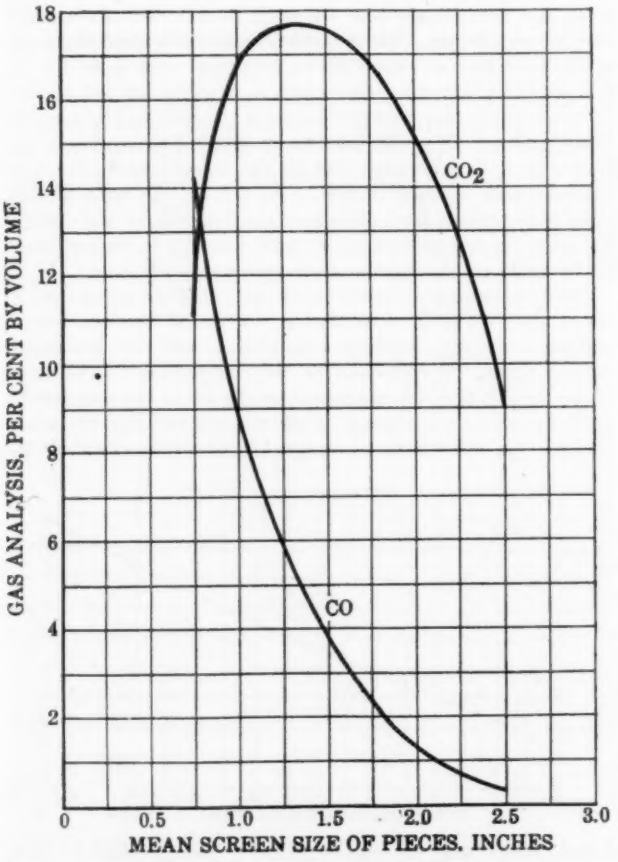

FIG. 5 CO_2 AND CO IN GASES ARISING FROM FUEL BED, AVERAGED OVER PERIOD BETWEEN FIRINGS, AS RELATED TO SIZE OF COKE, FOR HIGH-TEMPERATURE COKE BURNING AT THE AVERAGE RATE OF $3^1/_2$ LB. PER SQUARE FOOT PER HOUR

around the door, then that admitted could be gradually reduced until a $2^1/_2$-in. mean size of coke was reached when no secondary air would be required, and the necessary air to give a 12 per cent CO_2 would come through the fuel bed. Actually, there is considerable leakage and, based on tests of a commercial furnace, Fig. 6 shows that such leakage would supply all the secondary air required by a $1^1/_2$-in. mean size coke. Therefore, the assumed condition of 12 per cent CO_2 could not be obtained with cokes larger than $1^1/_2$ in., and the total air used would rise, as shown by its curve.

The same forms of curves would have resulted if 10 per cent average of CO_2 had been adopted for the basis of comparison. The quantities of primary air would of course have remained the same; the quantities of secondary air would have been increased by approximately the same amount for all sizes.

The slots in a firing door are in effect orifices, and knowing the draft in the furnace, the correct size of opening to admit the required amount of secondary air can be predicted; however, from this required opening an area equivalent to the cracks around the door must be deducted to give the slot area. The simple thin-plate orifice law is:

$$\text{Weight of air} = \text{constant} \times \text{area} \times \sqrt{\text{draft in furnace}}.$$

Tests made by the Bureau of Mines of a door of a domestic furnace showed, as would be expected, that there was appreciable friction in addition to the orifice effect, and the index for the draft is 0.57 instead of the square root.

A domestic furnace is not operated at the same rate all the time. It is of interest to see whether it would be advisable for a householder to adjust the slot opening to a definite position and leave it the same during all the season, or whether he should change it according to the weather. Fig. 7 shows the relative area of slot opening for a given furnace by different sizes of coke, as dependent on rate of burning, and to give equally good combustion. It will be seen that the size of slot opening increases with the rate, and that it would be more efficient to have more opening in December to February than in the Spring and Autumn. However, things would even up somewhat if the opening best for a mean rate of burning of about three pounds were chosen.

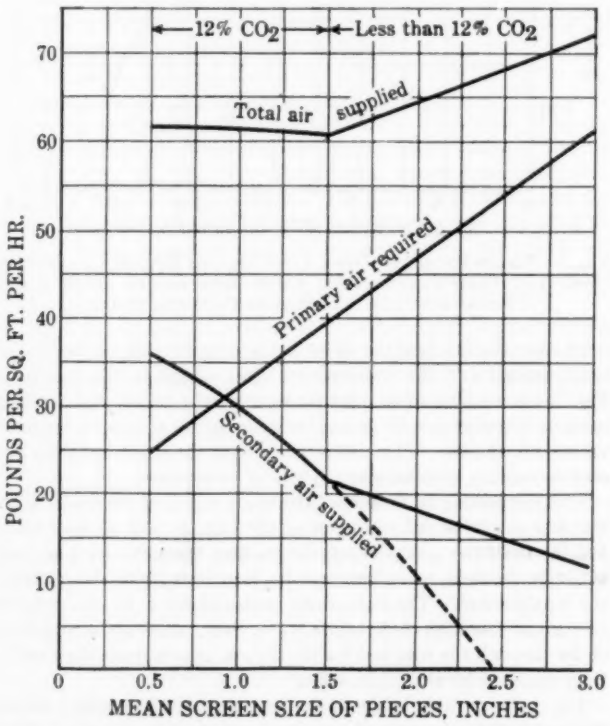

FIG. 6 WEIGHTS OF AIR REQUIRED AS PRIMARY AIR SUPPLIED FROM THE ASHPIT AND SECONDARY AIR SUPPLIED OVER THE FUEL BED TO OBTAIN THE SAME EFFICIENCY OF COMBUSTION WHEN USING DIFFERENT SIZES OF COKE AT THE SAME RATE OF BURNING, FOR HIGH-TEMPERATURE COKE BURNING AT THE AVERAGE RATE OF $3^1/_2$ LB. PER SQUARE FOOT PER HOUR AND WITH 12 PER CENT AVERAGE CO_2

Fig. 7 shows at what rate of burning for each size of coke the full opening of the slots would not be large enough to supply the secondary air required, which, for instance, would be at 7 lb. an hour for the 1- to $1^1/_2$-in. coke. However, more air could be drawn in by partly closing the ash-pit damper as Fig. 7 is based on zero ash-pit pressure. This figure also shows, for each size of coke, the rate of burning which must be reached before it is necessary to begin opening the slots. This for a $1^1/_2$- to 2-in. coke would be 4 lb. per sq. ft. per hour.

There is therefore an area of slot opening which for a given

coke burned in a given furnace at a given rate will, on the average, give the best results, and the data shown indicate what it should be for the coke tested. These data are based on a zero ashpit pressure, that is, with the ashpit damper open. The closing of this damper increases the draft above the fuel bed by an amount equal to the draft produced in the ashpit, and is equivalent to increasing the resistance of the fuel bed by carrying a greater thickness of ash. Such increase of draft above the fuel bed will therefore decrease the area of slot opening required. The effect upon Fig. 7 of closing the ashpit door will be to move the curves to the right and also to decrease their slope.

It is of interest to consider the function of the ashpit damper. It has been seen that closing it increases the draft over the fuel bed, and therefore the quantity of secondary air that will be drawn in for a given opening of the slots. Also, because it increases the equivalent fuel-bed resistance, it makes it easier to adjust the rate of burning in that it requires a larger movement of the stack or choke damper to obtain the same change in the rate of burning. When burning large coke, the householder will find that he can adjust the rate more easily if he keeps the ashpit damper closed, but by doing this he may draw in more secondary air than is needed, even though the slots be closed. With small coke the resistance of the fuel bed itself is higher, and, if his chimney draft is small, to obtain the rate he may find it necessary to open the ashpit damper; at the same time he should increase the slot opening. This will be satisfactory as long as the slots are large enough to supply all the air required while still maintaining zero pressure in the ashpit, but will limit the best control if the slots are not large enough.

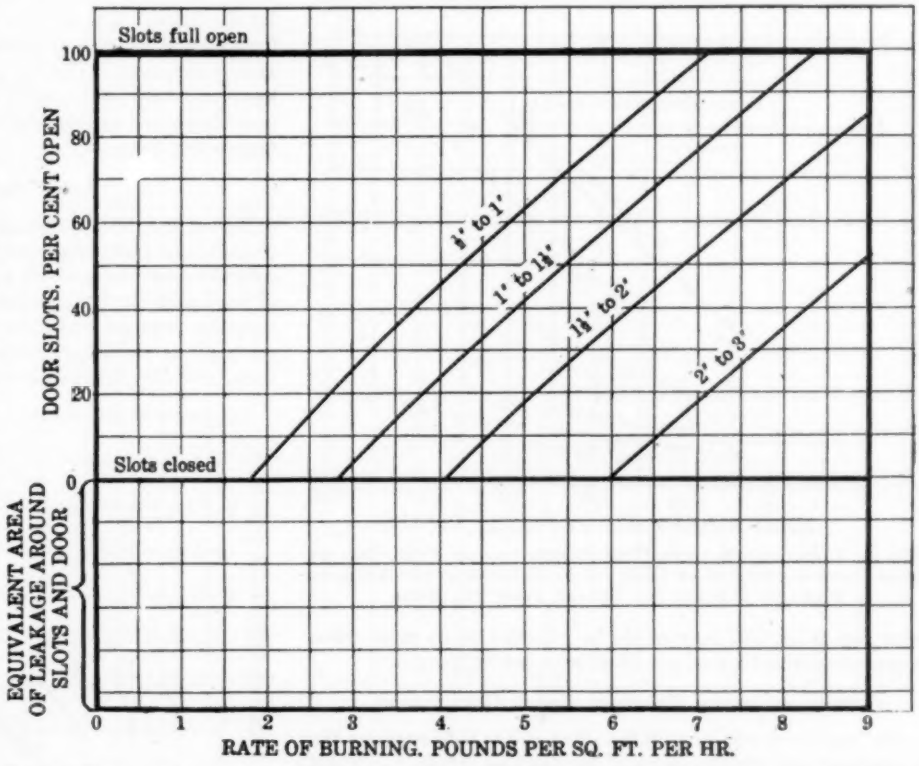

FIG. 7 RELATIVE AMOUNT OF FIREDOOR SLOT OPENING REQUIRED IN A GIVEN FURNACE TO GIVE EQUALLY GOOD COMBUSTION FOR HIGH-TEMPERATURE COKE OF VARIOUS SIZES WHEN BURNED AT VARIOUS RATES

The question can be asked whether a householder using coke and guessing at the amount of slot opening to allow will benefit more by tending to keep it large or small. It is important not to have unburned CO passing into the chimney because the resultant loss in efficiency is high. An average of 1 per cent CO means a loss in efficiency of $3^1/_2$ to $4^1/_2$ per cent, whereas a variation in the excess air as expressed by a variation in the CO_2 from 10 to 16 per cent is not great (17). It would therefore seem preferable to allow more than enough secondary air. On the other hand, the mixing of the secondary air with the gases is not perfect, and some CO gets to the stack even with high secondary air. Tests have shown (12) that the difference between the CO content with 12 and with 16 per cent CO_2 is small; that is, it is possible to operate a domestic furnace with a low excess of air when burning coke.

SIZE OF COKE, UNBURNED FUEL, AND EASE OF STARTING

Fig. 2 shows that the method of test was to use 30 lb. of coke to start the fire, then run two full firing periods, and then allow the fire to burn itself out. The residue was taken out and the weight of unconsumed combustible in it determined. Fig. 8, curve *A*, shows the pounds of combustible per square foot of grate area for the 20-in. furnace. The curve shows that the unburned fuel increases rapidly with the size of coke.

A desirable quality of a fuel, from a householder's viewpoint, is that it shall keep alight as long as possible, so that he will not have to relight the fire if he delays to refire it. The quantity of unburned fuel is a measure of its ability to keep alight, and the curve shows that it will be necessary to refire earlier with large coke than it will be when a smaller size of coke is used.

A fire that goes out more easily is for the same reason hard to start. The ease of starting was also measured directly by recording the time it took to burn the same weight (gas was used to light the coke), and the values come in the same order but are not as reliable data. The fact that it is more difficult to start a fire with large sizes of fuel is common experience, although there is a limit to the smallness because of the coke falling through the kindling and smothering the flame.

EFFECT OF SIZE OF FIRE POT

The data shown previously were for a fire pot 20 in. in diameter. The influence of size is limited to the relative cooling effect of the sides on the fuel bed; therefore, as the area of the fuel bed is increased it would be expected that:

1 The resistance of the fuel bed to the flow of air would be somewhat less, because the area near the sides has less resistance than the center portion. On the other hand, the temperature head of the hot gases will be somewhat greater. The changes in these two effects will be small, but both will tend to reduce the draft required.

2 The combustion of the fuel will be better because the cooling effect is smaller, and therefore less primary and more secondary air will be required with the larger fire pot.

3 There will be less combustible per square foot of grate area left in the fire pot when the fire dies out, because the greater portion of such combustible is found around the sides.

The tests when using the 28-in. furnace supported these expectations. The composition of the gases was slightly higher in carbon content and the combustible in the residue less as shown by curve *B* of Fig. 8. As might be expected, the effect of the size of the furnace increases as the coke pieces are larger. The differences between results with the 20- and 28-in. fire pots

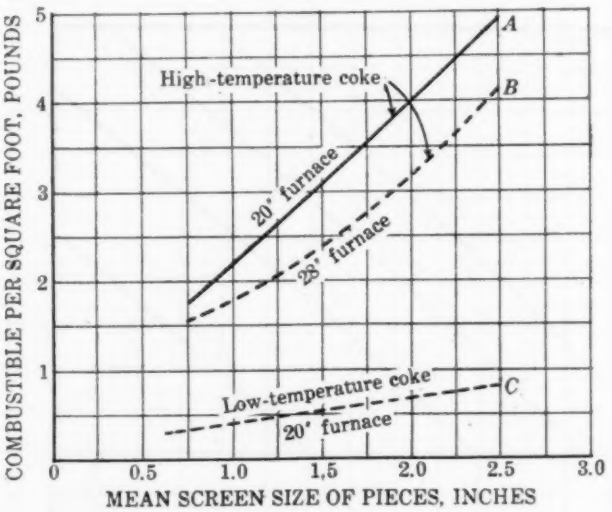

FIG. 8 COMBUSTIBLE LEFT UNCONSUMED IN THE FUEL BED AS DEPENDENT ON THE SIZE OF COKE—FUEL BURNING AT THE AVERAGE RATE OF 3½ LB. PER SQUARE FOOT PER HOUR

were not great, but they would be expected to be more when comparing a smaller size, say 15-in. with one of 20-in.

SUMMARY OF THE EFFECT OF SIZE OF COKE PIECES

The easiest way to sum up the effect of size is to compare the advantages and disadvantages of the smallest (½ to 1 in.) and the largest (2 to 3 in.) size of cokes tested.

Advantages. With the small coke the favorable points are: (1) It is easier to start the fire; (2) it is less likely to go out; (3) there is more range of damper adjustment, and thus the furnace will be more easily controlled; and (4) firings will not have to be quite as frequent.

Disadvantages. The poor qualities with small coke are: (1) A much greater draft is required; (2) a hotter fire can be obtained and thus worse clinkers may be formed; and (3) the efficiency will be lower, both because the CO will be higher due to poor mixing of the gases and air and because the exit temperature of the gases will be higher due to there being more combustion above the fuel bed and a higher initial temperature of the gases entering the passes.

Householders will differ in their preference for the large- or small-size coke, but usually would be more critical of qualities that caused them personal trouble or annoyance. It can be believed, however, that the best average satisfaction would be obtained with a medium size, and a 1½-in. mean screen size would bring fewer complaints. This size presents the further advantage of requiring little or no slot opening, especially if the ashpit damper is kept closed.

DIFFERENCES BETWEEN HIGH-TEMPERATURE COKES

Differences in high-temperature cokes because of the nature and amount of ash they contain need not be considered, and they are fixed by the coal from which the coke is made.

Extensive studies have been made by the Bureau of Mines (15, 16, 17) and the Massachusetts Institute of Technology (14) of the properties of coke made by different processes from the same coal. The chemical compositions of the cokes were closely the same, and the differences found in their use in domestic heaters can be associated with their physical characteristics. Those which were lighter in weight were also softer, and tended to abrade and create fines and dust more easily. A complete set of tests was run on a heavy- and a light-weight coke, the data previously shown being for the latter. The average composition of the gases over the fuel bed and the ratio of primary to secondary air were approximately the same. The light coke ignited more easily and left less combustible in the residue. Fig. 9 shows this weight of combustible plotted against size for a heavy (by-product) and light (gas-house) coke.

LOW-TEMPERATURE COKE

It may be expected that there will be greater variations in the chemical and physical properties of low- than of high-temperature cokes because the methods proposed, in the experimental stage, of producing the low-temperature coke vary materially in temperature, pressure, and time duration of treatment. The chemical analyses which have been published have shown wide variations, and the physical properties will evidently vary still more

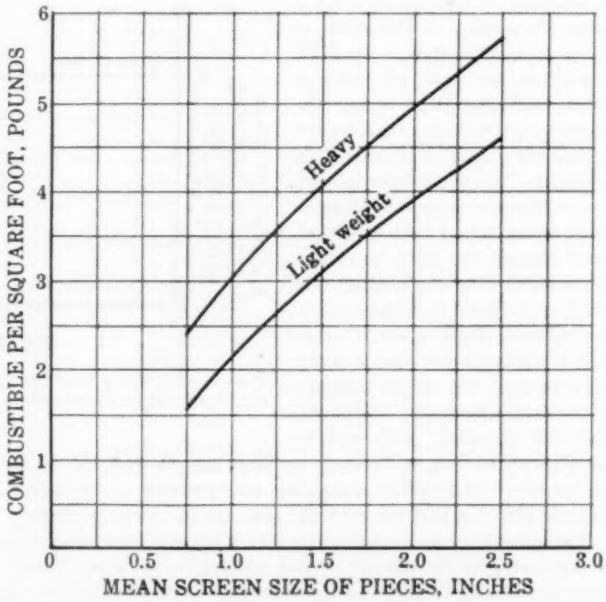

FIG. 9 COMPARISON OF AMOUNT OF UNBURNED FUEL IN RESIDUE FOR A HEAVY- AND LIGHT-WEIGHT HIGH-TEMPERATURE COKE

because the processes vary considerably, some including a briquetting under heavy pressure of the coked product. It follows that the characteristics of low-temperature cokes when burned in domestic furnaces will differ and that generalization should not be made from tests of a few.

It is, however, of interest to consider the tendencies that some of the characteristics of low-temperature coke can be expected to show relative to those of high-temperature coke. A complete set of tests identical to those described for the high-temperature cokes have also been made on one low-temperature coke. These tests were complete and determined not only the CO, but also the hydrogen and hydrocarbons arising from the fuel. Only a few of the data will be presented.

The proximate chemical analysis of the low-temperature coke was:

Constituent	Per cent
Moisture	2.6
Volatile matter	13.2
Fixed carbon	69.3
Ash	14.9

Fig. 10 shows the average percentage CO and CO_2 in the gases arising from the fuel bed, plotted against size, when burning at the rate of $3^1/_2$ lb. per sq. ft. per hr. a low-temperature coke, a high-temperature coke, and a Pennsylvania anthracite. The difference between the values for the high-temperature coke and anthracite is not great, but the low-temperature coke differs materially from both. It indicates that the low-temperature coke unites with the oxygen of the air and forms CO much more readily than do the other two. This is expressed technically by saying it has a higher combustibility and reactivity, and popularly by saying it burns more readily.

It will be noted from Fig. 10 that the relative difference between the percentages of CO and CO_2 for the low- and high-temperature cokes is greater for the large sizes than it is for the small; that is, the properties more nearly approach each other as the size gets smaller. It will also be seen that the CO and CO_2 of the $2^1/_2$-in. size low-temperature coke are about the same as those for the 1-in.

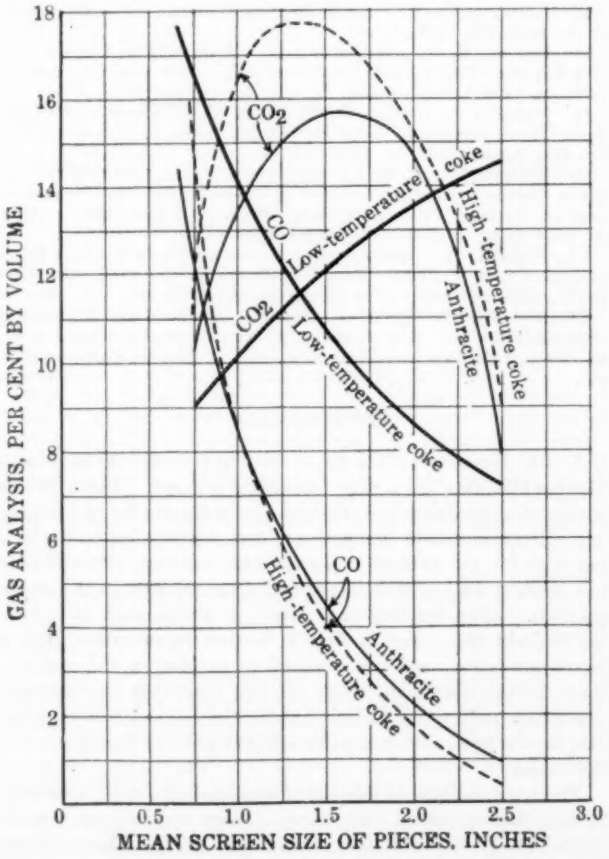

FIG. 10 COMPARISON OF AVERAGE COMPOSITION OF GASES ARISING FROM THE FUEL BED WITH DIFFERENT SIZES OF A HIGH- AND A LOW-TEMPERATURE COKE AND AN ANTHRACITE—RATE OF BURNING $3^1/_2$ LB. PER SQUARE FOOT PER HOUR

high-temperature coke; that is, to obtain equivalent results in this respect a larger size of low-temperature coke must be used.

Fig. 11 shows the primary and secondary air required for the low-temperature coke; this corresponds to Fig. 6 for the high-temperature coke. It shows that the ratio of secondary to primary air is greater, and that less draft and more opening of the firedoor slots will be required for the low-temperature coke.

The amount of combustible in the ashpit residue was included in Fig. 8 as curve C. It is much less than for the high-temperature cokes, showing that the refiring can be delayed longer. One can also deduce that the low-temperature coke was easier to ignite, and this was found to be so for all sizes.

It has been shown generally that all low-temperature cokes have the properties described above, although it is to be expected that their departure from similar values for high-temperature

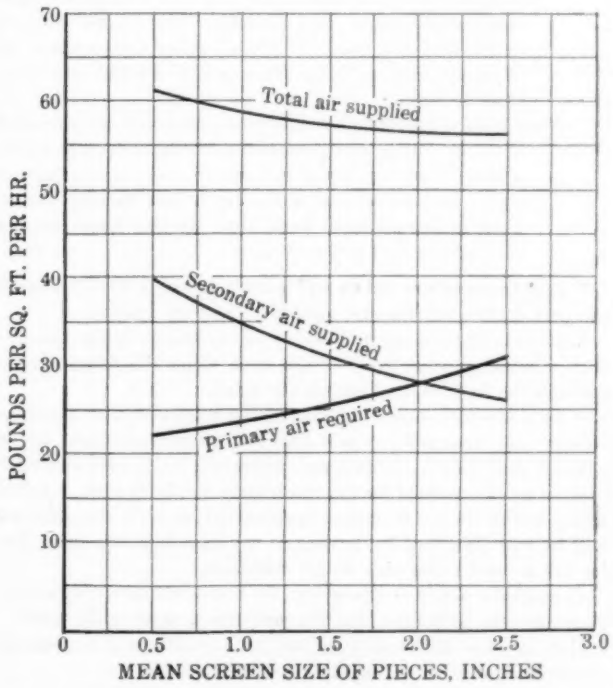

FIG. 11 WEIGHTS OF PRIMARY AND SECONDARY AIR REQUIRED BY A CERTAIN LOW-TEMPERATURE COKE BURNING AT THE AVERAGE RATE OF $3^1/_2$ LB. PER SQUARE FOOT PER HOUR AND WITH 12 PER CENT CO_2

coke will not be the same. Some tests which have been made on two other low-temperature cokes show that one tended nearer to the high-temperature coke and one further away than that discussed in the foregoing.

Certain safe deductions can be made on the relative performance and characteristics of low- compared with high-temperature cokes when burned in domestic furnaces. The numerical values corresponding to these deductions will vary with the furnace and with the attendance; the comparisons are on the basis of equal sizes of the two types of cokes:

1 Low-temperature coke will require less kindling and less time to start the fire.

2 Low-temperature coke will burn more readily and will require less air through the fuel bed and less draft; consequently, the dampers must be in good condition or it will not be possible to control the burning so that the house will not be overheated.

3 Low-temperature coke will require more air above the fuel bed.

4 Low-temperature coke when banked is never likely to cause trouble through the fire going out, leaving the fire pot full of unburned fuel, but rather it will be more likely to burn away before morning.

5 Low-temperature coke could be successfully refired with a smaller amount of live fuel in the fire pot.

6 The efficiency with low-temperature coke—

a will tend to be higher because there will be less combustible loss in the ashpit, and the amount, with reasonably careful handling, will be small.

b will tend to be lower because the gases from the fuel bed will contain a larger percentage of combustible, and there will be a greater probability of a larger amount passing to the chimney unburned because of poor mixing with the air supplied through the firing door.

c will tend to be lower because the larger amount of combustible gases above the fuel bed will require a larger combustion space, and therefore the flames will be longer and will tend to give a higher temperature of the gases passing to the flues and thus a higher loss in sensible heat.

d will tend to be lower because, when fired in large amounts with the consequent complete covering of the live coals, a larger loss will occur because of the volatile matter which is distilled out of the fresh fuel passing to the flues unburned until such time as the flame breaks through the bed and ignites it.

7 Low-temperature cokes will give a haze of smoke during the period after refiring and until the gases are ignited.

8 There will be more probability of explosions in the furnace with low-temperature coke at the time when the flame breaks through the fuel bed and ignites the gases.

A first consideration of the foregoing might lead to the conclusion that householders will find low-temperature coke to be a less desirable fuel. This is not necessarily so, as less discord is created in a household by too much than too little heat. A fuel which burns readily is always appreciated, and the householder will be less disturbed by having to try to reduce the heat that he will by not being able to get sufficient.

It would be a mistake, however, for manufacturers of low-temperature coke to believe that the production of an easily burning fuel is the sole desirability or that this quality will necessarily counterbalance the accompanying disadvantages.

Petroleum Coke

The sale of petroleum coke for domestic furnaces has been small and confined to the Middle West. E. B. Swanson, of the Bureau of Mines Petroleum Economics Division, in an unpublished report states that its largest sales occur in Kansas City, Chicago, Minneapolis, St. Paul, and Wichita, Kansas.

No analytical tests have been made of petroleum coke, but its burning qualities resemble those of low-temperature cokes, though the absence of ash necessitates a different method of handling. Most of the small amount of ash it contains is carried up the stack. None remains on the grates; consequently, the burning fuel is in contact with the grates and destroys them in a short time. They must therefore be protected by a layer of broken firebrick or of ash or clinker from some other fuel. The former method is preferable as the firebrick will take longer to fuse together.

Acknowledgments

The experimental work reported in this paper was conducted at the Pittsburgh Experiment Station of the U. S. Bureau of Mines under the authority of O. P. Hood, chief mechanical engineer; M. L. Orr, assistant fuels engineer; and W. M. Brewer, junior fuels engineer, assisted by Charles Schramm, cooperated in making the tests.

Discussion

A. M. Beebee.[5] This paper contains most valuable and worth-while data on a most important subject. There is one comment which impresses the writer as being worthy of bringing up. Experience both practical and technical has led to the feeling that for the average domestic-coke customer there is only one position for the slide in the fuel door, namely, in the closed position. After reading the paper it seems that the data, particularly the curve in Fig. 7, further substantiate such a recommendation, and yet a complete evasion of this point is made in the discussion, when through ignorance and previous experience with other fuels it has become almost general practice for the coke customer to be advised to leave the slide in the door open.

The tests outlined in this paper were carried out in theoretical rather than practical equipment. Work carried out for the 1926 A.G.A. Carbonization Committee by the Massachusetts Institute of Technology and the Koppers Company, report of which follows, was carried out in practical standard equipment and further confirms the logic of this recommendation. Reference to these data is particularly interesting. Therefore, it seems that in view of the already rather general practice it is highly desirable that rather definite recommendations be made with regard to the leaving of the slide in the fuel door in a closed position when burning all but the very finest coke fuel.

Proper Combustion of Coke—Slide in the Door Closed—1926 A.G.A. Carbonization Committee Report

Apparently the practice of leaving the slide in the door open is a result of the use of anthracite coal, which the following data show to be necessary in the case of coal. The 1926 Carbonization Committee brought out some points on the subject in the tests which were carried out as part of its program. H. W. Rose, Assistant Chief Chemist of the Koppers Company, in his report on a similar set of tests reports:

Two new Ideal Arco boilers were recently installed in a domestic-coke testing station. Using three different by-product cokes, it was found that both of these boilers, when operated at the normal 35 per cent rate with the secondary air damper closed, leaked enough air to burn up all of the CO, and gave, in addition, very high excess oxygen in the stack gas. In the majority of the cases no CO whatever was found, and the highest amount was 0.3 per cent, which is almost within the error of gas analysis. The average percentage of excess oxygen was 9.5 per cent (equivalent to 45 per cent air). When the secondary air damper was opened, the CO content of the stack gases was 0.0 per cent or 0.1 per cent, and there was 14.4 per cent excess oxygen (or 69% air). This means that there were more than two parts of air mixed with each part of true stack gas.

When the boilers were operated at the excessively rapid rate of 120 per cent, with the secondary air damper closed, the average CO percentage found in the stack gases was only 1.8 per cent. At the same time the average CO_2 content was 17.7 per cent and the oxygen percentage 1.9 per cent so that the efficiency was very good indeed. Even at this excessive rate of firing, every trace of CO disappeared as soon as the secondary air damper was opened, the following average analysis being obtained: 0.0 per cent CO, 16.2 per cent CO_2, and 4.7 per cent O_2.

In the paper by P. Nicholls of the U. S. Bureau of Mines before the A.G.A. in 1926 as a result of his tests appears the following statement:

The curves show that the secondary air required over a fuel bed decreases with increase in size of coke and that absolutely none will be required for the high-temperature cokes having a mean screen size of about 1¾; that is, the door slots should be kept closed. For larger sizes the air needs are negative, which is equivalent to saying that they could not be used with equal efficiency.

In Professor Haslam's paper on the combustion of cokes (in the 1926 Carbonization Committee report) in a domestic furnace the curves shown in Fig. 12 resulted. Note the large amount and continued duration of CO with anthracite and the small amount and duration in the case of various cokes. Professor Haslam concludes:

However, the larger amount of CO generated both in amount and time of duration with anthracite fuel shows the need for admitting secondary air over the fuel bed when using this fuel. Due to the smaller amount of CO generated with coke fuel, admission of secondary air is of less importance in securing maximum efficiency. The change in the ratio, however, indicates the necessity for more frequent adjustment in the case of coke than in the case of anthracite coal. Finally, in so far as these tests are representative of ordinary operating conditions, there is much less need of secondary air with coke fuel than with anthracite and less loss in proper air adjustments are not made by the householder.

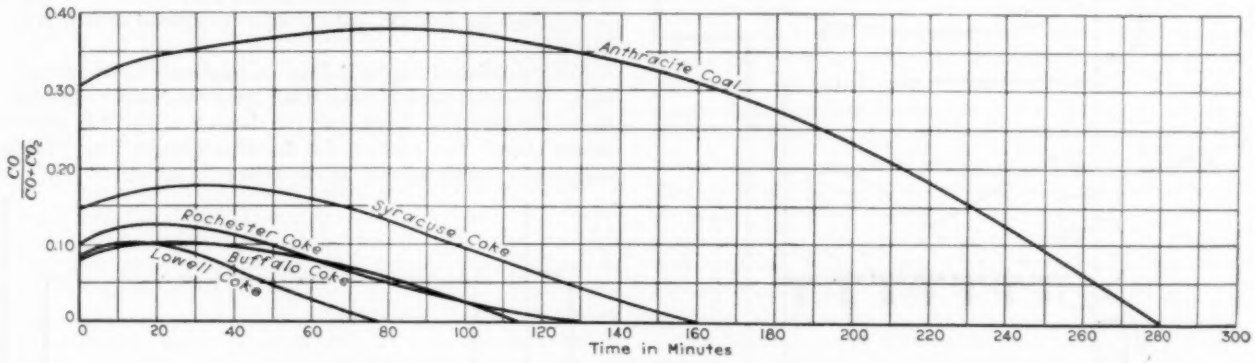

Fig. 12 Curves From Professor Haslam's Report on Combustion of Cokes in Domestic Furnaces—American Gas Association—1926 Carbonization Committee Report

Conclusion

From the above it appears that customers should be advised to keep the slides in doors closed, not only to improve combustion efficiency but also to reduce the danger of products of combustion being given off in the cellar of a customer, especially immediately after firing.

Henry Kreisinger.[6] High-temperature coke has been used by the writer for house heating during the last five winters with very satisfactory results. The size used is about 1 to 1½ in., and is the smallest size that can be obtained from local coal dealers. The indications are that better results could be obtained even with a smaller size than this. One winter the coal dealers did not have the regular sized coke on hand, so a load of a gas-house coke of much larger size was purchased. Some of the pieces were 3 to 4 in. in diameter and were entirely too large. It was difficult to keep the fire going with this large coke. Unless the fire was kept very hot it would go out, and therefore satisfactory uniform heating could not be obtained. I think that much of the difficulties encountered in burning coke are due to too large size. In my own case ½- to 1-in. size would give the most satisfactory results. Small size coke is especially desirable for overnight banking. It will keep fire much better than larger sizes.

The house in which coke has been used has 10 large rooms, but only six of these are regularly heated. The heating plant is a one-pipe steam system. The boiler is of square shape with a fire box 21 in. high, 24 in. wide, and 30 in. long. The ashpit is 12 in. deep.

The method of firing is shown in Figs. 13 and 14. Before firing the burning coke is pushed with the coal scoop to the rear part of the grate, and the front is then filled with fresh coke as indicated in Fig. 14. This method of firing keeps the surface of the rear part of the fuel bed always glowing so that the combustible gases rising from the freshly fired coke can be ignited and burned as they pass over the glowing coke. Covering only part of the fuel bed with fresh coke also produces more uniform heating, because the uncovered glowing coke keeps on generating heat which is available for producing steam during the period when the freshly fired coke is brought up to ignition temperature. Covering the entire fuel bed with fresh fuel is always objectionable no matter what fuel is used.

[6] Research Engineer, Combustion Engineering Corp., New York, N. Y. Mem. A.S.M.E.

In case the fire has burned down too low, it is advisable to put in a piece of wood as shown in Fig. 15 before placing the fresh charge of coke into the furnace. The wood insures the ignition of the fresh coke. It is not necessary to put in much wood. One ordinary piece of kindling wood goes a long way to hold the fire and start the ignition. It is common practice among blacksmiths to bury a piece of wood in the glowing coke in their forge if they wish to keep the fire over an extended length of time. The wood upon heating distils combustible gases which ignite easily and start the coke burning. The wood also keeps glowing with very reduced air supply through the grate, and may be particularly useful with banked fire.

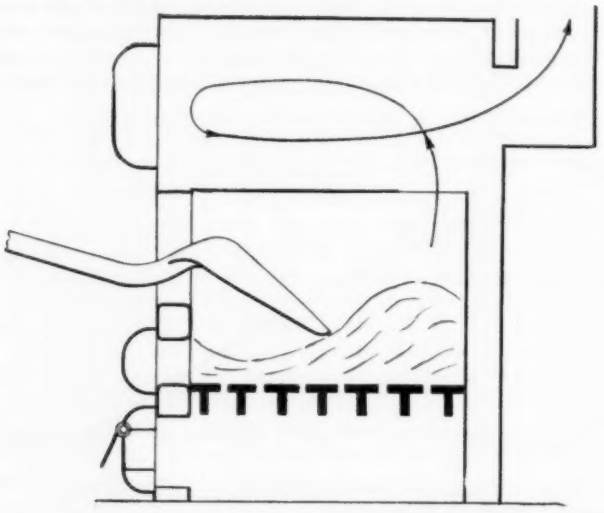

FIG. 13 BEFORE FIRING, BURNING COKE IS PUSHED TO THE BACK OF THE GRATE

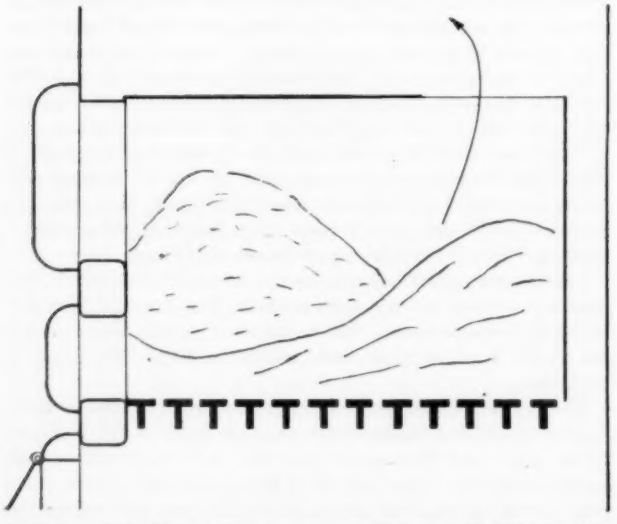

FIG. 14 THE FRONT SECTION OF THE FIREBOX IS FILLED WITH FRESH COKE

Banking fires for the night is accomplished in a similar way as the firing, with the possible addition that the pocket for the fresh coke on the front part of the grate is made somewhat deeper, the fuel with greater amount of small pieces is picked out for banking and piled up somewhat higher than for ordinary firing. It is very seldom that fire goes out overnight.

The frequency of firing depends on the weather. In mild weather two firings a day keep the house comfortable. In cold weather the number of firings may have to be increased to three or four or even five.

When burning coke it is of great advantage to have a boiler with a large furnace volume. Coke is much less dense than coal, and the pieces are more irregular and rougher, with the result that the coke makes a very loose pile in the furnace, and only about 50 to 60 per cent of the weight can be put in the same space as with anthracite. A large coal scoop greatly reduces the work of coke firing.

The coke used contains 8 to 10 per cent ash compared to about 20 per cent ash in anthracite available in this locality. The ash is generally fine dust that sifts through the grate bars into the ashpit by gently shaking the grate. Rocking of the grates is not desirable and necessary because it is sure to drop unburned coke into the ashpit. The total amount of ashes taken out is two to three bushel buckets a week. The amount of clinkers is very small and does not exceed 5 per cent. It is pulled out through the firedoor, and the labor connected with it is insignificant.

The regulation of the fire is done automatically by steam pressure. When the pressure exceeds 2-lb. gage the damper admitting air to the ashpit is closed, and the damper in the flue pipe is nearly closed. To prevent the flue-pipe damper from closing completely a small segment in the damper is cut out.

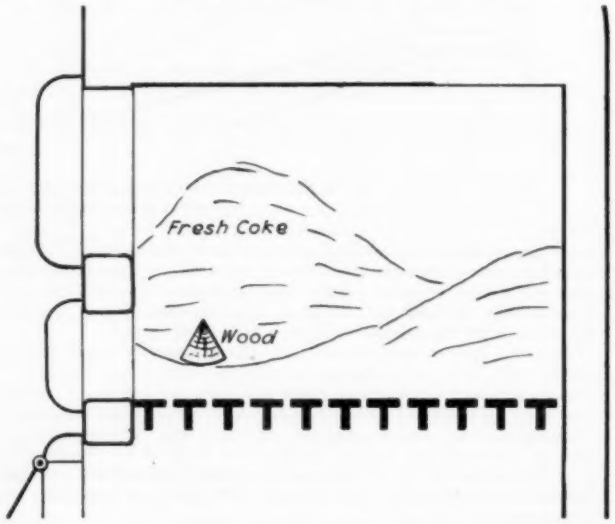

FIG. 15 A STICK OF WOOD HELPS TO IGNITE FRESHLY APPLIED COKE

H. J. ROSE.[7] There is a most important development which must not be overlooked in any discusion of coke as a domestic fuel. Domestic coke is a distinct type of coke, made to specification from selected coals, in order to produce the best possible fuel for the domestic trade. Less than 20 years ago (it is perhaps equally correct to say less than fifteen years ago) there was little coke offered as household fuel which could meet the above requirements. Much of the coke offered as household fuel was really not domestic coke at all; it was the rejects or small sizes of metallurgical coke. At some plants these rejects were, and today still are, good domestic fuel. But far too often such products were high in ash, had a low ash-fusing temperature, and were poorly sized. All three of these factors combined to cause clinker trouble and other complaints.

Coke from gas retorts was another variety which usually failed to raise coke in the public estimation. Perhaps the outstanding factor of genuine domestic coke today is its low ash content.

[7] Assistant Director of Research, The Koppers Co., Mellon Institute, Pittsburgh, Pa.

Certain coke plants are now producing domestic coke which contains less than 7 per cent of ash. We find that so long as low-ash coke is put into customers' bins, few customers are lost.

Proper merchandising methods and technical service are other factors in the outstanding success of those plants which are producing domestic coke that is made to specification. There are still many localities where it is difficult to buy the high-grade domestic coke that has just been described. Fortunately, it is being made and sold in continually increasing quantities.

HORACE C. PORTER.[8] The authors' statement that coke "is referred to as the ideal fuel from that standpoint" (smokelessness), might be challenged by the anthracite advocates since it is practically impossible to make smoke in burning anthracite coal of the better grades. Furthermore, anthracite has a small amount of smokeless volatile matter which in some respects improves its combustibility.

Among the objections or complaints listed by the authors as being applied to coke, they do not include (1) the additional bulk of fuel in storage, in other words, the extra space required for bins in the cellar; (2) the additional work of shoveling for the person handling the fuel due to its bulk, and the difficulty of shoveling caused by coke's peculiar way of falling from a pile or sticking in corners.

The curves given in Figs. 5 and 10, showing the relative amounts of CO and CO_2 in the gases over the fire from coke of different sizes, indicate clearly that small-sized coke gives much more CO than the larger sizes and therefore requires secondary air in order to maintain the best efficiencies. The same thing would apply no doubt in the case of small-sized anthracite. However, in practical operation of a household furnace, excess air is drawn through holes along the walls of the furnace which counteracts this difficulty. It would be of interest to have data on the amount of CO in the chimney gases under household burning conditions. Perhaps some one of the anthracite interests can furnish these.

The tests show that medium-sized coke 1 in. to $1^1/_2$ in. appears to work out the best. The coke producers have already found this out apparently, and are promoting sales of this size actively.

Low-temperature coke is well known to have in most cases a very high rate of combustibility. The unburned fuel in the ash should therefore be very low with this grade of coke, and the authors have called attention to the gain in efficiency that results from this factor.

Lykens coal (anthracite) has a much higher rate of combustibility than most of the other anthracites, and furnaces that burn Lykens coal or briquets made from it have much smaller losses of unburned fuel than those burning harder anthracites. Low-temperature coke would bear a similar relationship to high-temperature coke.

The factors listed by the authors as tending to cause lower efficiencies with low-temperature coke will not necessarily hold true if the right kind of furnace equipment is used, adapting it to the fuel.

The whole matter of improving solid fuels for household use is tied up with the new developments now going forward rapidly in automatic firing and automatic control. This development has been boosted by the increased use of oil and gas which are peculiarly adapted to such automatic control. There is some question whether the virtues claimed for coke in its low content of ash are fully justified beyond a certain point. A very low content of ash may give rise to a necessity for delicate and careful control of the fires that will make difficulties for the average householder. The designers of automatic control, however, are likely to find ways of overcoming this difficulty.

It would seem to be desirable for some agency like the Bureau of Mines to make comparative tests of efficiency and overall returns in house-heating by different fuels, using equipment and conditions especially adapted to the characteristics of the fuel that is being burned. Comparative tests heretofore have used equipment and conditions identical for the different fuels, and have thereby placed one or the other at a disadvantage.

[8] Consulting Chemical Engineer, Philadelphia, Pa.

AUTHORS' CLOSURE

The conclusion reached by Mr. Beebee that domestic users of high-temperature coke should be advised to keep the slides in the firing door closed is a rule which on the average should give the best results with the sizes of coke usually sold. There is no reason, however, why the companies that purvey coke in large quantities and have inspectors to assist their customers should not be in a position to discriminate more closely and advise some slot opening when it will be of benefit. The authors purposely avoided stating definite rules. The work which the Bureau of Mines is doing in determining the burning characteristics of fuels should be supplemented by some field surveys. Snap measurements of the composition of the flue gas of installations typical of those in a district would accumulate data which should be helpful to the coke companies in training their inspectors and would show how far the results of tests of commercial heaters made under test-block conditions are representative of regular use.

It is valuable to have the personal experience of Mr. Kreisinger. His choice of a 1- to $1^1/_2$-in. size for use in a heater which is amply large for the rooms heated agrees with deductions from the tests reported in the paper. It is doubtful, however, whether he would find the $^1/_2$- to 1-in. size as economical, unless bought at a lower price. The CO content of the gases from the fuel bed increases rapidly with decrease in size, and the loss of CO to the stack would be higher in the average heater; in addition, a greater quantity of clinker would be formed, and its removal causes some loss of fuel to the ashpit.

It is agreed that Mr. Kreisinger's practice of pushing back the live coke before adding new fuel is correct and will save some loss in efficiency. The loss, when the live fuel is smothered, from combustible gases passing to the flue between the time of firing and when the gases over the fuel bed are ignited has been determined by us, both for high- and low-temperature cokes. It varies with rate of primary-air supply and with size of coke, and is greater for the low-temperature coke because of its volatile matter. With high-temperature coke this loss increases rapidly for sizes below 1 in. and is negligible for sizes above $1^1/_2$ in. An inexperienced fireman would probably lose more fuel through the grate bars than he would save from the combustible gases; it would be safer not to recommend the practice for general use with high-temperature coke larger than 1 in.

The suggestion of Mr. Porter that coke may suffer in comparison with other fuels because of the larger bin it requires to hold a given weight is justified; also it is probable that most people will consider it more inconvenient to shovel than a sized coal, but opinions differ on this and womenfolk in particular have been found to prefer coke.

The authors, as far as possible, avoided comparisons between cokes and coals, and a paper to include such comparisons would be of much wider scope than that presented.

FSP-52-15

Effect of Fouling on Boiler Efficiency

By J. W. PIERSON,[1] CHICAGO, ILL.

The subject of this paper concerns a situation that confronts those in the Middle West who out of necessity are required to burn some of the low-grade fuels of Illinois.

The fouling conditions incident to the use of such fuel with chain-grate firing with high relative ratings are dealt with. Some of the objectionable characteristics of the fuel not shown by usual analysis are pointed out, together with the severe conditions which soot-blowing equipment of any kind would have to withstand.

The data presented show the efficiency characteristics of an operating cycle with this low-grade fuel compared to that which would exist when using a better fuel. Unfortunately the difficulties of the former cannot be solved by the simple expedient of using a better coal. The choice in such a situation is, then, to operate at high ratings with low overall efficiency or with lower ratings with improved efficiency. Lower ratings, however, would reduce station output, and is not a desirable solution.

OPERATION of a modern chain-grate stoker plant burning Central Illinois coal imposes ever-increasing difficulties when, due to the economics involved, still higher ratings than those of former practice are desired. Such a situation is exemplified in the boiler-room equipment of the Crawford Avenue Station of the Commonwealth Edison Company where the matter of maintaining clean heat-absorbing surfaces with such fuel conditions has developed into a major boiler-room problem. These matters are still far from a satisfactory solution.

Even though the coal burned has so many unfavorable characteristics, coal costs are such that the problem cannot be solved economically by the simple expedient of buying a better grade of fuel. The problem therefore is one of carrying on against the difficulties as they are, and will require considerable thought and development on the part of both designers and operators.

A typical analysis of the coal on the "as fired" basis may be expressed as follows:

B.t.u.	10,026
Per cent Moisture	16.95
Per cent Ash	11.95
Per cent Sulphur	4.04
Per cent Hydrogen	3.93
Per cent Carbon	53.10
Per cent Nitrogen	0.86
Per cent Oxygen	9.21

This analysis, however, does not show many of the characteristics of the fuel nor are they indicated by any of the usual forms of analysis. Due to its high volatile content it is a long-flaming coal, and requires liberal use of overfire air injection. Even under these circumstances some long flaming results. The ash has a fusion point of about 1950 deg. fahr., which on being carried as fly ash into the lower bank of tubes and superheater in a molten or viscous state, deposits and adheres firmly to the surfaces as a slag. This slag is composed largely of oxides of silicon, iron, and aluminum. Other portions of the ash were carried through to the economizer and preheater surfaces, where they present a problem of a different nature. The excess air required for complete combustion is higher than would be required for a better grade of fuel. This condition is also imposed by the necessity of limiting temperature conditions, to reduce refractory problems, and also somewhat to prevent worse fouling in the boiler passes.

The sulphur content is high, and while this may not directly affect the rate of fouling, it is important inasmuch as corrosion of economizer and preheater tubes requires equipment outages which impose an additional burden on the rest of the equipment.

There are 32 stoker-fired boiler units at this station, of the general arrangement shown in Fig. 1. The last extension of this

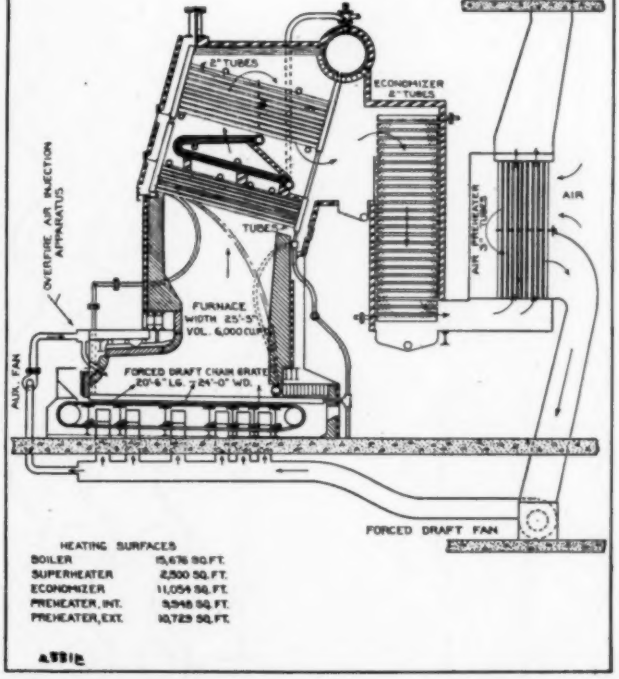

FIG. 1 GENERAL ARRANGEMENT OF BOILER NO. 2, UNIT NO. 1 IN CRAWFORD AVENUE STATION OF COMMONWEALTH EDISON COMPANY

boiler plant has 12 boilers equipped with water-cooled furnace walls. Previous experience with furnace walls indicated beneficial results of the cleaning problem together with reduced refractory maintenance costs.

Plant load conditions require a cleaning and maintenance program during the summer and early fall months which requires 26 boilers available for service. This means that each boiler unit must operate about 35 days, and is out about six days. At the end of the service period the boiler is badly fouled, and operating at a lowered capacity as a consequence. Winter conditions require 27 boilers for service, which means that each boiler unit must operate about 42 days, with the result that steaming capacity and efficiency fall still further before outage. The soot blowers are operated every twelve hours, and the boilers are air or water lanced every fifth night. It is obvious that

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

demands for still higher loadings only lead to a vicious circle, making the cleaning problem a matter of direct or even greater ratio to capacity demand.

The demand for higher superheat largely influenced the design of the interdeck superheater arrangement as shown in Fig. 1, which also shows the location of the blowing elements. It is obvious that the temperatures normally prevailing in the zone of the lower-tube bank and superheater subject blowing equipment to rather severe conditions, particularly to two central elements on the lower bank and the two in the superheater, all of which are in the direct line of maximum temperature. Where failures have occurred they usually take the form of warping or breaking, and in some cases burning off.

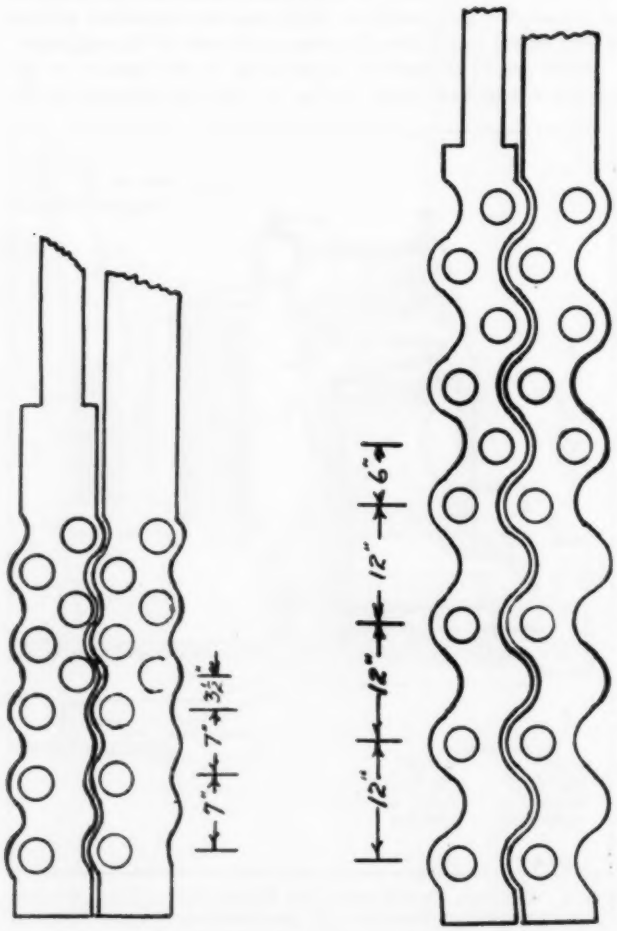

FIG. 2 TUBE SPACING ON LOWER DECK; AT LEFT, EARLY INSTALLATION; AT RIGHT, LATER INSTALLATION

Difficulties have been experienced with bearings which depend upon some form of clamping to hold them in position. Arc welding of steel strips to the boiler tubes to which are bolted alloy straps that hold the elements in place is apparently a solution inasmuch as the bearing is cooled more effectively.

The installation of more elements while seriously considered presents structural difficulties as well as increased steam use which has already reached undesirable proportions; consequently this does not seem to be a satisfactory line of procedure.

The nature of the soot deposit on economizers and preheaters is such that permanently installed blower elements were not considered as an effective means of removing it. Under conditions as stated washing is the only effective method so far found. This is done as the unit is being taken out of service so that excess moisture is evaporated quickly.

Experience with these general conditions has proved that cleaning by means of permanently installed blower elements must be augmented with hand lancing if the best results are to be obtained. One method is the use of the air lance on the lower-tube bank. The air has the effect of keeping the lance cool, enabling the operator to work on the slag deposits more effectively.

The tube spacing as shown at the left in Fig. 2 is that of the early installations comprising the first 14 boiler units. This tube spacing will not permit lancing or rodding from the side above the slagging rows. To meet this difficulty it was necessary to resort to a method of water lancing. While using the water lance the boiler is operated at a low rating, and a stream of water from a $^1/_8$-in. nozzle is directed against the slag from

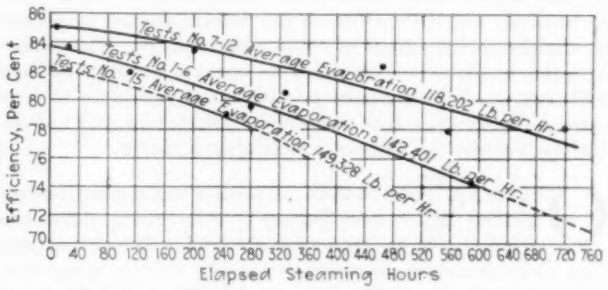

FIG. 3 GRAPHS SHOWING DROP IN EFFICIENCY DUE TO FOULING OF BOILER BURNING CENTRAL ILLINOIS COAL

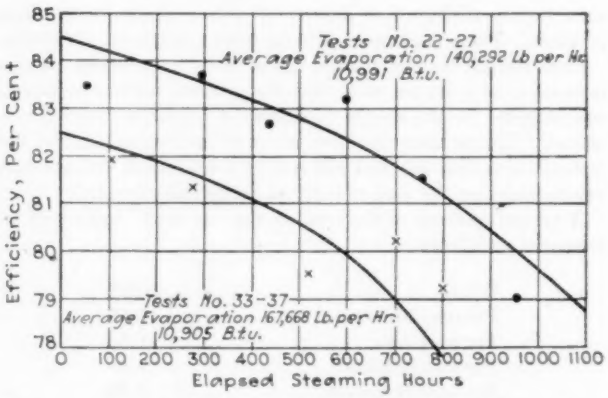

FIG. 4 GRAPHS OF DROP IN EFFICIENCY DUE TO FOULING OF BOILER BURNING WEST KENTUCKY COAL

above and below, which, due to sudden cooling, readily cracks off. This method is not entirely effective because of the inaccessibility of some of the surface.

The tube spacing as shown at the right in Fig. 2 is that of the later installations. It permits greater accessibility both from the front and sides.

Water-cooled furnaces have the effect of reducing the slag deposits by lowering the temperature of the ash before it enters the tube bank. The character of the deposit is different than that found on boilers with refractory furnaces, and is more easily removed.

All these conditions, as may be expected, have their effect on the overall operating efficiency of the boiler room. Evaporative boiler tests do not necessarily indicate the overall operating efficiencies that would be obtained by a given boiler room. As considerable difference occurs, particularly under the circumstances being dealt with, a series of tests representing a cycle of

operation were conducted to illustrate more clearly the true situation with this grade of fuel.

The data presented herewith represent conditions which exist in the operation of a boiler with a water-cooled furnace having the tube spacing as shown at the right in Fig. 2. It is reasonable to conclude that the situation here would be more favorable than that with refractory furnaces.

The boiler unit with its cleaning equipment was put in first-class condition, and operated at a fixed capacity during the day so far as operating conditions would permit. During the night it was operated at reduced rating in order to follow the cycle of boiler-room operation. Boiler tests of eight hours' duration were conducted weekly during the regular operation of the boiler, the coal and water being weighed, and all readings taken to conform to standard test code. The first series of tests were conducted at a capacity of 118,000 lb. of steam per hour, then a series at 142,000 lb. of steam per hour, and finally one at 150,000 lb. of steam per hour.

From Fig. 3 it will be seen that at a capacity of 118,000 lb. per hour the efficiency is 85 per cent at the start, decreasing to approximately 77 per cent at the end of 720 elapsed steaming hours. With a capacity of 142,000 lb. per hour the initial efficiency is slightly lower, but the rate of fouling is greater so that at the end of 590 elapsed steaming hours the efficiency has dropped to 74 per cent.

In the case of the series at 150,000 lb. per hour it was found after about 300 hours of service that it was impossible to maintain this capacity due to the fouling of the surfaces. The choice in operation is then either to operate the boiler units at high capacity with lowered overall efficiency or at lowered capacity with improved efficiency, the latter meaning reduced station output.

In order to show how much this situation would be improved with the use of a better grade of coal, a similar test program was carried out with results as shown by Figs. 4 and 5. The coal in this case was Western Kentucky with a heating value as fired about 11,000 B.t.u. The ash content is lower, and the fusing temperature of the ash is higher, all of which makes the whole cleaning problem easier. This was shown in the periodic lancing, and the condition of the heating surfaces at the end of the service period. Fig. 4 shows the efficiency at two capacities, one at an average evaporation of 140,000 lb. of steam per hour and another at 167,000 lb. per hour. The interpolated curves of Fig. 5 show the general situation as it appears to be for the two different kinds of fuel. While only a hypothetic picture, it is based on actual data.

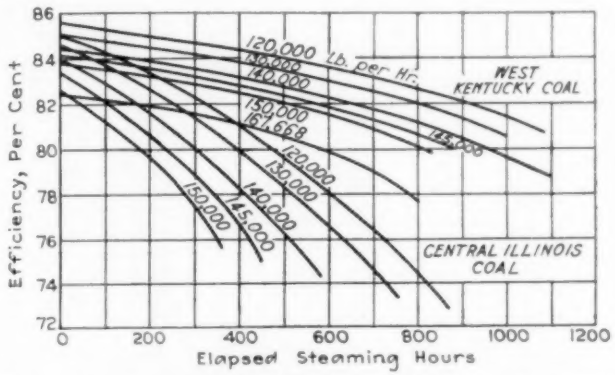

FIG. 5 BOILER AND STOKER EFFICIENCY AT VARIOUS CAPACITIES AND DURING VARIOUS OPERATING PERIODS

In general the curves are similar but show that when using the better grade of fuel the boiler can be operated twice as long before the same drop in efficiency is reached as when using Central Illinois coal. Also with the same operating cycle much better overall efficiencies could be maintained with the better fuel. As the cost of coal, however, imposes the necessity of continuing to burn this low-grade fuel, the problem of efficient operation must take these fuel characteristics into consideration if high boiler ratings and efficiencies under such circumstances are an economic necessity. It is evident, under the existing conditions, that with higher boiler ratings the difficulty of burning this low-grade coal economically will increase in greater proportion.

FSP-52-16

Sampling of Pulverized Fuel

By HORACE C. PORTER,[1] PHILADELPHIA, PA.

IT IS NECESSARY to sample pulverized fuel particularly in order to determine its fineness. In every case where pulverized fuel is used, the fineness of division has a very large influence on the performance of the furnace or other utilization device. It is also necessary to know the percentage of ash, volatile matter, and moisture, and the character of the ash in respect to fusion tendencies. These characteristics can, however, be determined from coal samples taken in the ordinary way before pulverizing.

The American Society for Testing Materials in 1926 adopted a Tentative Standard Method of Test (D 197-26 T) for the fineness of powdered coal in which was specified a method of sampling from the air stream in a pipe. This method has stood as tentative for three years, largely for the sake of securing results of further investigations into the accuracy of this and other methods. Sub-Committee No. 1 on Methods of Testing of Committee D-5 of the American Society for Testing Materials has this problem under consideration.

In 1928 Dr. Lincoln T. Work of Columbia University presented a paper before the American Society for Testing Materials on sampling of pulverized coal from air streams in which he presented data showing how wide can be the variation between samples taken from air streams by different methods.

The use of pulverized fuel has grown with astonishing rapidity. In 1924 it has been estimated a total of 16,000,000 tons was used in this country for all purposes. Now, it is probable that close to 30,000,000 tons is being applied in boiler firing alone. While for marine use the low cost of bunker fuel oil is holding back American development, the British, who have less oil, are becoming deeply interested, and it is reported that $500,000 will be used by the government next year on this development.

Rudolph Pawlikowski, at Görlitz, has made his internal-combustion engine work successfully on powdered German lignite, developing one kilowatt-hour on about 11,500 B.t.u. He expects to better this figure considerably with further improvements in the fuel and the machine. Since this engine uses only $^1/_{10}$ to $^1/_{20}$ the amount of water used for steam-turbine plants, the economic possibilities of further development in this field (power making from solid fuel) are most stimulating to the imagination.

In all of these applications of powdered fuel, higher efficiencies and smoother operation are obtained by having a maximum of uniformity in the fineness of the coal. Also to a certain extent results are better the finer the pulverization, so accurate methods of checking plant operation are needed in this respect.

Coal, when it is pulverized to pass 90 per cent through a 100-mesh screen and 75 to 80 per cent through a 200-mesh screen, is made up of very many particles that are finer even than the 200-mesh opening. Dr. L. T. Work, to whom reference was made previously, gives figures for a microanalysis of particle size in two different commercial samples of pulverized fuel, one that he calls a rather fine grade, and the other somewhat coarser than the average. C. M. Bouton and J. M. Pratt, also, in "Cooperative Coal Mining Investigations," Bulletin No. 12, Carnegie Institute of Technology, U. S. Bureau of Mines, give a similar size analysis of commercial pulverized coal.

SIZE ANALYSIS FOR TWO SAMPLES OF COMMERCIAL PULVERIZED COAL, BY DR. LINCOLN T. WORK, COLUMBIA UNIVERSITY

Microns	Coal No. 4, per cent	Coal No. 12, per cent
100.00–75.00	20.06	14.87
75.00–50.00	25.85	22.66
50.00–37.50	16.00	13.57
37.50–25.00	18.26	11.68
25.00–18.75	7.43	10.77
18.75–12.50	5.00	12.80
12.50– 9.38	3.03	5.38
9.38– 6.25	2.38	4.29
6.25– 3.12	1.23	1.94
3.12– 0.00	0.76	2.04

SIZE ANALYSIS OF PITTSBURGH COAL DUST 75 PER CENT THROUGH 200-MESH (20 GRAMS TAKEN) (BOUTON AND PRATT)

Size, microns	Amount, grams	Per cent
0–15	1.15 (approx.)	6
15–26	1.00	5
26–32	0.44	2
32–51	2.92	15
51–74	10.40	32
74–300		20
Losses	...	20

When these data are arranged in somewhat different groupings of the various particle sizes, they appear as follows:

Microns	Inches	Work I	Work II	Bouton and Pratt
Over 75	Over 0.003 (200-mesh)	20.1%	14.9%	25.0%
25–75	0.001–0.003	60.1%	47.9%	58.8%
12.5–25	0.0005–0.0010	12.4%	23.6%	8.7%
Under 12.5	Under 0.0005	7.4%	13.6%	7.5%
		100.0%	100.0%	100.0%

It will be seen from the preceding that in some commercial powdered coal as fired, from 15 to 35 per cent of the particles are smaller than $^1/_3$ of the opening in a 200-mesh screen.

This has an important bearing on the sampling. The velocity in a stream of air in a pipe varies over its cross-section, and the density of the coal and air mixture will correspondingly vary over the cross-section. Friction of the wall retards the flow to some extent. The larger particles tend to hug the walls. It may be seen from these considerations how difficult a matter it is to obtain a representative sample as to fineness from a moving air stream.

Samples, of course, can be taken from other parts of the system than from the air stream. Henry Kreisinger, in his well-known tests made in 1924 of the Oneida Street Station of the Milwaukee Electric Railway and Light Company, took samples from the feeder bin, dipping out about one pint from every 800-lb. weighing hopper added to the bin.

There are three main systems in use for firing powdered coal, which are as follows:

(1) The unit system, in which a pulverizing mill stands near the furnace and sends by means of a direct-connected blower the powdered fuel directly into the furnace without intervening storage.

---

[1] Consulting Chemist and Fuel Engineer.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., Oct. 7 to 10, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

(2) The storage system of the indirect type, where the coal is pulverized some distance away from the furnaces, carried by fans through pipes to storage bins, and then drawn off from the storage bins, delivered to feeders, intimately mixed with air, and blown through the burners.

(3) The storage system of the so-called direct type, where the coal is pulverized and stored in bins, from which it is drawn off and conveyed by means of a fan through pipes as a combustible mixture with air.

In the storage systems, the pulverized coal may be sampled from the storage bins, the conveyors, or the pipes delivering to the bins, or from the air stream in pipes between pulverizer and cyclone separators, or between storage bin and burner. It is best, in sampling from pipes, to use a vertical pipe. In the unit system it can be sampled only in the pipe leading from blower to burner.

The author is indebted to Max Hecht, Chief Chemist, Duquesne Light Company, Pittsburgh, Pa., for the following detailed description of his company's procedure for obtaining pulverized-coal samples for fineness tests from the Lopulco system—this is an indirect storage system:

"*Sampling Location.* An opening is available in a vertical duct, connecting the bottom of the cyclone separator with the storage bins or screw conveyors. A quart Mason jar is inserted in the opening, and moved across the cross-section of the duct, as the pulverized coal discharges from the separator.

"*Collection of Sample Aggregates.* Ten-gallon milk cans with tight-fitting covers are used for holding the aggregate collections. The sampling interval is five minutes for tests of two and three hours' duration and routine samples. The sampling interval is lengthened to 10, 15, or 20 min. when the test runs are correspondingly longer.

"*Mixing of Gross Sample.* When the can is approximately two-thirds filled, the lid is fastened tight, and mixing is accomplished as follows: The can is rolled back and forth five times and is then up-ended on its bottom. This is repeated and the can then up-ended on the cover. This is also repeated. This cycle is repeated 20 times. The sample can is emptied on a sampling cloth, and the coal is mixed by rolling the cloth.

"*Preparing Laboratory Gross Sample.* The amount of coal is reduced by passing it over a large riffle sampler. When the final sample volume is reduced to 10 lb., the coal is spread on canvas, and Mason jars are filled in duplicate by taking selected portions of the flattened pile.

"*Laboratory Preparation.* The sample is air-dried and then well mixed by rolling, and five 50-gram samples are selected from various portions of the flattened pile. The screens, after placing 50 grams each thereon, are nested with receivers. U. S. S. screens Nos. 16, 30, 50, 100, and 200 are used with a mechanical shaker. After an initial shaking of fifteen minutes, the coal remaining on the No. 200-mesh screen is weighed. The screens are again assembled in the shaker, and after a five-minute shaking, the weight is again checked. The coal remaining on each screen is then weighed. Results are reported as passing No. 16, 30, 50, 100, and 200 U. S. S. sieves."

At the Detroit Edison Company's Trenton Channel plant, which is also an indirect storage system, several different methods and locations for sampling have been tried. The author is indebted to W. A. Carter, technical engineer of power plants, and V. S. Barretta, boiler room engineer at Trenton Channel, for the following information:

It has been found most satisfactory to take samples by means of a "thief" sampler of a double-barreled construction arranged so that the open slot can be closed before taking from the coal stream. There has been some difficulty with the corroding of the cylinders with coal, but they are now making up a new sampler designed to overcome this trouble.

This is used in the coal-discharge pipe from the cyclone separators. As long as the cylinders remained clean, the results were consistent, varying only 3 per cent in fineness as against 15 to 20 per cent obtained when using other methods. A previous method was to insert a quart jar into the coal-discharge pipe from the cyclone at different points, but this proved unsatisfactory because the duct had to be left open to the atmosphere, which created a disturbing velocity condition different from that existing when the duct was closed.

Fairly satisfactory samples were obtained by taking portions periodically from the bunker, using a cup on the end of a pole, but this could not show the results obtained with each mill.

Sampling from the coal-and-air stream in the feeder pipe above the burners has also been tried at Trenton Channel, using a small pipe with the nozzle pointed in the direction of the coal stream. Results were unsatisfactory with this method due to large variations depending upon the position of the nozzle in the coal stream.

As was brought out in an earlier paragraph, the difficulties in sampling from an air stream in a pipe arise from the varying velocity, the varying density of coal, and the varying fineness of coal over the cross-section of the pipe. The varying velocity of the stream at different points causes not only a variation in the quantity of coal in suspension, but also a variation in the fineness of the particles at different points. When a sampling tube is inserted, the stream must be withdrawn through the sampler tube at the same velocity as that of the main stream in the duct at that point.

These factors have been carefully worked out by Prof. P. A. Willis of the University of Missouri and are explained by him in an article on "Accurate Sampling From Unit Pulverizers," in *Power*, December 18, 1928, pp. 1003–4. Professor Willis has worked out a method which he reports as satisfactory for taking samples from the coal-and-air stream in the duct leading from the pulverizer to the burners, 4 ft. above the fan. This duct was rectangular in cross-section, 18 in. × 23 in. In his preliminary study, he made a traverse of the area by dividing it into 12 equal squares, and taking a sample from the center of each for one minute, making these up into a composite. He used for this a specially prepared ell of $^1/_2$-in. pipe, and found that by having an opening in the end of this measuring $^{21}/_{32}$ in. he secured a velocity condition such as to withdraw in his composite sample the same amount of coal per unit area per unit time as passed through the entire duct. In other words, he withdrew a proportionate quantity, and this indicated an equal velocity condition in his sampler tube.

He then found that, by placing the opening of his sampler at a point $7^1/_2$ in. from one end on the center line of the duct, he obtained a sample of the same fineness test as that of the composite. He has not proved by this, however, that his composite sample truly represents the fineness of the whole coal stream. The degree of fineness and the density of the stream both vary from point to point in the cross-section, and it is incorrect to composite equal portions from every point.

This method of Professor Willis is being used daily in a large power plant on six large unit pulverizers, with results that are said to be entirely satisfactory. Each sample is taken during a period of five minutes. The precaution as to velocity in the sampling tube is especially important when the pulverizer parts have become worn and their performance is more or less irregular. It is necessary to have a different opening in the sampler pipe for each different operating rating of the pulverizer. If the rating is changed, the velocity in the duct changes, and therefore the velocity in the sampler tube must be changed to conform with it.

It appears to the author that both Professor Willis' method and the Tentative Standard Method of the American Society for Testing Materials have some questionable features. The A.S.T.M. method provides that the sampling tube (made of a thin-walled brass elbow) shall be moved through a stuffing-box "uniformly back and forth across the diameter of the pipe." It would seem from the considerations outlined that an error is introduced by withdrawing the sample uniformly, that is, for equal periods of time, at the various points in the cross-section.

On account of the varying density of the coal stream and the varying velocity in the pipe, it is hardly correct to withdraw the sample for equal periods at different points. Professor Willis draws from only one point, selected so as to conform to a composite, which may not be right. L. T. Work, in his paper previously referred to (American Society for Testing Materials, Part 2, 1928, Technical Papers, page 815) made a comparison of results obtained with the A.S.T.M. type of sampler and a certain type of "fixed sampler," and found more satisfactory results by use of the former. The fixed sampler consisted of a cross of pipe, placed in the duct, and having small holes bored at intervals facing the coal stream. Dr. Work's comparison, however, does not prove that the A.S.T.M. method gives accurate results, and it is undoubtedly true that further experimental study is needed to obtain a large amount of data on which to base an improved sampling method.

The following precautions are essential for securing good samples:

1 The sample should be taken from a vertical pipe, if taken from the air-coal stream
2 The sample should be taken at least 10 ft. away from an elbow, branch, or any other irregularity in the line
3 The sample should be taken as far away as possible from the disturbing action of fans or blowers
4 A stuffing box should be used through which can be moved freely a sampling pipe with right-angled bend at its inner end, facing the air stream, and without irregularities on its inner surface. This tube should be moved systematically to different positions in the cross-section of the pipe so as to correspond in its time schedule with the known variations in density of the coal-and-air mixture
5 Samples should be taken at a number of different places in the piping system, and be mixed in order to obtain an average.

Automatic or fixed samplers consisting of, say, a 1-in. pipe or a spider of crossed pipes inserted into the air stream, and bearing openings that face toward the stream, are not usually accurate samplers. The size of the openings and the placing of the openings must be chosen with care so as to take out the coal in relative proportion from different parts of the stream, as the density of the stream varies. The openings quickly become more or less clogged and thus interfere with accuracy.

Dr. Work mentions a sampler of this type used in a large power plant, which left a considerable part of the cross-section of the stream near the walls of the pipe unsampled. This part of the cross-section was the one that carried the larger proportion of coarse sizes.

On the other hand, when a sampler like the A.S.T.M. Tentative Standard is used, the results will depend in a considerable measure upon the personal equation. The operator has to move the tube in and out in accordance with a specified schedule of time intervals, leaving it for a definite period at each point in the cross-section. The accuracy will depend on how well he sticks to this prearranged schedule and how uniformly he maintains it at the different times and places of sampling.

The accuracy of sampling, as a general rule, can always be increased by taking a larger number of increments at a larger number of points in the system, combining these increments, mixing, and quartering down.

The American Society for Testing Materials, Committee D-5, which is studying these problems would welcome cooperation from committees of the American Society of Mechanical Engineers engaged in similar work. They would like especially to have reports of sampling methods now being used by plant operators and reports of any tests made upon them as showing their accuracy. The matter is one of large importance as affecting the determination of pulverizing-mill performance, pulverizing characteristics of different coals, and efficiency of performance of the furnace or burner.

Discussion

LINCOLN T. WORK.[2] In this paper Dr. Porter has discussed the problems of sampling in both the storage and the direct-fired systems. His own presentation, as well as other literature data, make it evident that the problem of greater moment lies in the sampling of powdered coal from air streams, as in the case of the direct-fired system. With reasonable precautions and with but slight adaptation of equipment, coal may be sampled accurately when prepared for firing from storage bins.

The writer's paper to which reference has been made dealt with the sampling of coal from air streams. On analysis of the principles, the following were shown to be the requirements for accurate sampling: (1) Minimize the effect of separation of coarse and fine coal. (2) Withdraw the stream at exactly the velocity which normally prevails at each point of sampling.

The reasons for minimizing the effect of segregation of sizes are apparent. With due care these effects can be avoided. The sampler should be placed at a point in the line where segregation is at a minimum. The first three precautions cited near the end of Dr. Porter's paper are sound means for doing this. However, it is seldom if ever possible to reach that objective in view of the present design of conveying equipment. Hence, small samples are taken at many points in the cross-section, and a composite of these is tested. The last two precautions cited in Dr. Porter's paper bear on this. Procedures differ, but none can be called final until it is possible to control the velocity of the sampling stream at each point. Good field evidence can be secured by sampling one cross-section of the pipe and then another after a few bends. If these samples are of similar fineness, the procedure may be considered acceptable.

The control of velocity into the sampling tube is much more difficult, and yet it is vital to the accuracy of the sample. The coarse particles moving in the line of the sampler are projected into the opening while the fines are diverted with the air stream into the sampler if the velocity in the tube is the greater, and away from the sampler if the velocity in the pipe is the greater. Static and velocity pressures, and resistance to flow in both burner and sampling circuits control this distribution. These problems have not been solved with even the best sampling devices in common use at the present time, and the limitations imposed thereby must be recognized.

Dr. Porter has discussed the proposal of Professor Willis for the simplification of sampling methods with pulverized coal in air streams. It must be recognized that a sample taken at one point may give the true percentage through one sieve, say 200 mesh, but that the sample so taken may give erroneous values in the coarsest sizes, and may be entirely unfit for testing in the sub-sieve sizes.

[2] Department of Chemical Engineering, Columbia University, New York, N. Y.

H. P. Reid.[3] In the first part of this paper the author refers to size analysis of pulverized-coal samples as determined by several different investigators. It would be interesting to know the methods used for controlling the fineness when grinding these samples. One would not expect the same general relation between the undersizes in coals pulverized by roll mills having screen fineness control as might obtain in coals pulverized by similar mills using air-separator methods for fineness control; nor again as might obtain in coals pulverized by ball or tube mills which discharged over a partition, and in which the fineness was controlled entirely by the rate of feed. It would seem that the sample taken would be much more representative when there was but small variation in sizes or in other words when there were comparatively few of the undersizes.

In obtaining a sample from an air-coal stream the paper states that this sample should be taken (1) from a vertical pipe, and (2) that it should be taken at least 10 ft. away from an elbow, branch or any other irregularity in the line. Often the set up is such that one can find but very little if any vertical pipe carrying this air-coal stream. Is it to be inferred that representative samples cannot be taken from horizontal pipe sections? Or is it possible to maintain sufficient velocities to carry the pulverized coal in such a way that representative samples may be taken from horizontal pipes. Again might it not be possible to insert a venturi throat in the pipe, using this both to mix the coal of differing sizes through the stream and also to increase the stream velocity so that the mix after the venturi restriction would be quite regular from which to sample. Does not the author mean ten diameters of pipe distant rather than 10 ft. distant from elbows, etc.?

When sampling pulverized materials from hoppers or from flowing streams of the pulverized material, is it not necessary to guard against segregation of particle sizes due to the rolling action of the larger particles? We have all seen how in piling coarse coal, for instance, the coarser particles tend to ride over the smaller ones, and slide down to the sides of the pile. If this is true with the visible particle sizes, may it not also be true with the smaller sizes.

In sampling from the discharge air-coal stream from a unit pulverizer will there not be a difference in the particle sizes at any given point in the stream due to fluctuations in air volumes passing the mill? And will there not be decided fluctuations in these volumes from time to time as effected by temperature, moisture content, and amount of coal load in the mill?

A. R. Mumford.[4] The sampling of pulverized fuel in power plants is not required to be of the utmost accuracy unless other than regular operation is the purpose. Coal is charged against a plant generally by checked railroad weights, and in order to determine how much coal is charged, it is necessary to sample the fuel as it enters the plant, and in every instance within the writer's acquaintance such a sample would cover raw coal only.

The sampling of pulverized fuel is necessary for operating information, and to follow in a general way the performance of mills and boilers. During technical studies of operation it may be necessary to obtain samples of pulverized fuel which accurately represent the total fuel used, but normally if the samples are relative so that variations from day to day can be determined, the results are sufficient for the purpose. The writer finds that variations of several points in the amount of pulverized coal passing through a 200-mesh screen does not appreciably effect the plant operation or efficiency, and he believes that this finding has been confirmed by others who have investigated the effect of normal variations in the sizing of pulverized coal. The writer gets the impression from Mr. Porter's paper that extreme accuracy is the aim of his committee's work, but as far as power-plant work is concerned extreme accuracy does not seem at present to be warranted by improvements in efficiency.

Sampling systems have been designed which would undoubtedly give a very representative sample of pulverized fuel, but the building volume necessary to house the sample machinery and the cost of the equipment does not seem to be justified over the somewhat less accurate but cheap method of relative samples.

Author's Closure

The discussion by Dr. Work brings out clearly the principles governing sampling from moving air streams. His statement, however, that "the sampler should be placed at a point in the line where segregation is at a minimum" leaves a little to be desired from the practical standpoint as to just where this point is best located. There is some segregation of sizes always in a moving stream of air and coal, and hence the precaution that a number of samples should be taken at different points in the conveying system, and compounded.

Mr. Reid's discussion brings out several interesting points. He may be right as to placing the sampler beyond bends, etc., a distance depending on the pipe diameter, but the author is inclined to hold still that a minimum of 10 ft. is advisable. He asks for more data as to how the coals, whose fineness is quoted as examples of common practice, were pulverized in the different cases. The author cannot give this detail, except that the samples were obtained from different plants. He asks whether correct samples cannot be taken from horizontal pipes. This would be difficult, but probably is not impossible if some such method of agitation as he suggests is made use of. It is to be hoped that he will experiment along this line.

It is necessary, as Mr. Reid suggests, when sampling pulverized coal out of a bin or from a flowing stream of the coal, to guard against segregation of sizes due to rolling action of the larger particles. This action, however, is not as great in powdered coal as in the coarser grades, and its effect can very largely be eliminated by taking a number of small portions from different parts of the bin or moving mass. His point about the effect of fluctuations in air volumes in a unit pulverizer is well taken, and endeavor should be made to take samples for comparative purposes under like conditions. Mention is made in the paper of the need for taking into account the capacity rating at which the pulverizer is running.

In answer to Mr. Mumford's question as to the need for any such accuracy as the Testing Materials Society is working for, it is sufficient to say that experiments have shown a variation between two samples taken by different but common methods amounting to 100 per cent. In other words, the percentage held on a 100-mesh screen in one case was twice as great as it was in the other case sampled by a different method. It may be all right for some plants to use rough methods for their own purposes, that is, to get relative conditions from day to day, but unless, in these methods, the place of sampling, the operating rating, the velocity of coal stream and of sampling stream, the choice of sampling point in the cross-section, and certain other conditions are kept uniform or allowed for in reasonable measure, there will be so large a variation in the results that it were better not to attempt any sampling at all.

Use of Fuel in the Manufacture of Portland Cement

By H. P. REID,[1] CHICAGO, ILL.

Heat is required in the manufacture of Portland cement for evaporating the water from the coal and from the raw materials used in making the cement; for preheating these materials to temperatures necessary for calcination; for breaking up the carbonates and oxidizing the undesirable elements, principally organic matter, from the raw materials; for further raising the temperature of the material to the point necessary to effect the desired chemical reactions; and for producing the power required for mechanical operation. All of these requirements except that of removing the moisture and the production of the power are met inside the cement kiln, and are commonly included in the term "burning." Furthermore, with the wet process the moisture is evaporated in the kiln also.

THE USES of heat in the manufacture of Portland cement can be classified as for (1) drying, (2) burning, and (3) power. For the generation of this heat fuel is required. In some cases separate fires are maintained for each of these three requirements, while under other conditions power is generated from the waste heat in the gases leaving the kiln. Generally speaking, of the fuel used for drying and burning 10 per cent to 25 per cent is required for the former and 75 per cent to 90 per cent for the latter. In all dry-process plants and in many of those of the wet process, sufficient heat may be reclaimed from the waste kiln gases to generate the necessary power required to operate the mechanical equipment. As this power is generated from heat produced by fuel burned in the kiln, it is proper to credit the "burning" with the fuel equivalent of the power generated. Such an adjustment would charge the power with from 25 per cent to 35 per cent of the total plant fuel, "burning" with 45 per cent to 60 per cent, and drying as given. These percentages are to be considered as representative of the cement industry as a whole, and not necessarily actual for any definite plant.

Natural gas, producer gas, blast-furnace gas, oil, and pulverized bituminous coal are usable as fuel in the Portland-cement industry. According to a bulletin of the U. S. Bureau of Mines recently published, of the cement produced in 1927 in this country, over 80 per cent was from plants using coal as fuel. The selection of the kind of fuel is made on the basis of cost of heat units delivered at the burner. It is therefore logical to expect to find oil and natural gas used in such places as are distant from suitable coal supply but near the oil and gas wells. Blast-furnace gas is used where the cement mill is operated in connection with blast furnaces, and a surplus of gas is available. Referring again to the same bulletin of the Bureau of Mines, the average fuel consumption in 1927, per barrel of cement produced with the various fuels, was with coal 135.8 lb., with oil 0.2743 bbl., and with natural gas 2450.5 cu. ft.

Practically any bituminous coal when prepared properly can be used as fuel in the cement kiln. Bin systems rather than unit mills are commonly used, and therefore the coal is usually dried before pulverizing. There are, however, a number of unit mills successfully operating at installations made in the past few years.

The cement kiln considered as a furnace is radically different from the pulverized-coal fired boiler furnace, and because of this difference it has been found necessary to pulverize the coal finer than is the usual power-plant practice. Uniformity of fineness is essential, and the kiln must have reasonable guarantees against shut down, even for short periods, to insure uniform quality of the product, and to preserve the life of the refractory lining. To insure even fires the coal as fired should be of nearly uniform moisture content, which condition is somewhat difficult to maintain in winter when snow and ice often exist in the coal as received. The given requirements account largely for the installations of the bin system in the majority of the cement plants. On the other hand, the development of the modern unit pulverizer with its air separator to control the fineness, with the use of preheated air in the mill to absorb moisture from the coal, and the improvements in design and selection of materials of construction to reduce operating delays will undoubtedly result in greater use of this type of mill by this industry.

When using the bin system the moisture in the coal must be reduced to such an amount as will permit economical pulverizing-mill operation, and such that the prepared coal may be conveyed to the bins and be drawn from them without blocking. The permissible amount of moisture depends largely on the character of the coal and on the type of mills, transport system, and burner feeders. Where air separation is used for fineness control considerable moisture may be removed by the mill air. Especially is this true when the coal fed to the mills has been preheated by partial drying or when the quantity of air vented from the system is large. Additional mill drying may be accomplished by introducing preheated air to replace that vented from the system. A small amount of moisture is removed from the coal in the screen type of mill, but usually the air circulation through such mills is insufficient to carry away much moisture. There is, however, the problem of recovery of the fine coal from mill-vent air, and also that of maintaining the temperature of this vented air high enough above its dew point to keep the ducts clean, and to remove fire hazards from such ducts.

It is customary in the cement industry to dry Pittsburgh and West Virginia coals down to 1 per cent or 2 per cent moisture as they leave the mills, and Illinois, Indiana, and Kentucky coals to from 2 per cent to 4 per cent. These percentages are often more a matter of practice than absolute necessity, as it is much more economical to take care of the moisture of the coal in the kiln than to remove it in dryers, provided that this moisture is low enough to permit uniform feeding, and such as will not make it difficult to hold the kiln fires.

Precautions and good housekeeping are as essential in the coal-preparation buildings of these plants to insure safety as they are in similar buildings of other industries. There is, however, a coal fire hazard peculiar to the type of machines used in cement plants. The discharge end of the cement kiln, where the fuel is admitted and ignited, is open except for a shielding hood. As this hood is stationary and as the kiln rotates, there is of necessity an opening between the two. In some cases this opening is closed by a rotating seal, but more often it is not. Furthermore, openings are necessary for the admission of secondary combustion air, and

Presented at the Third National Fuels Meeting, Philadelphia, Pa., Oct. 7 to 10, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

for the burnerman to watch his kiln operation. In starting up a cold kiln the coal is liable to burn very irregularly until the kiln walls become sufficiently heated to hold the fire; also irregularities in the coal feeders may result in more or less violent explosions within the kiln. While the force of such explosions is largely dissipated within the kiln, yet ignited fuel and hot gases are forced out of these openings, and may be dangerous for some distance from the kiln end. Pulsations in the flame are quite common in rotating kilns. These may be caused by irregular discharge of coal from the feeder, by too high a percentage of primary air, or by too strong a draft.

High ash content in the coal is probably less troublesome in the operation of a cement kiln than in most other industries. Generally speaking high ash indicates relatively low B.t.u. content, and ash purchased as coal is expensive cement raw material. As high percentages of silica and alumina are found in Portland cement, the ash of the coal may be absorbed by the clinker in the kiln. The chemist in his control must, however, consider this ash as its weight amounts to approximately a quarter of a per cent of the clinker weight for each per cent of ash in the coal.

Drying Processes Used

The dry and the wet processes are both widely used in this country for the manufacture of Portland cement. Both processes have, in general, similar operating problems. In the dry process the moisture is driven from the raw materials before they are ground, while with the wet process more water is added, and the materials are ground in a slurry form. This slurry is pumped or conveyed to the kiln feeder. In some cases part of the moisture is filtered out before entering the kiln, while in others all is fed to the kiln. Whatever moisture there may be in the kiln feed must be evaporated in the back end of the kiln by the hot gases.

With the dry process it is the usual practice to pass each of the raw materials through its separate rotary dryer. Such dryers are cylindrical tubes made from steel plates, mounted on two concentric steel tires, and rotated about their longitudinal axis. To effect material travel through these tubes, they are usually pitched $^1/_4$ in. to $^3/_4$ in. per foot of horizontal length. Some dryers have no pitch but depend on the construction of internal lifters or flights to effect the forward travel of the material.

Heat as applied to the drying material is obtained by burning fuel either in furnaces in front of the dryers or in air suspension within the dryers. It is difficult to obtain efficient combustion, and at the same time large output with these machines. If a furnace is used in order to effect complete combustion of the fuel before the gases enter the dryer, the heat transfer from the gases to the material and the moisture therein, must be largely by convection rather than radiation. Such transfer requires large drying surfaces, which results in very large units in order to obtain capacity. If, on the other hand, the fuel is burned in suspension, the cold dryer walls and the heavy concentration in the dryer atmosphere of fine material particles so chill the flame as to quench many burning fuel particles. Consequently, combustion is not completed and losses by unburned fuel run high. In order to hold a fire at all with such a system, ignition is effected in a small refractory-lined chamber whose walls are held at an incandescent heat. However, with such a flame properly directed over the material large amounts of heat are transferred to the material by radiation, and the output of such a machine is generally greater than it would be were a furnace used.

Some dryer manufacturers build a small furnace before the dryer for use with powdered coal or oil. Such a furnace is little more than a large ignition chamber for the fuel. By the time the blast of air and fuel has passed through the furnace, the fuel is well ignited and partially burned, combustion continuing in the front end of the dryer. With the use of such a furnace better combustion is obtained, and considerable radiant heat transfer occurs also. Greater fuel economy should be expected than is possible when burning entirely inside the dryer, and the capacity should be greater than when combustion is complete in the furnace.

Some raw materials have low moisture content, and are of such a nature that this moisture is readily driven off. With such the drying problem and the dryer efficiency is of relatively small importance. Other raw materials contain high moisture or are of such nature that the moisture is difficult to remove. With the latter the efficiency with which the fuel is burned may reflect heavily on the production costs.

At many of the older plants, most of which are dry process, the cost of fuel was so low when they were built that combustion efficiency was then of small importance. In the construction of such plants the dryers were usually so bound in by other mill machinery that there is not sufficient space now to rebuild with machines that would be more economical in the use of fuel.

The application of heat at high temperatures in amounts sufficient only to evaporate theoretically the moisture will not effect complete drying in most raw-material dryers. Such application of heat would result in the gases leaving the dryer not only saturated with moisture but also carrying considerable superheated steam over and above the moisture absorbed by the gases. Consequently, excess air must be added, usually in very large percentages, to the combustion gases to provide sufficient moisture-carrying vehicle. From the thermal viewpoint, such a dryer is of necessity quite inefficient. As has been pointed out, good combustion is difficult, heat losses in the stack gases are great due to the large volumes of drying vehicle necessary, and as the material must be heated up in order to evaporate the moisture, considerable heat is carried away by the dried material. Much work has been done in efforts to improve the thermal efficiency of these machines, yet it can be appreciated that for this type of work such a machine can not be made highly efficient from the thermal viewpoint. If heat otherwise lost around the kiln could be reclaimed and used for this drying considerable economies might be effected.

The Rotary Kiln and Its Operation

The rotary cement kiln used almost exclusively in the U. S. A. is a cylindrical tube fabricated from steel plates, and resembles the rotary dryer in general appearances excepting that usually it is much larger. Early kilns were made about 6 ft. in diameter by 60 ft. long, some even smaller, while modern kilns are as large as 12 ft. in diameter by 350 ft. long. To protect the steel shell from the heat, refractory lining is used. This lining is usually 6 to 9 in. thick in the front or hottest end, and 4 to 6 in. thick further back where the temperatures are less.

The prepared material, wet or dry, is fed into the back or high end of the kiln, and is moved forward by the rotation and pitch of the kiln. For this pitch $^1/_4$ in. to $^3/_4$ in. per foot of horizontal length is used. The speed at which the kiln is rotated varies widely, some kilns running as fast as 2 r.p.m. while others make but 1 revolution in $2^1/_2$ to 3 minutes. It can therefore be appreciated that the time required for material to pass through the kiln is a factor of length, pitch, diameter, and rotary speed.

Fuel in blast suspension is admitted at the front end of the kiln, and the combustion gases travel against the forward moving feed. Both the surface of the feed and the exposed lining of the kiln absorb heat from the flame and the gases. While a small amount of the heat absorbed by the refractory lining travels through the bricks and is radiated from the outer shell, most of it is transferred to the feed as the kiln rotates.

With the wet process the moisture in the slurry or in the filtered feed is evaporated in the back end of the kiln. In some kilns this back end is an open tube similar to the rest of the kiln except that metal rather than refractory lining is used. With other

kilns various devices are employed to facilitate evaporation. These devices in general use some system designed to increase the area of surface exposed to the gases. One such device employs a large number of chains so fastened to the kiln shell that they drop in loops from that portion of the shell above the kiln center, and lay on the shell below that center. The hanging loops present large metallic areas to the gases, and thus absorb heat from the latter. As the kiln rotates and the wet feed rolls over these chains, the moisture and material absorb the stored heat, and leave the chain surfaces wet as they again come in contact with the gases.

From the time the moisture is evaporated in the wet-process kiln the two processes are similar. The dry feed is gradually heated to higher and higher temperatures as contact is made with hotter and hotter gases as it travels forward until the carbonates of calcium and magnesium begin to break down, and the sulphur and organic matters ignite and burn. This calcination of lime and magnesium begins at temperatures of about 1500 deg. fahr. and is completed by the time the material has reached 1750 or 1800 deg. fahr. In completing this process an average of about 950 B.t.u. per lb. of clinker produced is absorbed by the material. There are wide variations from this average depending on the composition of the raw materials used. The material then enters a second stage of heating until its temperature is raised to approximately 2600 deg. fahr. As the higher temperatures are approached the calcium, silica, and alumina regroup themselves into complicated chemical structures. The exact temperature necessary for the foregoing reactions will depend on the fineness of the particles of material, their proportions in the mix, and also quite possibly upon the presence in small amounts of other metals. The time required for the transaction has not been determined to the satisfaction of the average operator. It is the general belief that safety for quality lies in a relatively long zone in the kiln where these higher temperatures are maintained. Forward from this hot zone there are several feet where the clinker, formed by incipient fusion of the materials under the high heat, gives off some of its heat to the incoming combustion air and fuel.

Clinker leaving the kiln will be from 1800 to 2200 deg. fahr. according to the length of this cooling zone, which varies widely in the same size kilns at different plants, and to some extent on the same kiln according to the temperature of the air entering and to the amount of draft used.

In many of the older plants the clinker as it leaves the kiln is sprayed with water to cool it sufficiently to permit the use of metallic conveyors or elevators for removing it to cooling or storage piles. Further cooling may be effected by water spray, by exposure to air, or by a combination of the two.

In plants of more recent design, mechanical coolers are used. The most popular type of these clinker coolers appears to be a rotating cylindrical shell through which atmospheric air is blown against the clinker travel. Such quantities of the air heated in cooling the clinker as are required for combustion are delivered into the kiln. Some of the air may be passed through the coal mills to assist in removing the moisture when unit mills are used. There yet remains a large volume of air containing considerable heat which must be wasted. Such air would be of value in drying coal and raw materials were it possible to transport it to the dryers without too great a heat loss.

In describing the combustion within the kiln, pulverized coal will be considered as the fuel; such description can be applied readily to other fuels by those interested in them.

The pulverized coal is blown into the kiln with blast or primary combustion air at such a velocity as to insure its being carried by the gas streams until combustion has been completed. This velocity may vary according to the open inside diameter of the kiln, the fineness of the coal and the draft used. While many attempts have been made to use improved burners which would mix the coal and air intimately, and produce gas turbulence for scrubbing the films from the burning particles, most such efforts have not proved a success, and the open pipe is almost exclusively used as a burner with the rotary kiln.

The fuel is ignited, combustion takes place, and the gases deliver their heat to the material all within a straight, nearly horizontal rotating tube, and the burning fuel can not be allowed to impinge on the refractory. Therefore, the time required for complete combustion of a given size particle must be much longer than would be necessary were turbulence of the gas stream possible. It is practically impossible to maintain refractories with their surfaces directly exposed to the high temperatures of the flame, and at the same time to the erosive action of the clinkering materials rolling over these surfaces. No attempt is made to burn on the exposed lining, but it is coated in the hotter zones by material fused to it. As the material mass traveling through the kiln is heated to a state of incipient fusion it will adhere readily to surfaces which are slightly cooler than it. To enable the refractory to present and maintain this cooler surface to the semi-fused material, heat transfer must take place outward through the refractory to the shell and atmosphere. The rate of this transfer is governed largely by the thickness and nature of the refractory. If too thick the heat flow is too slow, and the face of the refractory will burn away until the heat equilibrium is established, and the protecting coating fuses to it. If at any subsequent time the fire becomes too intense or localized, this coating will be melted away. The ease with which such a coating may be formed and held is largely a function of the raw materials used for the cement, and also of the skill of the burnerman.

Sufficient heat must be generated to raise the temperature of the material to, and maintain it at approximately 2600 deg. fahr. As the chemical reactions take place a small amount of heat of reaction is liberated at the higher temperatures. The temperatures in this hot zone must be held within the limit of the life of the fused coating or the refractory will be ruined in a few hours. Normally such a refractory lining should last from nine months to two years.

With turbulent or short-flame burners there is not sufficient radiant-heat absorbing material around their short combustion zone to cool the flame to safe temperatures. With the open-pipe burners, because of the lack of turbulence, the combustion is sufficiently slow to permit enough heat transfer to keep the temperature of the flame within safe limits. Also this slow-burning flame may be made so long that a safe length of clinkering zone can be maintained readily for the proper chemical reactions. The length and position of the flame with a given installation may be altered over a wide range by the fineness of coal pulverization, by percentage and temperatures of primary air, by temperature of secondary air, and by the draft on the kiln. The operator usually has control of the rate of coal feed, the volume of primary air, and the draft.

Very wide ranges of the percentages of primary-combustion air are used in the industry. Some installations use as little as 20 per cent while others use more than 50 per cent. Generally speaking, high percentages of primary-combustion air tend toward short flame and short refractory life. The permissible percentages of this primary air depend largely upon the characteristics of the coal used.

While preheating of the primary and secondary air can be used with economy in many installations, it should be introduced with care on existing equipment as it tends likewise to shorten the flame and thus create excessive zone temperatures. Because the fuel must be burned in suspension in a long horizontal gas stream, the necessity of fine pulverization of the coal is evident. The exact value of a coal particle which drops out of the gas stream

into the material traveling through the kiln is unknown. However, as the heat requirements of the kiln are the maintainence of certain temperatures, it may be that the B.t.u. of such coal particles are not as effective as when they are dissipated at higher temperatures found in the flame. Certainly delayed combustion of coal particles which remain in the gas stream is undesirable, as under such conditions their heat is liberated in that portion of the kiln where an excess amount of heat already exists.

Balling of the pulverized-coal particles is probably much more prevalent with the bin system than is commonly appreciated. After having expended power to grind the coal to a given fineness, more attention should be given to the conveying and mixing equipment to see that the full advantages of the fine grinding are obtained, and not largely counteracted by feeding the coal to the burner in lumps or balls. Uniformly mixing this fine coal with the primary air should also be accomplished. It may be possible that by using proper precautions against balling, by maintaining proper air and coal mix, and then with the use of preheated air obtained from the clinker, economies might be obtained in coal preparation, as these features should overcome to a certain extent the drawbacks of coarser coal and higher moisture content.

Heat-insulating materials can be used between the refractory lining and the steel shell in that portion of the kiln from the feed end forward to within a few feet of the clinkering zone. However, there are no refractories economically available that would stand the clinkering-zone temperatures were heat-insulating materials placed behind them. As the refractories are held in place within the steel shell solely by the arch action of the complete circle, insulation must be placed with extreme care behind the brick of this circle. To reduce relative motion between the brick and insulation, and to minimize the crushing effect of the load on the insulation, key brick are placed against the shell at frequent intervals.

While different brands of Portland cement may vary in calcium and magnesium content depending upon the raw materials used, a cement having a CaO equivalent of 65 per cent and a MgO equivalent of $2^1/_4$ per cent may be said to be representative. Assuming that all this lime and magnesium existed in the raw materials as carbonates there would be about 195 lb. of CO_2 liberated in calcining sufficient of these materials for one barrel of cement. For burning such a cement approximately 100 lb. of coal would be used in the kiln with the dry process. This coal should produce about 275 lb. of CO_2, making a total of 470 lb. of CO_2 per barrel of clinker produced or 4.7 lb. of CO_2 per pound of coal burned. Because of the slight turbulence in the gas stream as it flows, it is difficult to maintain 0 per cent CO with less than 2 per cent of O_2 in the gases leaving the kiln. To insure proper oxidation of the undesirables in the kiln feed, this amount of O_2 which corresponds roughly to 11 per cent excess air is probably necessary. However, to maintain a definite percentage of CO_2 as indicated from the foregoing is impossible with many raw materials because the lime is not always in the form of carbonates, but may exist as other calcium compounds, thus varying the amount of CO_2 evolved. Also the quantity of coal burned per barrel of clinker is not constant, and very slight changes in the draft radically change the amount of induced air at the front end. Again, the thickness of the coating on the refractory and consequently the free-gas area is variable, thus altering the resistance to gas flow through the kiln. It is therefore evident that a constant draft on the kiln will not result in uniform operation.

Control meters on the gas content, whether CO_2 or CO, have not proved a definite aid in control of the kiln. Pyrometers and draft gages when properly located and interpreted may give some valuable information to the operator. However, because of the adhesive properties of the fine particles in the gases, all such instruments require considerable attention to function properly.

Waste Heat Power Generation

The temperature of the gases leaving a dry-process kiln will be from 1000 to 1700 deg. fahr., depending largely on the length of the kiln; 1400 deg. fahr. seems to be accepted as a fair average temperature. With the wet kiln this temperature is much lower, being anywhere from 550 to 1100 deg. fahr. The longer the kiln of either type the greater the heat transfer to the feed, and consequently the lower the exit-gas temperatures. With the modern type of kilns one would expect exit temperatures of around 1000 deg. fahr. from a dry kiln, and 500 deg. fahr. from a wet kiln.

With the average dry-process kiln there is recoverable heat in these exit gases sufficient to generate power to operate the entire plant, and in some instances to generate a surplus for other purposes. With the modern wet-process kiln the amount of heat possible to recover from the waste gases may be so small that waste-heat boilers would not give sufficient return on the necessary investment to justify their installation.

Recent Developments in Stoker Design

By H. D. SAVAGE,[1] NEW YORK, N. Y.

In this paper recent developments in stokers are discussed. The presentation covers all stokers manufactured by the firms who are members of the Stoker Manufacturers' Association. Stokers for the larger size of steam-power boilers have undergone a different development from the smaller stokers. There has been a distinct advance in size, in practical combustion rates, and in the convenient arrangement of stokers in general. The problems of preheated air and the development of small stokers for domestic and industrial uses are also presented.

EACH manufacturer of stokers has made improvements according to his conception of the art of stoker firing and the requirements of the market. Research and test work has been undertaken in diligent effort to improve not only the design of stokers themselves, but also the conditions under which they will render the most satisfactory service. In addition to this work on stokers themselves, the problems of furnace design have been the subject of an immense amount of study.

General Development

The development of stokers has taken place along two radically different lines, in each case synchronizing with a positive commercial demand. Stokers adaptable to large steam-generating units have developed principally along the line of size; those of small boilers principally along the line of convenience.

All are aware of the well-defined trend toward steam-generating units of larger and larger size. It has been found economical to build steam-turbine generators in sizes of 150,000 kw. and 200,000 kw. The same factors of economy are responsible for a demand for steam-generating units, ranging in their larger sizes from 500,000 to 1,000,000 lb. of steam per hr.

Pulverized-fuel firing has proved somewhat more popular for the bulk of these very large modern steam-generating units. It has been comparatively easy to expand the combustion principles, and multiply the mechanical apparatus of pulverized-fuel systems. Mechanical stokers have also been increasing rapidly in size, and it is quite certain that during their recent growth no obstacle so far encountered has indicated any specific limitation, either mechanical or economical.

This growth in the size of stokers is perhaps more remarkable when the mechanical difficulties that confront the designer are fully comprehended. In either the multiple-retort or the chain-grate stoker, a material increase in size may render its former structural formation entirely impractical. The larger stokers may require almost 100 per cent new design in order to secure the necessary strength of structure, resistance to heat, and the feeding and distributing of the fuel and air.

An interesting feature of this development work in large stokers is the fact that both stoker manufacturer and customer join in the responsibilities that are involved. Models are out of the question, and a newly designed larger stoker must make good as a practical operating machine, and must meet its predicted performance tests in the customer's plant, without the benefit of preliminary trial installation.

[1] President, Combustion Engineering Corporation. Mem. A.S.M.E.

Presented at the Third National Fuels Meeting at Philadelphia, Pa., October 7 to 10, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The fact that such stokers practically always equal or better the expectations of their sponsors is a splendid tribute to the accurate knowledge of the art of combustion shared in general by both stoker and power-plant engineers. There is, furthermore, a certain elasticity in the underlying principles of stoker firing which accounts for the success attained by various stoker manufacturers in working out their particular development

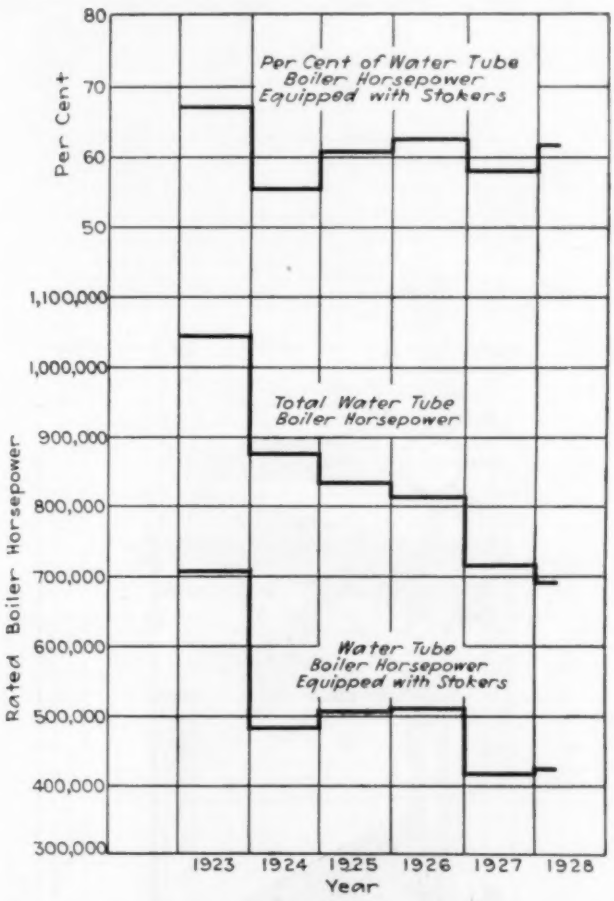

Fig. 1 Chart Showing Department of Commerce Figures on Total Horsepower of Water-Tube Boilers, Water-Tube Boilers Stokered Each Year and Percentage of Total Horsepower of Boilers Represented by the Horsepower Stokered

programs along lines which are not always parallel, but along which each manufacturer attains a definite measure of success.

Development of Size

From a production of, say, 100,000 lb. of steam per hr., stoker installations have gradually increased in size till today the production of 400,000 lb. per hr. is both feasible and economical. For one installation 500,000 lb. of steam per hr. is expected. The projected areas of stokers required for such steam production are of the order of 700 sq. ft., and a number have been or are being built of approximately this size.

In the multiple-retort type, single-end stokers ranging up to 713 sq. ft. of projected area and double-end stokers up to 716 sq. ft. have been or are being built. A steam production of the

order of 400,000 to 500,000 lb. is contemplated from these installations.

The chain-grate type of stoker has developed from the 420 sq. ft. of grate surface, furnished at Crawford Avenue some years ago by several manufacturers, to 528 sq. ft. in one installation and 684 sq. ft. in another, both in the United States, with 700 sq. ft. the maximum in England. The contemplated steam production with these stokers is appreciably lower than with the multiple-retort underfeeds, due chiefly to the application of the chain-grate stokers to the burning of low-grade fuels.

Considerably large stokers can be built, and modern high-combustion rates can be consistently maintained upon them.

The principles of construction now used in the larger stokers are directly applicable to the structure required for much larger sizes. High average combustion rates are a product of operating skill and refinement in stoker and furnace details; the problem here with respect to still larger stokers is but the carrying on of the best practice now in effect.

COMBUSTION RATES

It is difficult to make any compilation that will evidence an increase in combustion rates. It may be perfectly true and somewhat obvious that combustion rates have been and are gradually increasing. Various comparatively old records of 70 to 75 lb. of coal per sq. ft. of stoker area per hr. would seem to rob any recent achievements in this line of all claim to recent development. The more prosaic figures of maximum operation under ordinary plant operating conditions would be much more important, but they are somewhat too elusive for accurate compiling.

There is, however, improvement to report along this line which will have recognized, if not quantitative, value. The problem of increasing combustion rates for regular operation involves pretty much all of the related functions of a stoker. Particularly must the feeding and distributing of the fuel be worked out so as to handle correctly the larger quantities of fuel per square foot, and to secure its economical combustion. Air distribution, speed of stoker mechanism, and fire thickness are factors of this problem which do not offer much difficulty. Ash elimination is a serious problem only in the case of coals having a low fusion ash, or extraordinary clinkering tendency. Furnace design is of extreme importance, and its problem with respect to high-combustion rates has been solved successfully by the work of stoker engineers in combination with the manufacturers of water-cooled walls

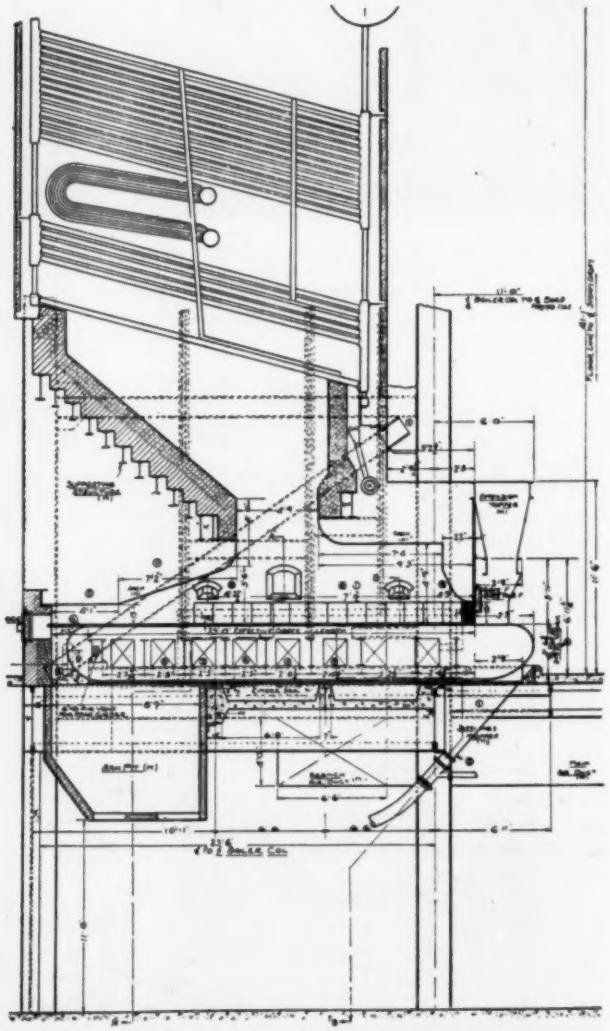

FIG. 12 HARRINGTON STOKER FOR ANTHRACITE COAL AT HUNLOCK CREEK STATION OF LUZERNE COUNTY GAS & ELECTRIC COMPANY—THIS STOKER IS 21 FT. WIDE BY 23 FT. LONG, HAVING 483 SQ. FT. OF STOKER AREA

and air-cooled refractory walls. This subject, however, is not regarded as within the scope of this paper.

Various stoker manufacturers have attacked the problem of development individually, as they visioned the requirements. This has led to a different stressing of the fundamental details in the various cases. In each case, the manufacturer has achieved some material measure of success, and in the large sense of a craft report, the total of these improvements and developments is along the line of higher consistent combustion rates forstokers.

In multiple-retort underfeed stokers, one manufacturer has developed particularly the length of retort, together with special control of secondary rams; the object being to secure high combustion rates for his large-size stokers. Another manufacturer has developed a deep ram and deep retort, and also special functioning of secondary rams; the object being practically the same, although the method is different. Still a third manufacturer has centered his development particularly on the overfeed section of this type of stoker, enlarging and articulating it according to his view of the requirements of proper combustion, and this also is a still different method of attacking the common problem. In these three developments the object is to provide for practical handling of the fuel as a fire, over greater distances from the point of feeding than formerly. The problem has been difficult and very serious, but by no means insurmountable, and in each case a certain measure of success has resulted.

For the chain-grate type of stoker, higher combustion rates have been largely the result of improved furnace design. The various modifications of the rear arch have lifted the old 45-lb. per sq. ft. rate up to the present 60-lb. rate. Of course, there are instances of higher rates. Special high rates are not to be emphasized, but the gradually increased rate of coal burning in every-day practice should be.

Along with improved furnace design, there has been an increase in speed-of-grate travel. For bituminous coals the grate speed has increased from an old limit of about 30 ft. per hr. to a present-day usage of about 60 ft. per hr. For anthracite coal the older limit of about 45 ft. has been superseded by present maximum speeds of about 100 ft. per hr.

The development in higher combustion rates has always been gradual. For all the various fuels, and with all the various stokers, there has usually been a pioneer installation that demonstrated some principal point of improvement. This point has then been tried out and varied in other subsequent installations, with the result that its advantages have been gradually but thoroughly worked into the whole practice of the art. In time the discoveries and improvements, whether originating in operating skill or vision of stoker owners, or finding their inception within the organization of any particular manufacturer, are absorbed and distributed widely throughout the whole field of combustion of fuel on stokers. This, while far from specific, and incapable of mathematical precision of expression, does constitute a real and practical advance in the art.

Preheated Air

Preheated air has caused all stoker manufacturers to build stoker bodies, and all parts in contact with the preheated air, so as adequately to provide for structural expansion. There is a trend toward making the air openings through the various kinds of grate surface in the different types of stokers generally larger for preheated air than for air at normal room temperature.

The allowable limit of preheated temperature of air to stoker fires depends partly on the characteristics of the fuel. Certain coals with preheated air have a tendency to fuse or mat over, thus becoming almost impervious to commercial forced-draft air pressures. In certain cases, 300 deg. fahr. has been found to be a limit on this score.

A temperature of 350 deg. fahr. for preheated air with stokers seems to be regarded as safe both by stoker manufacturers and the public which they serve. There is a divided opinion as to the practical effect on stokers of air at higher temperatures. The burden of objection to higher temperatures is on the score of excessive maintenance of grate-surface elements.

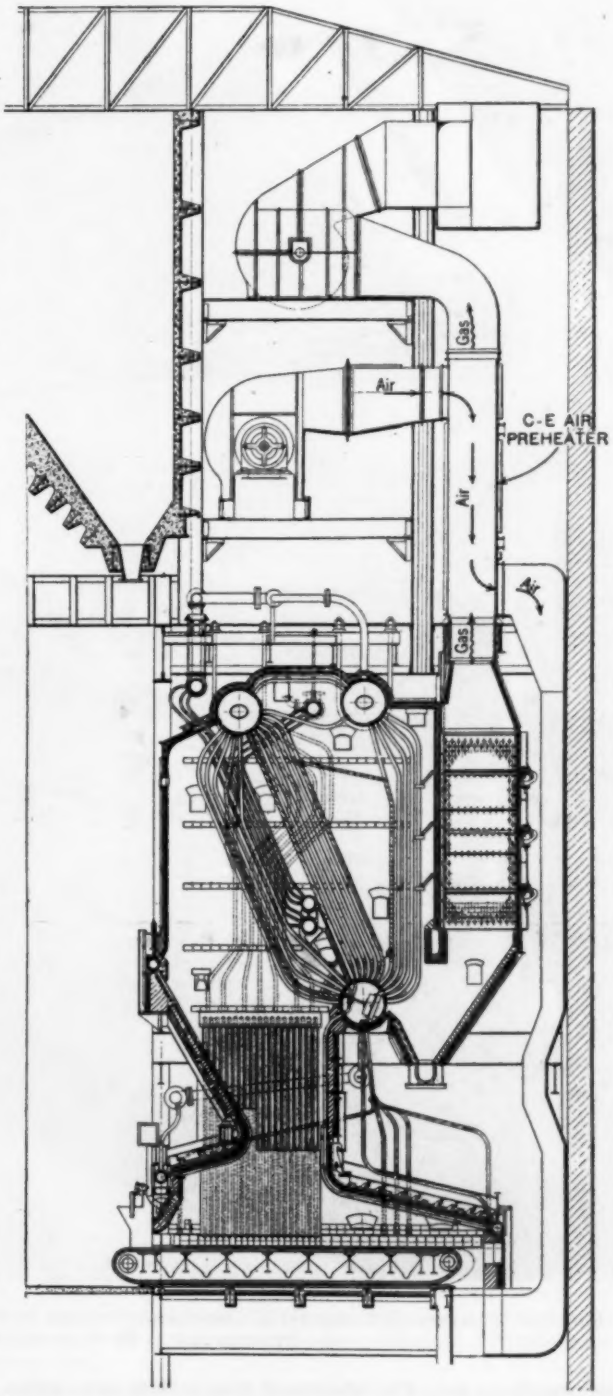

Fig. 13 Combustion Engineering Corporation Stoker for Midwest Bituminous Coal at Grand Avenue Station of Kansas City Power and Light Company Under 1516-Hp. 700-Lb. Pressure Boiler—The Stoker Is 24 Ft. Wide by 22 Ft. Long, Having 528 Sq. Ft. of Stoker Area

Small Stokers

The single-retort stokers, usually considered for boilers of from 200 to 600 hp. in size, have, as a class, developed recently only with respect to convenience in the arrangements for feeding coal and supplying air. The interiors of these stokers have undergone practically no change. But a rather definite demand for electric drive and self-contained source of air supply has caused the development of compact combinations of geared drive and fan worked out for simultaneous driving from a single motor.

In still smaller sizes a large market has recently opened up for stokers to fit under small heating boilers. Practically all of these machines use the combination of speed-reduction gear for coal feeding, together with a small fan for forced-draft air, both driven from a common motor. In fact the development of this style of combined-fuel feeding and source of forced-draft air in these very small stokers has set the style for this arrangement with the small stokers for power boilers.

The stokers for heating boilers are almost all of the screw-feed

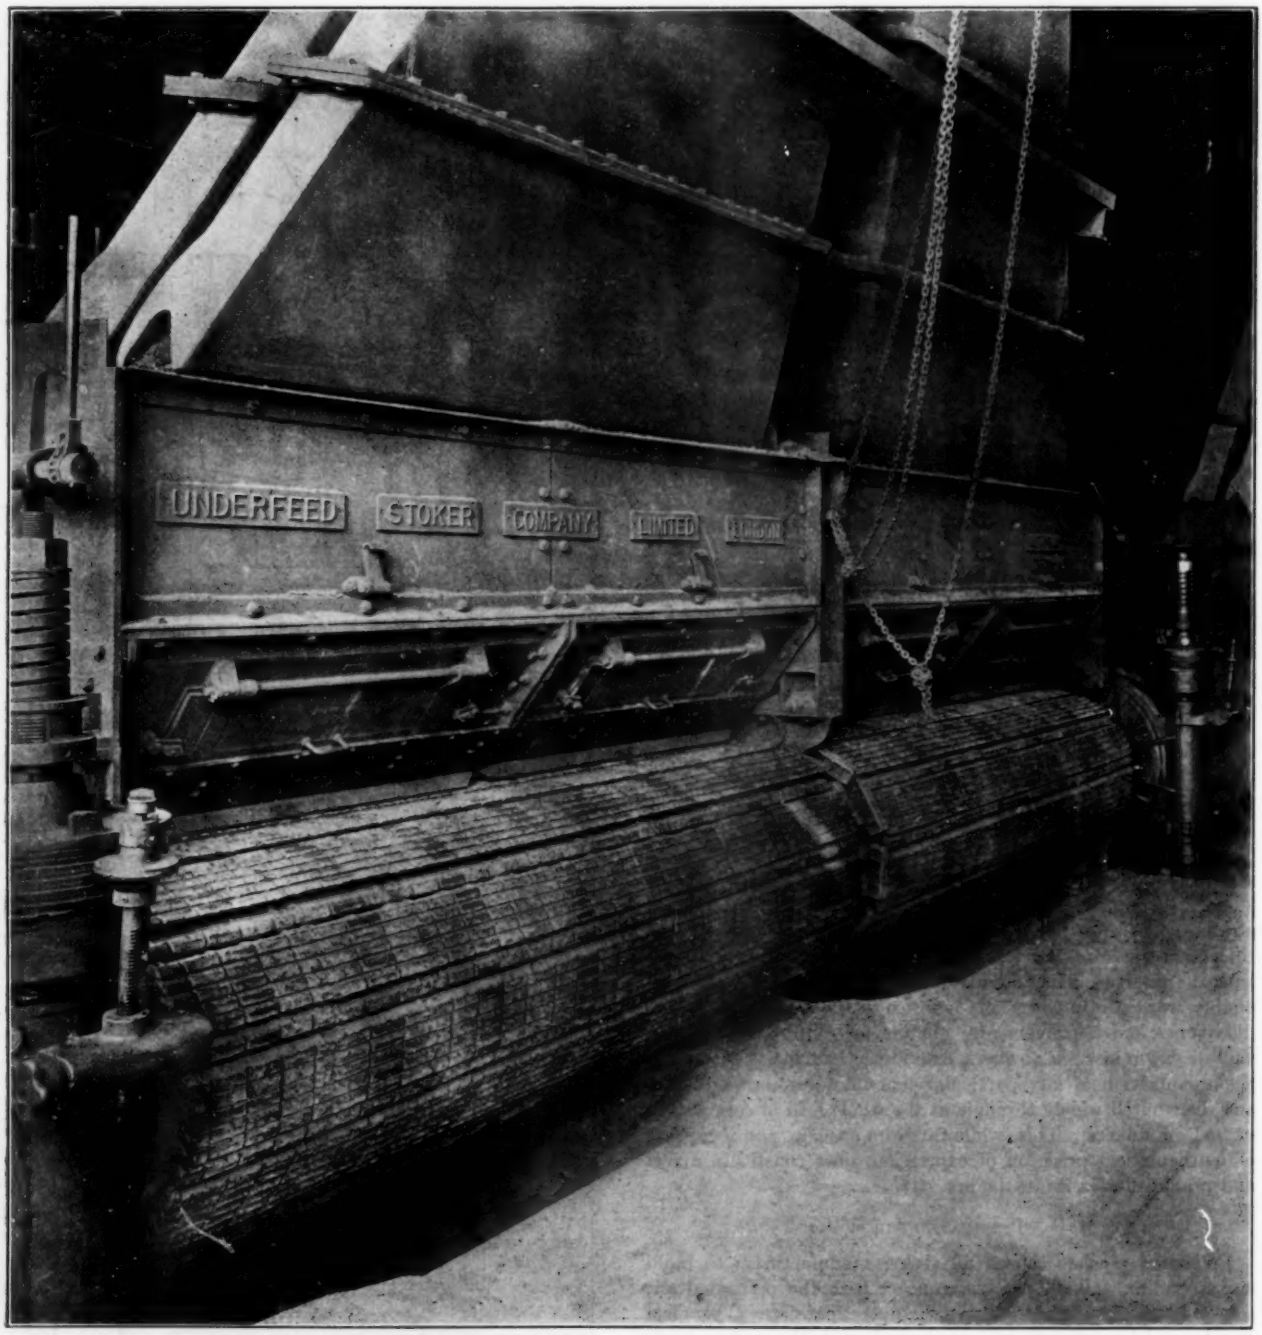

Fig. 13A Combustion Engineering Corporation Stokers in Deptfort Power Station of the London Power Co., Ltd. These Stokers Are 31 Ft. Wide and 700 Sq. Ft. of Stoker Area Each

type, where the coal is fed from the bottom of a hopper, through a delivery pipe, into the bottom of a retort, by means of a slowly revolving screw. Single-retort stokers for small-power boilers

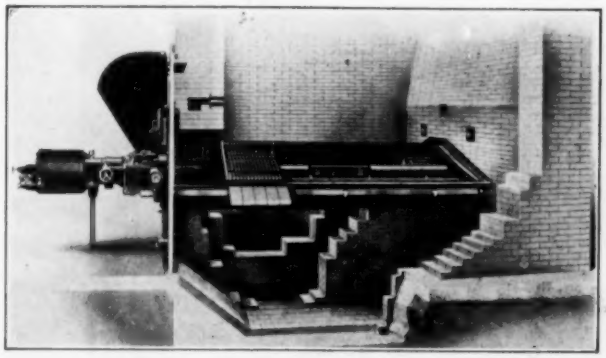

FIG. 14 TYPICAL VIEW OF WESTINGHOUSE SINGLE-RETORT STOKER, SHOWING THE LINK-GRATE FOR AGITATION OF FUEL BED

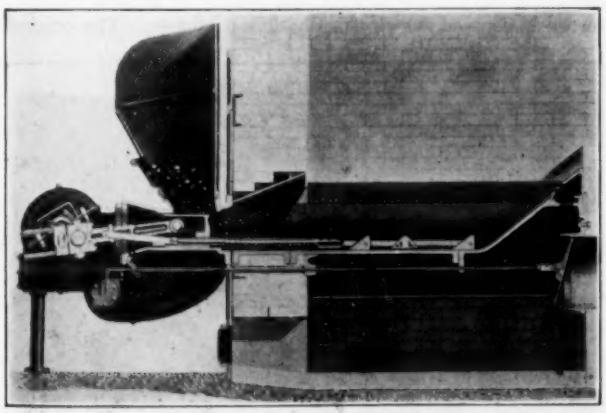

FIG. 16 TYPICAL VIEW OF DETROIT SINGLE-RETORT STOKER, WITH RAM TYPE OF COAL FEED AND AUXILIARY PUSHERS

are usually larger in size, and utilize rams for feeding the fuel from hopper to retort.

As a class, the heating-boiler stokers do not provide any agitation of the fire, whereas the small-power boiler stokers have means for agitation in order to break down the coke masses, and in this point they resemble the action of the large multiple-retort stokers.

THE FIELD FOR STOKERS

A study of the statistics compiled by the Department of Commerce has yielded information that indicates the continued popularity of the stoker as a means for burning fuel under steam-power boilers. These statistics include a summary of the horsepower of water-tube boilers sold each year in the United States,

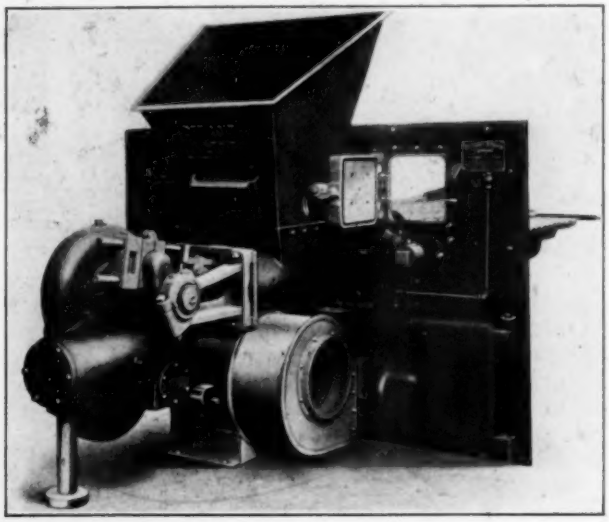

FIG. 17 FRONT VIEW OF DETROIT UNISTOKER, SHOWING THE COMBINATION OF GEARED DRIVE AND FAN, DRIVEN FROM A COMMON MOTOR

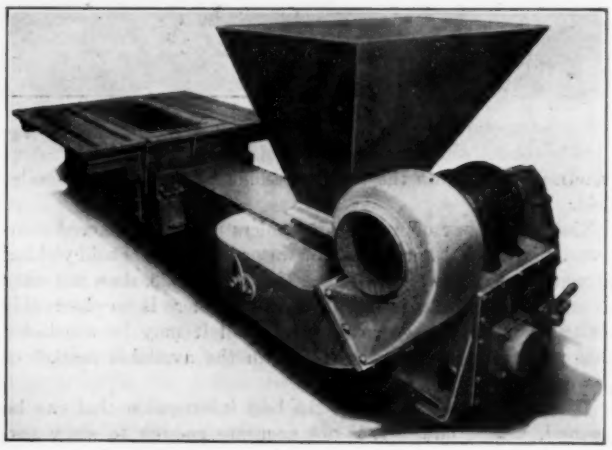

FIG. 18 COMBUSTION ENGINEERING CORPORATION SMALL INDUSTRIAL STOKER WITH COMBINATION GEARED DRIVE AND FAN, DRIVEN FROM A COMMON MOTOR

and reported separately from the horsepower of fire-tube boilers. It may be assumed without serious error that the horsepower of water-tube boilers represents the potential market for all methods of firing steam-power boilers. This set of figures dates from 1919.

There are also further figures for the number of stokers purchased each year, and these are divided into totals for fire-tube and for water-tube boilers. In addition, the horsepower of boilers fitted with stokers is given. These figures date from 1923, and while not entirely inclusive will serve with sufficient

FIG. 19 FRONT VIEW OF HUBER STOKERS

exactness to indicate the trend of stokering in the power-boiler field.

The horsepower of water-tube boilers that are stokered compared to the total horsepower of water-tube boilers sold yields a percentage figure which, commencing with 1923, does not vary to any great amount from 60 per cent. There is no observable tendency in this curve to drop off, and it may be concluded that stokers are holding their own in the available market of power boilers.

It may also be added that the best information that can be secured, which, however, is not accurate enough to show as a curve, indicates something like 20 per cent of the horsepower of all water-tube boilers are being fired by the pulverized-fuel method. This supplementary market for mechanical firing is doubtless largely in the field of exceptionally large units. The final residue of about 20 per cent of this boiler-firing market is probably being sold for the methods of gas and oil firing, and for hand firing. It is very interesting to note that stokers are maintaining their popularity as the major method for firing steam-power boilers.

Discussion

JAMES W. ARMOUR.[2] Among small stokers, the importance of which the author has pointed out, there is a decided tendency toward a demand for electrically driven stokers. The original

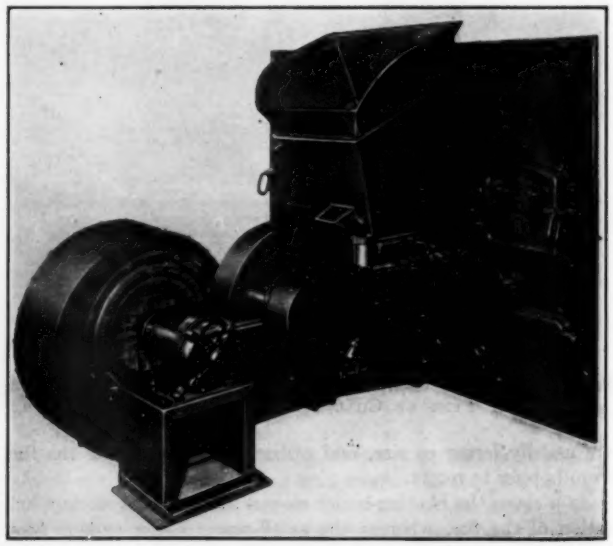

FIG. 20 RIFLEX STOKER DRIVE

[2] Vice-President and Engineer Manager, Riley Stoker Corporation, Worcester, Mass. Assoc-Mem. A.S.M.E.

single-retort small stoker was steam-driven. This type of drive lends itself to automatic control and quite a variation in range of coal feed. Electrically driven stokers do not lend themselves so well to this wide variation in range. Alternating current usually is the available power, and it is very difficult to control the variation in speed of the load such as is imposed by the plunger of a single-retort stoker. Direct current works very satisfactorily, but there is still the objection that the mechanical drives driven by a worm reduction cannot be run very fast. Since these stokers are quite frequently installed for heating loads, such as in schools and apartments, the operator must get on the job early in the morning in order gradually to build up his fire, and he must start early in the evening to build up a bank to last him through the night. It would therefore be highly desirable to have a stoker which can be operated extremely fast for short periods in the same manner as a steam-driven stoker can be operated.

Such a stoker drive, known as the Riflex, was recently put on the market by the company with which the writer is associated. (See Fig. 20.) Speed variation up to 6000 lb. of coal an hour can be obtained. A constant-speed squirrel-cage motor is used, thereby getting away from difficulties encountered with brushes and commutators.

R. A. Foresman.[3] The author has stated that the trend in boiler-plant development is to larger and larger sizes of boiler units and that the major method of generating steam from coal is with stokers. During the past decade the economic problems arising from this development have been of an extremely varied character. The indications are they will continue so and that stoker manufacturers must be prepared to develop their equipment in accordance with these constantly changing conditions.

It was further pointed out that the manufacturer was given no opportunity to determine what the performance of a major development would be by trial installation. With users demanding performance that can be secured only by a major change to existing equipment or by designing a complete new machine, the stoker manufacturer is confronted with a most difficult problem. Not only must the mechanical design be sound and the performance results good, but these should be produced without any more delay and interruption to the service than would occur with a completely developed commercial machine. Under these circumstances there have occurred notable examples of failure to obtain predicted results or to secure them only after protracted effort and great expense.

In any industry that depends upon empirical science to guide it, as does the stoker industry, this is to be expected, and instances of this will continue to occur. This is a cost that the industry must pay if it is to progress.

The record that has been made in saving coal and reducing steam-power costs in recent years is a very gratifying one and proves the sound economic value and good commercialism of the research and experimental work performed to overcome these difficulties and reduce to common practice the improvement it was found possible to make.

Without dwelling on the developments that have been reduced to practice, the writer will mention some that will have a major influence on the economics of steam generation of the future.

(*a*) Notwithstanding that the double-end multiple-retort stoker is not a popular type, it has inherent characteristics that make it superior to the single-end stoker. Comparing these two types, each having the same area and burning the same amount of coal, the principal advantages of the double stoker are:

1 Feeding and distributing coal from the two ends of the furnace
2 The lineal travel of the coal and its speed reduced to one-half
3 Radiant heat from either fuel bed is directed upon the other, which will minimize to a substantial degree the effect of water-cooled walls upon the ignition and combustion of the coal
4 A stream of rich gas from each end of the furnace and one of lean gas from the center, converging at the boiler uptake and causing a turbulence that produces an ideal combustion condition
5 It is more responsive in every respect to varying load
6 It is capable of producing more steam per boiler unit than has been required up to the present
7 It eliminates the first cost and maintenance of an expensive bridgewall.

The question immediately arises as to whether these advantages will not be offset by the double-stokered unit requiring a greater amount of space per unit of power developed, the additional coal bunkers, and the operating cost of looking after two stokers instead of one. With a steady increase in the size of the boiler unit and the capacity that is required, it is possible the first two may prove to be an advantage. The large coal consumption of the boiler unit of the future may make it possible to reduce this cost by using a bunker over each boiler aisle when distribution of weight, space utilized, coal handling, and reserve capacity and performance results are carefully considered. The last will certainly be assured by the improved performance and lower cost per unit of power developed.

Therefore, there is a strong probability that among the major advancements in the economics of steam generation in the large plants of the future the double-end stoker will be important.

(*b*) As to sustained high-combustion rates, the responsiveness of the multiple-retort underfeed stoker to variable demands has always been one of its most valuable characteristics. Originally, performance at or near its maximum was of relatively short duration. This provided a considerable margin between normal and maximum operating performance. The development of the large boiler unit has materially reduced this margin because of the economic necessity of operating continuously for relatively longer periods at combustion rates more nearly approaching the maximum. Much progress has already been made in this respect, but more is going to be required of the future. It is necessary to amplify this thought somewhat.

There is still a relatively big gap between test and operating results. With respect to capacity the measure of a boiler plant's value is the greatest amount of power it can be depended upon to produce, for a given time, without interruption.

It is not a very difficult thing to operate a single unit on a test at or near maximum combustion rates for a period of six to eight hours or longer, but it is an entirely different matter for the operators to take a number of identical units or a group of boilers comprising an entire station and duplicate this performance on each and every one of them for a like period. There are still too many variable factors in actually burning coal for this margin to be entirely eliminated. However, there has been steady improvement in this respect in recent years. The time is rapidly approaching when the highest combustion rates it is economically sound to operate at can be maintained on all the boiler units comprising a group as long as may be desired.

It is not expected to see our present maximum coal-burning rates per unit of area of stokers greatly exceeded. What the writer has endeavored to bring out is that the stoker of the future will be a machine which under the normal service conditions will enable the operator to maintain higher and more uniform combustion rates on each and every unit with absolute dependability and for longer periods than can be secured at present.

[3] Chief Engineer, Stoker Department, Westinghouse Electric & Manufacturing Company, Philadelphia, Pa. Mem. A.S.M.E.

(*c*) As to stoker maintenance, up to the present time a stoker is usually taken out of service for reconditioning in not to exceed 90 days. In but few cases does the service period exceed 60 days. Considerable progress has been made in reducing stoker maintenance, but the stoker of the future will have to operate for still longer periods.

Instead of a service period of 90 days, the manufacturer will have to look forward to producing stokers which will operate consistently for service periods approximating six months at the very least.

(*d*) In general, the appearance of the boiler unit has not been particularly attractive, and the stoker equipment has added but little, if anything, to this. Frequently after being in service for some time the evidence is only too conclusive that no effort is spent upon the stoker beyond what is an actual necessity.

The stoker of the future will undoubtedly present a more pleasing appearance, prevent dust and dirt from escaping from it, and by its design and finish become sufficiently attractive so that it will be kept in good condition.

This phase of the development may not be considered an economic development, but it is a foregone conclusion that the better appearance the equipment makes the more effort there will be in keeping it up, and the more effort there is in this respect the better it will be maintained, Therefore, it is quite likely to prove an economic benefit to both the user and the manufacturer.

RALPH A. SHERMAN.[4] Neither the author nor the discussors have brought up the question of overfire air for the underfeed stoker. All are familiar with the improvements made in the design of furnaces for traveling-grate stokers in which secondary air is admitted at the front of the stoker, at the throat of the front and rear arches, or that which comes through the rear of the fuel bed and is brought forward to mix with the combustible gases by means of a long rear arch.

The fuel bed of an underfeed stoker is deep; therefore, gas with a high combustible content rises from various parts of the bed, particularly in the front where the volatile matter is being driven off. Free oxygen finds its way through the middle of the bed through cracks formed by the shrinkage and movement of the coke, and through the thinner bed on the extension grates. The walls of the furnace generally rise vertically toward the boiler tubes, and no provision, other than the natural turbulence and diffusion, is made for mixing these gases. That the underfeed stoker is an admirable mechanism for firing coal is unquestioned, but the combination of these combustible gases with free oxygen above the fuel bed seems to be more a result of chance than of the design of the stoker or furnace.

That stratification does exist in the furnace and that carbon monoxide, and even hydrogen, pass unburned to the uptake was proved during tests on two underfeed stoker-fired furnaces in the course of the investigation of furnace conditions which affect the life of refractories.

Some experimental work, which has not been published, has been done by one operating company on the admission of overfire air at the front wall of an underfeed stoker with apparently good results. It is understood that overfire air is being provided in one of the installations pictured in the author's paper.

However, much work remains to be done. A thorough investigation of the process of combustion in the underfeed stoker has never been made. Such an investigation with a modern stoker should give valuable information on the proper use of the controls of shape of fuel bed and of the zoning of air with which stokers are now equipped. It should show whether the design of the furnace generally used is correct. Perhaps a front arch would be helpful; the available water-cooled arches do away with the difficulties inherent to the refractory arch. It would indicate whether overfire air is necessary or desirable and the proper points for its admission. Furthermore, it should show why, when at least one-half of the process of combustion occurs within the relatively small volume of the fuel bed, the average rates of heat release for the entire furnace are little greater than for powdered-coal furnaces.

FSP-52-19

Electrically Heated Hardening and Tempering Baths Compared With Fuel Methods of Heating

By WIRT S. SCOTT,[1] MANSFIELD, OHIO

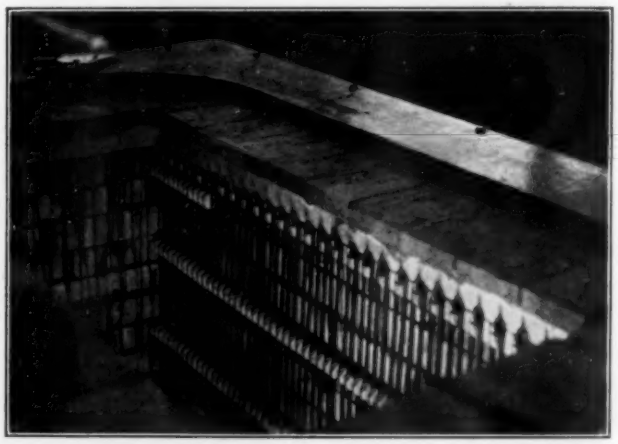
Necessity for uniform products and improved working conditions led the Warren Axe and Tool Company to replace its fuel-heated furnaces with electrically heated types. A reduction in costs of manufacture has also resulted, so that, based on actual book profit, the new equipment will pay for itself in 18 months. The new equipment, its control and operation, is described in this paper.

PRIOR to electrification the axes manufactured by the Warren Axe and Tool Company were heated in semi-muffled gas furnaces. Individual treatment for each axe was thought to produce the ultimate in heat treatment. The possibility for error in judgment on the part of the heat treater was appreciated, but this was minimized as much as possible by employing only experienced high-grade heat treaters.

The "Sager Brand" axe is of a dark blue color, the natural color of the tempered steel. Securing of this color in tempering was the aim of the heat treaters, but the accomplishment was a matter of judgment alone, and subject to many variables, resulting in different shades of tempered steel and different degrees of hardness. The desirability of improving the quality of product and of securing the most dependable uniform quality was apparent, and a decision was made to eliminate some of the variables and reduce others to a minimum through the use of electric heat, regardless of the operating cost.

Electric furnaces were put in operation Feb. 1, 1929. The entire method of heat treatment was revised. Batch-type, semi-continuous operation was used; bath-type furnaces replaced hearth type; separate hardening and tempering furnaces were used; one hardening and one tempering furnace replaced five combination hardening and tempering furnaces. This was the program decided upon, based upon experience gained and results produced in other fields.

The electric furnaces are of the rectangular bath type, consisting of a box-like steel-plate shell riveted and welded together, and lined with heat-insulating and refractory brick to form a heating chamber. Heating elements formed of return-bend coils of nickel-chromium resistors are suspended from hooks anchored in the sidewalls, and are placed in the bottom in suitable refractory spacer blocks.



The vessel for the bath is made of cast nickel-chromium alloy, supported in the heating chamber by means of a flange resting on the brickwork. A nickel-chromium protective apron is placed around the flange, and over this is laid a steel top plate so as to protect thoroughly the brickwork from damage, and to prevent the molten bath from entering the heating chamber.

The axes were to be suspended by suitable hooks in heated lead and salt baths, held at the proper temperatures for the hardening and tempering operations. Due to the fact that lead is heavier than steel, means had to be provided for holding the axes down in the lead bath.

The hardening-bath furnace is operated at a bath temperature of 1405 deg. fahr.; has a vessel, the inside dimensions being 22 in. wide × 60 in. long at the top × 14 in. deep. The electrical capacity is 65 kw., two phase, 60 cycles, 220 volts. The tempering-bath furnace is operated at a bath temperature of 580 deg. fahr.; has a vessel, the inside dimensions being 12 in. wide × 46 in. long at the top × 12 in. deep. The electrical capacity is 57 kw., two phase, 60 cycles, 220 volts.

Each furnace is divided into two equal circuits, each circuit operated by separate magnetically operated contactor switches, which in turn are operated by means of temperature-recording and controlling pyrometers.

Two thermocouples are used with each furnace, one of the protected type located directly in the bath, and the other a bare type within the furnace chamber. This double protection and control is necessary fully to protect the heating elements against excessive temperatures, particularly during the heating-up periods, at which time the temperature of the bath does not rise as rapidly as that of the heating chamber, and the chamber temperature tends to rise much faster than the heat can be absorbed.

CONSTRUCTION OF HEATING CHAMBER USING ROD-TYPE ELEMENTS

The production consists of two distinct classifications of axes, the Sager Brand or all-blue tempered, and the various other brands under distinctive trade names. These later brands are finished in various colors of enamels, and are not required to have the blue finish. The production in one month consisted of 6400 blue-finished single-bit axes, 9500 blue-finished double-bit axes, 10,900 single-bit in other finishes, and 525 double-bit in other finishes. The total number of bits or cutting edges to be heat treated was 37,350 in the month referred to.

The axes are made of two different kinds of steel. The body is forged from low-carbon steel, and to this is welded the cutting edge, consisting of high-carbon crucible steel. Only the blade or

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cutting bit need be heat treated, hence it is unnecessary to heat the entire axe, except for the purpose of obtaining the blue finish on the Sager Brand, which is done in the tempering bath.

In the hardening bath, 23 axes are suspended point down, and immersed in the lead bath up to within one inch of the hole for the handle. On top of the molten lead is placed a blanket or cover of granular carbon, which has the effect of reducing the radiation losses from the surface, reducing the oxidation of the lead, and giving a wiping action for removing lead globules from the axes. After the axes have been in the bath a definite length of time they are removed, quenched in brine, rinsed in clear water, and are ready for tempering.

A tempering salt is used, which if held at the proper temperature for a definite length of time produces just the shade of blue desired. The temperature, of course, had to be that required for a proper draw, and at the same time had to be sufficient for thorough saturation and no more.

In bluing, the Sager axes must receive the finished polishing after hardening and before tempering. With the process now used a beautiful dark-blue shade is obtained uniformly over the body of the axe, and a slightly lighter shade over the cutting edge or bit. Just so long as the temperature remains constant within certain limits, and the work is kept submerged in the salt for just a definite length of time, the same shades of blue are reproduced exactly.

One of the most interesting phases in the use of electric heat is the possibilities of accomplishing results heretofore unattainable, and often the securing of results unlooked for, which in themselves more than justify the installation. The possibilities with equipment now available are not always appreciated, and not used to the fullest extent until confronted by conditions that call for further refinement of control beyond that previously used.

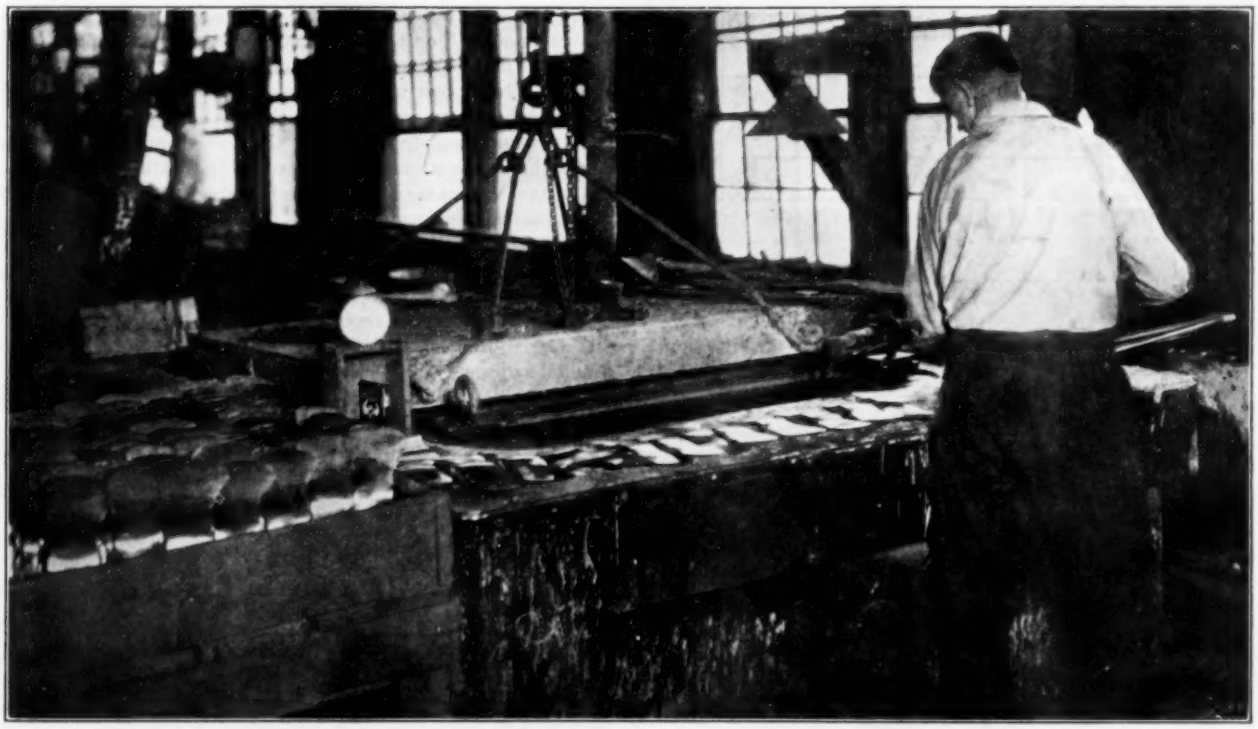
An illustration of this fact was brought out in an attempt to obtain a much closer temperature control of both the hardening and tempering bath than had previously been obtained with electric furnaces. With bath-type furnaces, due to the inherent sluggishness of the bath to respond to changes in heating-chamber temperatures, the temperature of the bath does not follow immediately that of the heating chamber. For example, should the temperature of the bath begin to drop below normal, and by doing so cause to be liberated or turned on an increased amount of heat energy, the temperature of the bath will continue to drop from 30 to 50 degrees below normal (depending upon the type of furnace used) before it begins to rise again. This increased heat energy or source continues adding heat to the bath until normal temperature is regained. However, by this time the entire furnace chamber, consisting of refractory firebricks, has been heated to a much higher temperature than the bath, and has absorbed a considerable quantity of heat, which it begins to liberate to the bath just as soon as the heating medium is reduced or cut off entirely. The net effect is to continue to supply heat to the bath after the proper temperature has been reached, with the result that the temperature of the bath continues to rise from 30 to 50 deg. above normal.

By using an electric furnace having one thermocouple in the bath and one in the heating chamber, it is possible to make the bath temperature respond more nearly to that of the furnace chamber, cutting off the current when the heating chamber

GENERAL VIEW OF ELECTRICALLY HEATED LEAD-HARDENING FURNACE

(Double-bit axes are being heated. The bit only is immersed in the lead. There are three lamps on the wall at the extreme right with the white light indicating proper temperature and correct rate of production. The brine quench tank is directly back of the furnace operator. After finishing the day's production the rack for holding the axes in the bath is removed, and the insulated cover is placed in position over the lead bath so that the lead is still in a molten condition next morning.)

reaches a predetermined temperature, thereby preventing an excessive storage of energy, and later when the heating chamber has cooled off somewhat, cutting on the current again. This action anticipates to an extent the demands for heat within the bath. Such a system of control can be depended upon to hold the temperature of the bath within 20 deg. plus or minus.



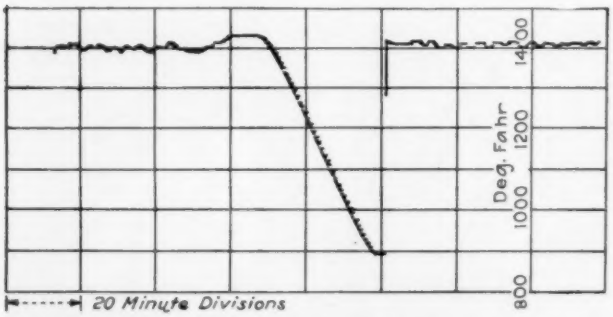
Theoretically, if a definite amount of heat be supplied each minute to a bath, it should be possible to put just enough work through the furnace each minute to hold the temperature constant. This principle in combination with the electric furnace described was put into effect. Since the axes had to be placed on and removed from the hooks by hand, some positive means had to be employed to indicate to the operator when he was operating at the production rate which would tend to keep the furnace at a uniform temperature. This was accomplished by placing three contacts on the pyrometer. These operate three lamps placed over the corresponding furnace. A white light indicates correct temperature; a blue light, temperature too low; a red light, temperature too high; a white and blue light, a downward swing in temperature; a white and red light, an upward swing in temperature.

With 23 hooks suspended over the hardening furnace, 22 of which always hold axes, the operator's job is to remove one heated axe and replace it with a non-heated axe at such a rate as to keep the white light burning. Should the blue light come on with the white, the operator must slow up; should the red come on with the white, he must work faster. Should the white light go off entirely, the operator must cease work until conditions become normal. The extent to which this is accomplished is shown graphically by the recorded-temperature chart in the control room.

In practice it is impossible to comply entirely with this theory. The weights of axes vary; consequently, the rate of heat absorption is not constant; hence variable amounts of power are required at different times. This condition necessitates a furnace having a capacity sufficient for heating the largest charge at a given production rate, and as a factor of safety, an excess capacity for unusual or unforeseen contingencies. The temperature variation of this combined system under the worst conditions was sufficient to hold the temperature within 15 deg. plus or minus of 1405 deg. fahr.

Control of the hardening temperature within 15 deg. was a tremendous improvement over any results anticipated by the Warren Axe and Tool Company, and the elimination of 80 per cent of the field rejects was assured provided the operator could be depended upon to watch his lights. A difficulty arose in this respect, however. One two-point control instrument was used on each furnace, the instrument, automatically every 30 sec., changed from the thermocouple in the bath to the thermocouple within the heating chamber. Since the indicating lights had to be connected to show the bath temperature, there was therefore a period of 30 sec. out of each minute during which the lights did not burn. This resulted in much uncertainty and confusion. The situation was remedied by replacing the two-point instrument with two single-point instruments, one for the bath and one for the heating chamber, thereby permitting the lamps to burn uninterruptedly.

The use of two control instruments, two separate contactor switches, and two circuits in each furnace opened the way for an investigation for further refinement of temperature control, insuring a closeness of control that would positively give a still better product, and eliminate field rejects due to improper heat treatment. As previously explained, the surging of the temperature had been reduced from 30 deg. to 20 deg. by controlling the temperature of the heating zone. If the amount of energy necessary to control on and off intermittently could be reduced, the corresponding fluctuation or surging in temperature would be reduced. This was accomplished by taking one circuit of the



TEMPERING DOUBLE-BIT AXES IN A SPECIAL SALT SOLUTION THAT TEMPERS AND BLUES THE AXE AT THE SAME TIME

furnace entirely off the recording-control pyrometer, and placing it on the control pyrometer for the heating chamber, with the net result that one-half of the furnace capacity was in constant service and one-half in intermittent service.

Since the electrical capacity of one-half the furnace was more than that necessary to supply the radiation losses, during the noon-hour period when no work was being heated the constant-heat circuit is cut out, and the temperature-control circuit alone used for maintaining the temperature. Furthermore, at all times whether one circuit or both circuits are on, they are under the control of the heating-chamber thermocouple and pyrometer which cuts off the current entirely should the temperature of the heating chamber rise to a predetermined point, and cuts it on again as the temperature is lowered.

The building up of excessive temperatures and excessive heat storage within the heating chamber is thereby effectively elimi-

WEEK-DAY CHART OF THE TEMPERATURE OF THE LEAD-BATH HARDENING FURNACE

Shutting down at 2.30 P.M. the bath temperature dropped to 890 deg. fahr. over night, and recovered to normal temperature again in 30 minutes.)

nated, and the bath temperature is under independent and positive control. With this scheme the temperature fluctuation from normal was reduced to $7\frac{1}{2}$ deg. fahr.

The furnaces are never permitted to cool off sufficiently to cause the bath liquid to solidify, except during the week end. Heavily insulated covers are provided which completely cover the entire furnace top. At the end of the day's run the covers are lifted from their stand by a chain hoist, and lowered to the furnace. With the current completely cut off the furnaces, the excellent heat storage and response to current applied are shown by the following data taken from temperature charts of the baths:

Hardening Furnace

Operating temperatures	1405 deg. fahr.
Hours operated per day	7
Operating hours	7 a.m. to 12 noon 12.30 to 2.30 p.m.
Number of hours each day furnace is shut down before current is again applied	$15\frac{1}{2}$
Temperature of bath when current is applied	840–900 deg. fahr.
Time required to recover or reach 1405 deg. fahr. in the bath	30–35 min.

NOTE: Furnace is held at 1405 deg. fahr. for 30 min. in the morning before the operation is begun to permit a more thorough heat saturation of the furnace chamber.

Tempering Furnace

Operating temperature	580 deg. fahr.
Hours operated per day	7
Operating hours	7 a.m. to 12 noon 12.30 to 2.30 p.m.
Number of hours each day furnace is shut down before current is again applied	$15\frac{3}{4}$
Temperature of bath when current is applied	450–480 deg. fahr.
Time required to recover or reach 580 deg. fahr. in the bath	20 min.
Time furnace is held at 580 deg. before beginning operations	20 min.

The method of operating one of the furnaces is worth recording in its sequence of operation, showing as it does the manner in which a batch-type hand operation can be made practically continuous.

SEQUENCE OF OPERATING HARDENING FURNACE

1 At the beginning of the working day, the furnace operator removes the insulated cover, and prepares to resume operation.

2 The furnace being up to temperature, a charge of 23 axes is placed on the hooks.

3 The bath drops in temperature due to the placing of the entire charge at one time in the bath. The lights change from white to white and blue, and then to blue alone.

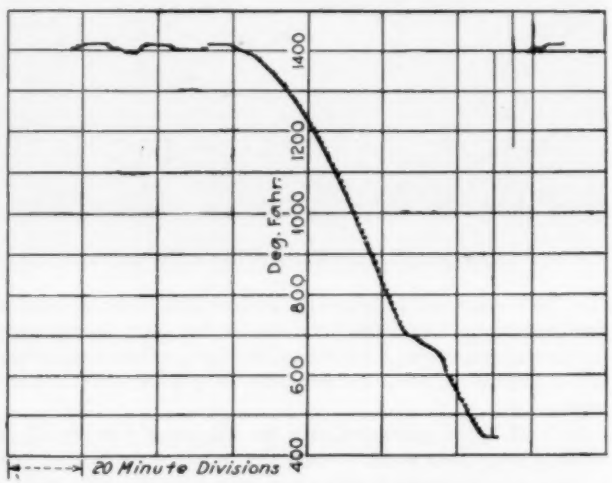
4 The bath temperature drops to 1380 or 1385 deg. fahr.

5 Within eight minutes from the time the charge is placed in the bath, the temperature is back to 1405 deg. fahr., and the white light shows alone.

6 The operator is ready to begin regular production, and makes a note of the time on a time sheet. (A clock is provided.)

7 The first two axes are taken off hooks No. 1 and No. 2, and quenched blade first in a brine solution, and hung on hooks in the quench bath to continue to cool.

8 One non-heat-treated axe is then placed on hook No. 1 in the bath, leaving a vacant hook for readily spotting the position.



9 Axe No. 3 is taken out of the furnace, quenched, hung on a hook, and the first axe previously quenched is dipped in a rinse tank containing clear water, and then placed in a box on a truck.

10 The second non-heat-treated axe is then placed on the next vacant hook in the furnace.

11 This operation is repeated, so that by the time the last axe has been quenched, and the last hook refilled by a non-heat-treated axe, the furnace has been entirely refilled with axes.

12 Twenty-three non-heat-treated axes are laid out on the furnace plate alongside the bath, ready for resuming operation.

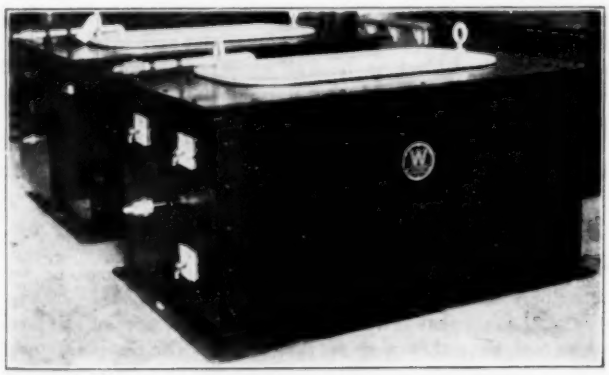
13 A record of the time is again made on the time card, and the quenching of the second batch started as before.

WEEK-END SHUTDOWN AND RECOVERY MONDAY MORNING

(Furnaces were shut down at noon on Saturday and started up again Monday morning, recovering normal temperature in one hour, ten minutes.)

With four-pound single-bit axes, five minutes is allowed for this complete cycle, permitting the operator to work at a very comfortable pace, without hurrying. With $6\frac{1}{2}$-lb. axes, an eight-minute schedule is required. Batch after batch was put through with only the white light showing, indicating a temperature variation of less than 5 deg. fahr. Occasionally, the white and blue or the white and red lamps would come on, in which case the operator

gaged his speed so as to cause only the white light to show. At no time did either the blue or red lights come on alone.



During the course of this investigation, the plant engineer was demonstrating the action of the pyrometers in control of the lamps, and in doing so opened the case of the instrument, disconnecting the control lamps. The control room is in another room parallel to the heat-treating department, but cannot be reached directly from that department, necessitating walking the length of the heat-treating room, into the connecting room, across the room, and back an equal distance to a point directly opposite the furnaces. In less than two minutes after the pyrometer case was opened, the furnace operator appeared in the control room to learn why his lamps had gone out.

The operation of the tempering furnace is substantially the same as the hardening furnace, except that the entire axe is submerged in the liquid when tempering the Sager Brand. With the double-bit axes of the Sager Brand, the entire axe being submerged, only one tempering operation is required per axe, whereas with the hardening furnace each double-bit axe is run through twice, once for each blade. The timing is worked out on the same basis as the hardening furnace, that is to say, each weight axe has a definite time cycle.

When tempering $4^1/_2$-lb. double-bit axes, both points at one time, the length of time any one axe was in the bath was eight minutes. The tempering bath holds 26 double-blade axes, or 29 single-blade axes by the changing of the jig.

The two furnace operators are on piecework, each man turning out from 1400 to 1500 axes per day, with an average of 1435 each, for the past four months. The two men operating the electric furnaces are turning out a larger production than five heat treaters previously turned out on the fuel furnaces, are not rushed as they were in the past to average a certain wage per day, and have infinitely better working conditions.

The reasons ascribed by the Warren Axe and Tool Company for electrifying are dissatisfaction with results obtained with fuel-

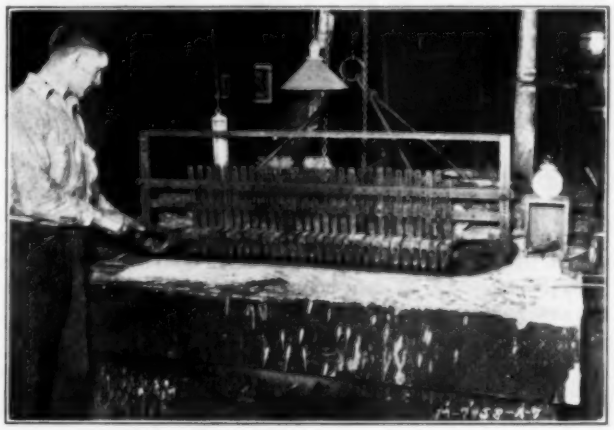
General View of Bath-Type Furnaces Before Shipment

fired equipment, both as regards uniformity of product and the amount of labor required. Fool-proof equipment was wanted also.

A survey of the conditions prior to electrification as compared to the present results shows the extent to which these objectives have been attained and the economics of the investment in so far as is determinable to date.

Cost of Fuel Versus Electricity

There were no meters on the gas furnaces nor on the electric furnaces, hence accurate costs were not readily obtainable. A survey of the electric bills since the electric furnaces were placed in operation and a similar survey of the gas bills for six months previous to discontinuing the gas furnace furnished a basis for a sufficiently accurate check.



Natural gas was used, the price paid being 43 cents per 1000 cu. ft. The gas bills showed a reduction of approximately $150 a month since using electric heating. The date of reading the gas meter not coinciding with the date of beginning the operation of the electric furnaces, that month's reading had to be approximated and checked against production.

Electric power is purchased from the American Gas & Electric properties at an average rate of $0.02 per kw-hr. including the demand charge. The total demand for the entire plant, over a 15-min. continuous reading is 312 kw. (month of April). The power bills for the past nine months for the entire plant are as follows:

October	$665.63
November	690.26
December	678.87
January	687.32

Electric furnaces added:

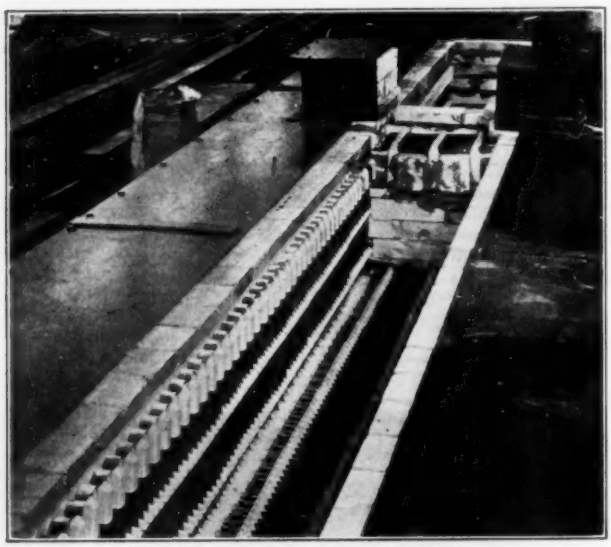
February	$924.97
March	875.40
April	993.55
May	1018.98
June	967.08

Salt Tempering Bath, With 29 Single-Bit Axes in the Bath. Axes Other Than the Sager Brand Are Not Immersed Completely

The production was constant up to Mar. 1, 1929, when it dropped slightly and then increased again slightly above normal. Averaging the last four months prior to installation of the electric furnaces gives an average power bill of $680. Averaging the last five months of operation gives a power bill of $956. The difference in these bills being a reasonably accurate result, shows that the electric furnace costs $276 a month, making no deduction for the increased production of the past three months over last year.

With a gas cost of $150 a month and an electric cost of $276, the increased cost of electricity over gas fuel is $126 a month.

Labor Cost. Using the gas furnaces, five heat treaters were employed on piecework to get out the production. The average daily production per man for hardening and tempering was as follows:



Common axes, single bit	400 per day
Sager axes, blue, single bit	325 per day
Common axes, double bit	200 per day
Sager axes, blue, double bit	165 per day

With electric furnaces, one man hardening and one man tempering, the combined production is as follows:

Sager axes, blue, single bit and Sager axes, blue, double bit and	1500 hardened 1500 tempered 750 hardened 1500 tempered

The direct labor cost per 100 axes hardened and tempered, using gas fuel, was as follows:

Single bit	$1.73 per 100 axes
Double bit	3.46 per 100 axes

Construction of Heating Chamber Using Ribbon-Type Elements

Since using electric furnaces, the scale has been adjusted so as to give the men the same wages in a seven-hour working day as formerly received in an eight-hour day. The direct labor cost per 100 axes hardened and tempered is as follows:

Single-bit axes	$0.85 per 100 axes
Double-bit axes	1.24 per 100 axes

On the basis of a production of 8320 double-bit and 25,350 single-bit axes the comparative labor cost is as follows:

Direct labor gas furnace operators:

83.20	×	$3.46	= $288
253.50	×	1.73	= 438
Total			$726

Direct labor, electric furnace operators:

83.20	×	$1.24	= $103
253.50	×	0.85	= 215
Total			$318

Average monthly saving in direct labor since using electric heat, $408.

Quality of Product. With gas heat, an attempt was made to hold the hardness between 53 and 57 Rockwell, "C" Scale (518 to 568 Brinell). With electric heat, the results are coming uniformly between 54 and 56 Rockwell (530–555 Brinell).

With gas heat, the difference in hardness of the inside and outside corners of the same axe bit frequently amounted to the low and high limits set. With electric heat, the difference is never more than 1½ points, Rockwell test.

Each axe is stamped with the year of manufacture. The principal outlet being the lumber or logging industry, approximately 50 per cent of the output is put into use almost immediately, and it is safe to assume that 90 per cent of the axes are in use six months from the date of manufacture. It is, therefore, possible to form a sufficiently accurate estimate of the period of manufacture corresponding to a given number of field replacements.

From the performance to date of the electric furnaces it appears certain that the field rejects due to heat treatment will be entirely eliminated. It is also certain that some of the rejects may be due to other causes, such as flaws in the steel and abuse of the axe. Since each axe is given a hammer test calculated to show up any flaws due to forging or welding, it is felt that but a very small percentage is due to this. To insure a high-grade uniform-quality product when using fuel furnaces, a considerable amount of added expense was necessary which has been eliminated in some cases and very materially reduced in others. The yearly value of this item in the reduction of testing, inspection, reduction in field replacements, etc., will amount to $8000 a year.

Improved Working Conditions. The two operators now on the electric furnaces had also been heat treaters on the gas-fired furnaces. One had been with the company 10 years, the other 15 years. An interview with these men disclosed their opinions of the relative difference in their working conditions before and after using electric heat.

With the gas furnace they worked eight hours a day, and had to work hard every minute of the day in order to get out the production to give them a certain wage. They had to be on the job practically every second, or they would have some overheated axes. The heat given off from the furnace was intense, and since they had to work directly in front of the open furnace all day, the working conditions, particularly during the summer months, were as severe as a person could stand.

With electric furnaces they work seven hours a day, and have plenty of time to do a good job, and in addition have from 1½ to two minutes rest out of every eight minutes. They are making as much money in seven hours as they formerly made in eight hours. There is no discomfort at all from heat, and they scarcely know or realize there is any heat in the baths. (The hardening bath, being covered with one inch of granular carbon, the surface of which is dead black, is, from all appearances, cold.) Instead of having the hardest and most uncomfortable job in the plant, they now have the easiest job, and just as comfortable as any. The electric furnaces have so improved their working conditions that it would be worth accepting less money rather than return to the old method.

Maintenance

Gas Furnaces. The maintenance of the gas furnaces was amazingly small, due to the simple construction of the furnaces, and to the fact that the heat-treaters supplied most of the labor at no cost, since they were on piecework. The records showed that an expenditure for materials amounting to $179 a year total, or $14.90 a month.

Electric Furnaces. No expenditures for repairs to the electric furnaces have occurred to date. The vessel of the hardening furnace depreciates in proportion to its hours of use, and there are other expenditures, such as for lead, granular carbon, and salt for the tempering bath, which must be considered as part of the maintenance. These figures should be of interest to those having applications for similar furnaces or as a comparison to results being obtained by means of fuel equipment.

Vessel Life. From data obtained from one installation having 24 large hardening and tempering baths, and from a number of other installations having a lesser number of baths, the average life of a nickel-chromium vessel, lead hardening, using electric heat, is from 5000 to 7000 hours. Tempering vessels have been in use for 13,000 hours with still no signs of depreciation. On the

basis of a vessel costing $800 installed in the furnace, and on a basis of 200 hours of use per month, the monthly depreciation is $23.20.

Lead Consumption. A total of 280 lb. of lead and 28 lb. of tin are used each month in the hardening bath to make up the loss.

280 lb. at $0.0875 =	$24.50
28 lb. at $0.2325 =	6.50
Total	$31.00

Granular Carbon. One ton of granular carbon will last nine months, and costs $50 delivered. Average monthly cost $5.60.

Salt Consumption. One barrel of tempering salt, of special mixture to Warren Axe and Tool Company's specifications, costs $75 and lasts from three to 3½ weeks. On the basis of three weeks, this amounts to $100 a month.

The monthly cost of maintaining the electric furnaces is as follows:

Vessel	$ 23.20
Lead	31.00
Carbon	5.60
Salt	100.00
Total	$159.80

Sales Value. It is the practice in most plants to take the direct labor cost and multiply this by a fixed amount to arrive at the total labor cost. The factory cost multiplied by a fixed amount gives the selling price. A reduction of $1 in direct labor may therefore permit a reduction of from $1.50 to $2 in the selling price. However, if in making this reduction in direct labor, a much higher quality of product is obtained, and at the same time, the trade distinction or appearance such as the Sager Blue is greatly enhanced, the sales value has been improved tremendously and if sold at the same selling price as before, gives a wider margin of profit. This added sales advantage can be estimated only, but on an estimated small value of one cent per axe, the average monthly value is $350, a figure considered very conservative by the management.

Investment Charges

Gas Furnaces. The investment tied up in the gas furnaces was relatively small, and in any event, since it had been charged off the books years ago, no monthly charge can be made against this equipment.

Electric Furnaces. The cost of the electric furnaces and control equipment, installed complete, was $9038.85. With an interest and depreciation charge of 15 per cent, the annual investment charge is $1355.83 or $133 a month.

COMPARISON OF MONTHLY OPERATING COSTS BETWEEN GAS AND ELECTRIC FURNACES AT THE WARREN AXE AND TOOL CO., WARREN, PA.

	Electric furnaces	Gas furnaces
Electric or fuel bill	$ 276.00	$ 150.00
Labor for heat treatment	318.00	726.00
Testing, inspecting, field rejects, etc.	167.00	667.00
Maintenance	159.80	14.90
Investment charge	133.00	
Total	$1053.80	$1557.90
Net actual book profit per month using electric heat		$504.10
Added sales value, per month		350.00
Total savings, per month		$854.10

Based upon the actual book profit shown for electric heat of $504.10 per month the equipment, completely installed, will pay for itself in 18 months, or a return on the investment of 66⅔ per cent. Such a situation is most gratifying to the Warren Axe and Tool Company, whose entire purpose in electrifying was the production of a uniform high-grade quality product, and who would have been satisfied had the operating costs increased by the same amount they have decreased, considering the quality of product now being obtained.

FSP-52-20

A Study of Electric House Heating

By A. R. STEVENSON, Jr.,[1] and F. H. FAUST,[2] SCHENECTADY, N. Y.

The use of oil and gas as fuels for domestic heating furnaces has been developed to avoid the inconvenient features of coal. Electricity as a source of heat has been given little consideration, particularly because of the idea that it is too expensive, although otherwise it is an ideal heat source. Two principal ways of using it are described—the direct conversion of electricity to heat, and the use of electricity as a source of energy to drive a heat pump. A plan is described based on using electric energy off peak in order to obtain low power rates and of storing the heat generated to be used as required.

IN THE attempt to overcome a number of inconvenient features in the use of coal, such as shoveling it into the furnace and taking out the ashes, various methods of using oil or gas have been evolved. Very little attention, however, has been paid to the use of electricity as a source of heat, principally because it has been considered too expensive, although in every other way it may be considered as a nearly perfect heat source.

It is hardly necessary to point out the cleanliness and convenience of electricity. Anything that can be said concerning the cleanliness of gas is obviously even more true for electricity.[3] With electricity, it is unnecessary to provide space for fuel storage; and by automatic control all labor can be eliminated.

In view of all these advantages it would appear that the use of electricity should be carefully investigated to determine its economic possibilities. It is the purpose of this paper not only to present the results of such an investigation or survey, but to show what has been done in the past and what is being done at the present in the way of electric house heating. No attempt will be made to discuss electric heating for industrial purposes, but attention will be given only to electric heating of homes and buildings.

There are two principal ways by which electricity can be utilized as a source of heat—the direct conversion of electricity to heat and the use of electricity as the source of energy to drive a heat pump. The direct conversion of electricity to heat may be accomplished in a number of ways, such as:

1 Using a metal resistance in an electric circuit to convert electricity into heat, which may be dissipated to the air directly from the resistance.

2 Using a fluid resistance such as water between two electrodes of an electric circuit and storing the heat in the water.

3 Using a copper tube as the secondary of a transformer. By passing water through the tube the heat formed in the tubing may be carried off in the water.

Any of these methods of directly converting electricity to heat may be accomplished at an efficiency of 100 per cent. If, however, electricity is used as a source of energy to drive a heat pump, as was suggested by Lord Kelvin as early as 1852,[4] it is possible to obtain an apparent efficiency greater than 100 per cent. For instance, a refrigerator is one example of a heat pump.[5] If it is driven by an electric motor, the heat output will be the sum of the heat equivalent of the electrical input and the heat pumped from the heat-absorbing element (the evaporator) to the heat-dissipating element (the condenser); consequently, the apparent efficiency, or the coefficient of performance of a refrigerating machine as it is called, is greater than one.

Since the use of a refrigerator as a heater has not been applied commercially, so far as we know, attention will be confined to the direct conversion of electricity to heat. As already mentioned, this conversion is consummated at an efficiency of 100 per cent, but it is possible in most localities to obtain electric power off peak at lower rates than on-peak power. By properly controlling the time of the conversion of electricity to heat, it is possible to obtain an apparent efficiency greater than 100 per cent compared with on-peak power costs. First there will be reviewed some of the methods of heating where the use of the electricity is not confined to off-peak periods.

The first method that suggests itself is resistance heating by radiation or convection from hot wires or grids. Such a method is extremely adaptable and flexible, because heating elements can be placed in every room and can be regulated manually or automatically to give any desired temperature. The heating elements are also of simple construction so that the first costs are low and there is very little that can go wrong.

In the usual types of radiant heaters a hot wire is placed in front of a polished metal reflector or a refractory material, and the heat is radiated to the walls of the room and to objects in the room. The advantage of this type of heater is that a quick heat may be obtained locally, and it is possible to feel warm in front of a radiant heater even though the air itself is cool.

The convection type of heater is usually operated at a much lower temperature than the radiant type, and it is not at all necessary that the heater be visible in the room to be heated. The heat from the hot wires warms the surrounding air, which sets up convection currents, thereby distributing the heat to the room. This method of heating gives a fairly even distribution of heat, but it has the disadvantage that the top of the room is heated first.

The method of heating water by passing an electric current from one electrode to another through the water has been used in Sweden, but it has had no practical application in this country.

The use of a copper tube as the secondary of a transformer to heat water has not been used practically. It is entirely feasible, although no great advantages over other methods are apparent.

[3] The economic value of cleanliness is illustrated by the following extract from "The Sky's the Limit," by Henry Obermeyer, Assistant to the Vice-President, Consolidated Gas Company of New York: "For example, the annual gas bill for the average family in Chicago is $30. Going back to our figure representing per capita cost of the smoke nuisance at $17 per year, the prorated annual cost to each family in Chicago is over $65 a year. The smoke nuisance therefore costs Chicago families on an average more than twice what they pay for gas. Chicago could pay over three times its present gas bill and still not be paying as much as its present gas bill plus the cost of the smoke nuisance."

[4] "On the Economy of the Heating or Cooling of Buildings by Means of Currents in Air," by Lord Kelvin. Glasgow Phil. Soc. Proc., vol. 3, December, 1852.

[5] There are other kinds of heat pumps, such as a thermocouple with a cold and hot junction supplied with a direct current, and an arrangement of batteries maintained at different acid concentrations so that heat is transferred from one location to another, but neither of these methods is at all practical. See "Energy Problems in Electric Heating," by Otto Gunwolt, *Graz ETZ*, Sept. 27, 1928, vol. 39, pp. 1437–1441.

Another method of resistance heating involves the heating of water by immersion heaters. This method is mainly used in off-peak heating systems, and it will be discussed in that connection.

Unfortunately, resistance heating with present on-peak power rates is far too expensive to interest the majority of people in this country, although it is recognized that under special circumstances the advantages of electric heat would outweigh the higher cost. It is understood that in England several department stores[6] have been equipped to heat with electric-resistance heaters, but they have been able to get a rate of 1 cent per kw-hr., which is considerably lower than the present rates in this country for on-peak power to be used in homes. It is interesting to note that, although the actual cost of electricity at 1 cent kw-hr. was higher than the actual cost of coal, oil, or gas, the decision to use electricity was arrived at solely from financial considerations after the factors of cleanliness, depreciation, handling charges, convenience, etc., had been taken into consideration.

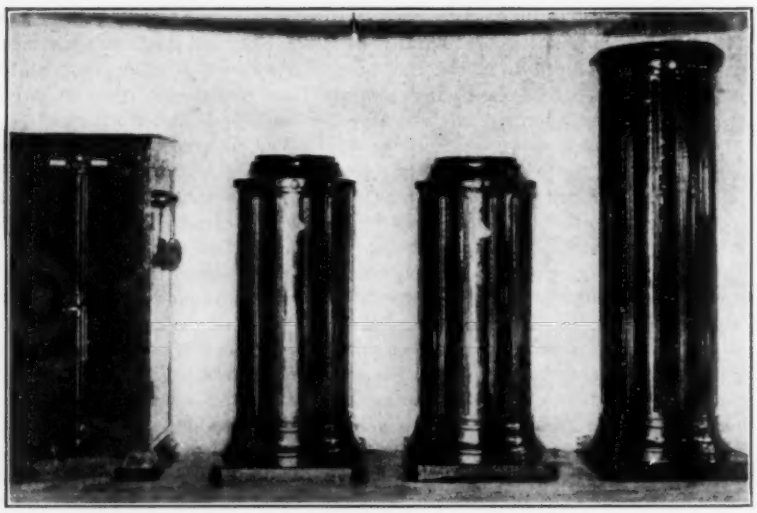

FIG. 1 THE FOUR STORAGE HEATERS USED IN THE CORK-INSULATED HOUSE

In this country, electric resistance heating has been installed in a few localities where power is cheap, principally along the Pacific Coast. It is a matter for speculation whether or not much progress will be made with this method of heating unless a rate of approximately 1 cent per kw-hr. for on-peak power should be established. Such places as gasoline filling stations, small stores, lodgerooms, clubrooms, churches, waiting rooms, etc., could probably use this form of heating most economically.

Within the past couple of years a number of experiments have been conducted to determine the feasibility of using electric energy off peak in order to obtain low power rates and of storing the heat generated to be used as it is required. The theory behind the use of off-peak power is as follows: The basic cost of electricity consists of fuel, labor, supplies, and investment costs. At low per cent load factors—i.e., when there are large peak loads and low average loads—the basic cost per kilowatt-hour is high. If an off-peak load can be introduced so that the off-peak demand never exceeds the on-peak demand, no additional investment is required and this item is excluded from the cost of generation of the electrical energy.[7] Consequently, the utility companies can afford to give a very much lower rate to customers using energy off peak.

There have been a number of actual installations of off-peak heating systems made recently. The results of a few experiments on off-peak electric heating and the results from a number of commercial installations were described in recent articles.[8]

Considerable work has been done in both an experimental and a commercial way by a new company[9] which was organized about a year ago to engage in the engineering, design, research, and sales of electrical devices for the heating of buildings, both of commercial and domestic forms, and for the heating of water for domestic purposes. Part of its program consists in cooperation with the electric utilities for the improvement of load factor and for the purpose of obtaining off-peak power rates sufficiently low to make electric heating economically justified.

One type of off-peak heating system developed in Germany and described by E. B. Dawson and I. F. Lamb[9] uses pea gravel as the storage medium. This type of heater was designed to be placed directly in the rooms to be heated. It apparently operated satisfactorily except that in the comparatively warm weather in the spring and fall it was difficult to keep from storing too much energy in the heaters. Fig. 1 shows the appearance of several of these heaters, and Table 1 gives some information from a German leaflet describing them.

The Hall Electric Heating Company has developed several systems of heating with off-peak power, and in the short time since it was organized it has successfully installed a number of various types of heating systems. These were in operation during the whole or part of last winter.

TABLE 1 STORAGE HEATERS IN INSULATED HOUSE

Rating, watts	Dimensions in inches. Height	Diameter	Net weight without gravel, lb.	Approximate list price[1]	Weight of gravel required, lb.
3000	51.7	23.6	353	$118	320
5000	71.5	23.6	467	157	485

[1] Based on an exchange rate of 23.80 cents per mark.

This company's system of off-peak heating consists of insulated water-storage tanks, electric immersion heaters, heat-transfer surfaces, and suitable control devices. The electric immersion heaters are automatically turned on during the off-peak period of the system, and the heat is stored in an insulated tank at 250 to 300 deg. fahr. The heat from the storage tanks is supplied thermostatically to the house as it is needed, either by circulating the hot water from the storage tank to conventional

[6] A very good description of one of these installations is given in a paper, "The Electrical Heating and Ventilation of Bourne & Hollingsworth Premises," by Arthur Henry Barker; excerpt minutes of the Proceedings of The Institution of Civil Engineers, vol. 22, 1928–29. "A Large Heating, Cooling, and Ventilating Scheme," the electrical installation which is running satisfactorily at the premises of Messrs. Bourne & Hollingsworth, *Electrical Review*, January 11, 1929.

[7] This is not quite exact, on account of the fact that the service connection with the transformer and sometimes a small portion of the primary system must be increased in capacity, if it is inadequate. Of course, the generating and main distribution system would not be involved at all.

[9] Hall Electric Heating Company, Philadelphia, Pa.

radiators in the rooms or by circulating air by forced draft through ducts to a finned-tube radiator placed near the storage tank.

The length of the off-peak period is determined by the characteristics of the load on the power station, but it usually lasts from ten to twenty hours and usually at night. In Fort Wayne, Indiana, for example, the power company allows customers to draw electricity at reduced rates from 9 p.m. to 7:30 a.m. and from 12 m. to 1 p.m. The off-peak period is determined by the power company, and it sets the control device in the heating system to give the desired results. The control contains a Telechron clock mechanism, which requires no winding, so that the heating system is entirely automatic.

Fig. 2 shows a typical warm-air installation by the Hall company in a home of average size, and Fig. 3 shows the interior construction of the warm-air heating system. It is claimed that it is possible to use only four warm-air pipes in this system as contrasted with twelve in a furnace installation. Also, owing to the forced circulation of air, no pitch is required, thus giving maximum headroom.

When a house is being constructed, a system can be adapted as shown in Figs. 4 and 5, thereby eliminating the necessity of a basement and reducing the duct work to a minimum.

Knowing the cost of fuel or electricity at any place and knowing the efficiency of the conversion into heat, it is possible to compute the amount of heat energy that can be obtained for a given sum of money. Of course, the price of fuel varies greatly

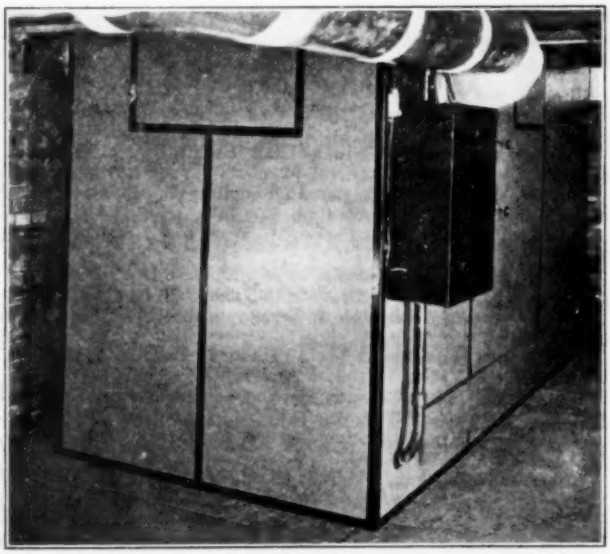

FIG. 2 TYPICAL HALL COMPANY WARM-AIR INSTALLATION

from place to place, and the efficiency of conversion into heat is never constant from day to day even in the same plant. The efficiency of conversion is influenced by the type and size of furnace, the frequency and method of firing, the size and cleanliness of the chimney, the weather, and many other factors, so that any estimate that is made will be subject to considerable variation.

Such figures indicate that electric off-peak heating systems using electric energy at 1 cent per kw-hr. are usually somewhat more expensive than coal or gas, from a heat energy standpoint. However, in considering this matter further, perhaps it may be shown that it is possible to make electricity more attractive from a cost standpoint.

When the Hall Electric Heating Company installs a heating system, it endeavors to do or to have done the following things:

1 Insulate the house with some form of insulating material and add storm doors and windows.

2 Automatically control the temperature in the house so that the temperature never becomes excessive at any time.

3 Reduce the temperature from 70 deg. fahr. in the day time to 55 deg. fahr. in the night time.

4 Instruct the occupants of the house to keep doors and windows closed as much as possible and to shut off bedrooms from

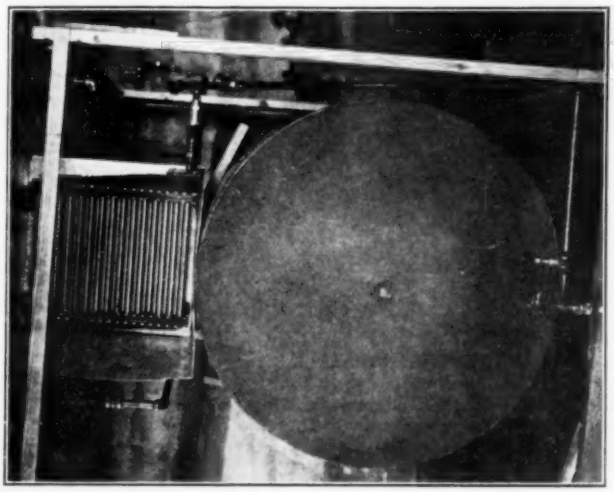

FIG. 3 INTERIOR CONSTRUCTION OF WARM-AIR HEATING SYSTEM (Storage tank, radiator, expansion tank, and sheet-metal work shown.)

the rest of the house when bedroom windows are opened during the night.

By thoroughly insulating a house it is possible to reduce the heating requirements by one-half, so that with the other savings effected the total cost of electricity for an off-peak heating system is not greatly in excess of the cost of coal, and perhaps somewhat less than the cost of gas. Of course, it may be reasoned that these savings could be applied to other heating systems and that consequently the electric method is unfairly favored. The fact remains, however, that in the majority of cases none of these savings would be effected with the usual type of heating system; therefore, if the company which installs electric heating can effect these savings, at least some part of the savings should be credited to the electric system.

The fact is or should be well established that the cost of heat energy is not the only factor entering into the operating cost.

When coal is used, a charge should be allowed for as handling and for labor involved in firing the furnace. The soot and dirt from a coal-burning installation will make it necessary to refinish the house and clean the draperies more often, and this should be taken into consideration. The factors of convenience, cleanliness, and reliability are important but hard to evaluate.

Besides the operating charges mentioned, there are the fixed charges, which include depreciation, interest on the investment, heating-plant insurance, and taxes.

With the electric method of heating the following advantages are claimed:

1 Absolute cleanliness throughout the house, as there are no products of combustion.

2 Absolute safety.

3 Complete automatic control.

4 Quick heating. It is said that the house can be raised from 55 deg. to 70 deg. at a predetermined time in the morning in about fifteen minutes.

5 No fuel storage.

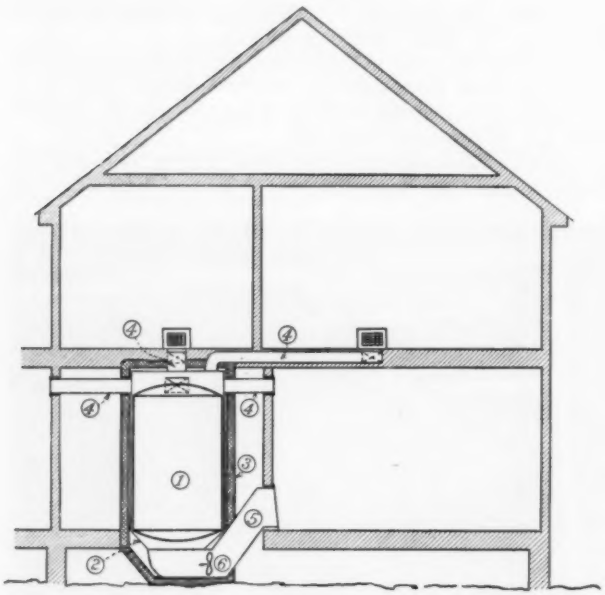

FIG. 4 ELEVATION DIAGRAM OF HOME OF SPECIAL DESIGN FOR APPLICATION OF ELECTRIC-HEATING WARM-AIR SYSTEM

(1, heat-storage tank; 2, sheet-metal casing to provide for passage of air over tank; 3, insulation inclosure around storage tank; 4, hot-air ducts to different rooms; 5, cold-air intake; 6, fan for positive circulation of heat.)

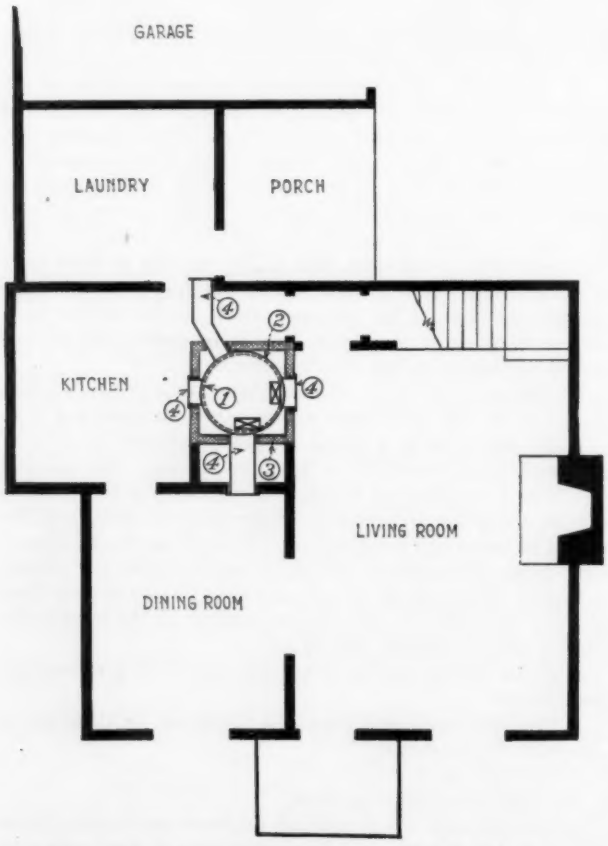

FIG. 5 PLAN VIEW OF HALL COMPANY HEATING SYSTEM

(1, heat-storage tank; 2, sheet-metal casing to pass air over tank; 3, insulation inclosure around storage tank; 4, hot-air ducts to different rooms.)

6 No labor required to operate the heating system.

7 Since electric heat uses no oxygen from the air and since there are no products of combustion, it should be the most healthful form of heat.

It is not claimed that off-peak electric heating is going to revolutionize present methods of heating with coal, oil, or gas. Even though this method were cheaper than all other methods, there is the limitation that a power company can supply only a limited amount of off-peak energy because beyond that amount the energy becomes on peak. This is easily illustrated by an example. The average utility company will have a load factor[10] of approximately 45 per cent. Any energy sold off peak which creates a peak higher than the normal peak cannot be sold economically at off-peak power rates. It is estimated that about 2 per cent[11] of all the wired homes could be equipped with off-peak electric heating systems before the load factor reached its maximum practical value. This gives a potential market of about 400,000 installations in the United States based on present statistics.

It is recognized that electric heating is more expensive from a heat-source standpoint than other methods of heating, but in view of the extra advantages obtained, it would appear that it should be possible to sell a large number of this type of heating system.

Off-peak electric heating of homes is new in the United States, although it has been used for a number of years in several European countries. On-peak electric heating has had a limited application in this country, although in one or two localities it has been used extensively.

Discussion

CHESTER I. HALL.[12] The heating of our homes and our workshops has been a pressing need for a great many years.

[10] Yearly load factor is the ratio of the average load in a year to the peak load in a short interval of time, usually fifteen minutes.

[11] This is a hard figure to determine accurately. Others who have studied this subject thoroughly believe that 5 per cent is a more representative figure. The smaller figure is used in order to be ultra-conservative.

[12] President, Hall Electric Heating Company, Inc., Philadelphia, Pa.

Throughout history the various stages of development of civilization have been marked by significant changes in the home-fire.

The use of fire for its heat-giving qualities started with the use of the campfire back at such an early date that its origin is lost in antiquity. Even at a later date when more permanent homes began to be built, the fire was built in the middle of the room with only a hole in the roof to allow the smoke to escape.

Through ages the heat-giving fire has been merely transferred in succession from one type of primitive home to the next through a long period of gradual improvement in the home-building art. The introduction of the fireplace in England marked an important stage in the effort to improve home-heating facilities. Improvements in fireplace heating continued until in 1774, when Franklin invented the iron stove, which marked another era in the history of fire in the home.

The next major development marked the moving of the fire to the basement to eliminate soot, smoke, dirt, and obnoxious gases in an effort to make the home more healthful and more attractive. Most of the efforts of our present day have been devoted to the improvement of the basement heater, and have resulted in the development of the modern warm-air, hot-water, and vapor systems, all burning fuel in the basement, and still unsatisfactory from the standpoint of efficiency, cleanliness, safety, healthfulness, and ease of operation.

Along with the advent of the telephone, the radio, the automobile, the airplane, and many other modern devices have come the many appliances and developments which have improved the living conditions and removed the drudgery from the home. But our heating systems have not kept pace with this development. Raw fuel is still delivered to the home and burned within the house, even while industrial plants are eliminating the furnace and the boiler in an effort to obtain improved conditions in our workshops.

But a new era in the art of home heating is dawning. The recent development of a new system of electric heating, using cheap off-peak energy by means of a storage principle, is destined to free us of the primitive practice of combustion in the home, and we now have available heat in the fall by the simple snap of a switch, perfectly controlled by a small, rugged, attractive, accurate thermostat, placed on the wall in the living room, and there is no combustion, no soot, no dirt, no insidious gases, and no elimination of the health-giving oxygen and other air vitamins, no cares of coal and ashes. The pure, unadulterated heat in the electrical form is delivered to the home by wire from the waterfalls or the base of coal supply.

H. S. Vassar.[13] The authors of this paper have clearly indicated the two principal methods of applying electricity to domestic heating; i.e., (1) the direct conversion of electricity to heat, and (2) as energy to drive a heat pump. Somewhat naturally they have dismissed the second method with but a single paragraph because no commercial application of the principle as applied to domestic heating has been made up to this time. I also note that their bibliography contains no reference to the experimental work of a French engineer[14] tending to indicate not only the practicability of such an application but also a coefficient of performance, or apparent efficiency, so far in advance of the direct conversion method as fully to warrant thorough investigation.

Such a development might be based on the two following well-established facts: (1) That we are surrounded by an unlimited supply of heat which requires only a change in thermal level to make it available for man's use, and (2) that it is possible to "pump" heat from a lower to a higher temperature level.

The fact that the ideas on house heating advanced by Lord Kelvin so many decades ago, up to now have not been commercially applied, in itself indicates nothing. A similar period elapsed after the beginnings of mechanical refrigeration before there was a great flood of domestic refrigerating machines by which we are now surrounded.

If it is practicable to pump heat from a refrigerator, and discharge that heat against the higher temperature of the room in which the refrigerator is located, why is it not equally practicable to pump heat from outdoors and discharge it into the house? If the present limitation is simply one of apparatus, will not intensive development remove that limitation?

The French engineer already referred to states that it is theoretically and practically possible to obtain upward of 16,000 B.t.u. by the expenditure of one kilowatt-hour when used as energy to drive a heat pump, as against the maximum of 3145 B.t.u. obtainable by direct conversion, a ratio of more than four to one in favor of the heat pump principle.

Until disproved, this statement in itself should be sufficient to stimulate development along these lines, particularly in view of the fact that if suitable equipment should be designed to apply the heat-pump principle to domestic heating, it also could be used for house cooling.

One of the authors of this paper in a recent address before the Franklin Institute, Philadelphia,[15] made the following statement:

"Approximately four times as much heat on the average can be delivered to a house by a refrigerating machine pumping heat from outside than by using the same amount of electric power in resistance heating units."

Charles Lamb in one of his essays tells the story of some early experiments in the application of heat to domestic problems. Perhaps in years to come we may look back upon the direct conversion of high-grade energy into heat with something of the amusement with which we view Ho-ti and his neighbors burning down a home when they feel a yearning for roast pig.

Authors' Closure

This paper did not discuss in detail the use of electricity as energy to drive a heat pump for the reason stated that no commercial application has been made as yet. H. S. Vassar is quite right in saying that development of this principle should not be retarded or governed because of the fact that the principle was stated by Lord Kelvin as far back as 1852, just 77 years ago.

About a century ago Carnot stated the following law:

$$C = \frac{T_1}{T_2 - T_1} = \frac{\text{Refrigerating effect of } T_1 \text{ deg.}}{\text{Work to pump the heat to } T_2 \text{ deg.}}$$

where C is known as the Carnot coefficient of performance and the temperatures are expressed in degrees absolute.

Assume the condition of a refrigerator operating as a house heater when the house temperature is 70 deg. fahr. and the outside temperature 25 deg. fahr. In order to transfer heat it is necessary to have a temperature differential, hence assume the condenser at 100 deg. fahr., and the evaporator at 10 deg. fahr. The coefficient of performance is then

$$C = \frac{T_1}{T_2 - T_1} = \frac{459.6 + 10}{100 - 10} = 5.22$$

To this may be added the motor input, which will make the

[13] Bloomfield, N. J. Mem. A.S.M.E.

[14] "The Practical Possibilities of Using Energy for the Combined Production of Heat and Refrigeration," by M. Lebre, Society of Civil Engineers of France, vol. 80, no. 5, May, 1927, pp. 669–708.

[15] "Refrigeration," by A. R. Stevenson, Jr., Journal of Franklin Institute, August, 1929, p. 185.

ratio of heat delivered to the heat equivalent of the electric input equal to 6.22. It must be remembered that this ratio can only be obtained by an ideal machine, and cannot be obtained in practice. Assuming a reasonable efficiency it is apparent, however, that the ratio of heat delivered to the house will be considerably more than the heat equivalent of the electrical energy supplied.

The use of a refrigerator to heat a house is possible today with existing equipment, but it will not be commercially successful until the many practical difficulties are overcome. The principal reasons for the failure to use refrigerating machines as heaters may be noted as follows:

1 No suitable refrigerating machine with the necessary characteristics of quietness, lack of vibration, and freedom from service has yet been developed in large enough sizes (5 hp. to 25 hp.).

2 The cost of electricity in most localities has been too high until recently to make this method of heating compare favorably with existing methods. Perhaps also we have all been somewhat blind to the economic possibilities already here with the gradual introduction of lower rates for electric ranges, hot-water heaters, and domestic refrigerators.

3 Special precautions would have to be taken to prevent the refrigerant, in case of a leak, from getting into the ventilating system, and thus rapidly contaminating the air of the whole house, unless apparatus can be developed to utilize a really harmless refrigerant.

4 The development of a complete system for using a refrigerating machine both for heating and cooling is a task involving so many problems that it cannot be undertaken lightly.

Although some of the difficulties enumerated above appear formidable, it is probably not impossible to overcome them. It seems probable that the limitations of this type of heating and cooling system could be overcome by intensive development as Mr. Vassar suggests. However, on account of the fact that the coefficient of performance of a refrigerating machine decreases with increase in temperature differential between the evaporator and condenser, this system of house heating is not as attractive in the north as in the south.

FSP-52-21

Liquefied Petroleum Gases as Industrial Fuels

By R. W. THOMAS,[1] BARTLESVILLE, OKLA.

THE OBJECT of this paper is to show (1) the general availability and the assured continuity of supply of large quantities of liquefied petroleum gases, (2) the adaptability of these fuels for exacting industrial processing such as heat treating and other operations of a highly refined nature, and (3) the advantages and limitations of liquefied petroleum gases in industrial fields, particularly from the economic viewpoint.

Ideal materials are ofttimes regarded as imaginary, fanciful, or impracticable, but however nebulous most so-called ideal commodities may be, all engineers recognize certain characteristics of an ideal fuel.

Such a fuel must be gaseous so as to be easily confined, transported, and controlled, and to permit a maximum quantity of heat to be released in a minimum combustion space in the shortest length of time. It must be free from foreign or deleterious substances and from corrosive constituents. It must have combustion characteristics that adapt it to the multitudinous demands of hundreds of industries and thousands of processes. It must be uniform and unchanging in composition to insure like results under like conditions. It must be generally available and in practically unlimited quantity, regardless of the point of use. It must possess flexibility and universal adaptability, and it must be economical in use. Such a fuel will naturally produce results superior to those obtained with ordinary fuels, and will therefore find a large and honored place in industry.

Practically every one will concede that natural gas most nearly fills these specifications. However, it is not generally available, the supply is not always adequate, and impurities such as hydrogen sulphide are ofttimes present.

We must then search further for a fuel approaching this ideal. Coal has availability, distribution, and economy in its favor, yet one recognizes its limitations for the higher classes of thermal processing, upon calling to mind the enormous investments and the high capital and operating costs involved in converting it to coke, to coal gas, water gas, and other more adaptable and therefore more valuable classes of fuel. Producer gas has its serious limitations, coal-gas production lacks the flexibility demanded by industry, and water gas not only presents the carbon-monoxide hazard but usually requires carburetion. All of these gases are inherently variable in composition, specific gravity, and calorific value, although these handicaps are minimized by judicious mixing in holders or by frequent adjustment of the combustion apparatus in use.

Oil is generally available and is usually more economical per unit of heating value than the higher forms of fuel evolved from coal, but it suffers by comparison with the ideal. It is not gaseous, it requires a large volume of combustion space, it is variable in quality, it usually contains sulphur compounds, and its precise control offers difficulties.

Liquefied Petroleum Gas

A secondary product originating in natural gas, and in "casing-head gas" produced with crude oil, is now attaining prominence because it fulfils many of the specifications of the "ideal" fuel. It produces large-scale commercial results equal to and often better than those obtained with natural gas in every respect save that of cost.

Origin. There are certain of the paraffin hydrocarbons that occupy that zone intermediate between the so-called permanent gases and the liquids, and which carry the generic name "liquefied petroleum gases." These are too volatile, if liquefied, to be of much practical value when included in the motor-fuel fraction. If allowed to remain in natural gas in quantities, they are likely to cause difficulty by condensation under high pressures and low temperatures. Their very physical properties which make them undesirable as components of gasoline or of natural gas are capitalized when the various fractions are segregated, as their transportation in concentrated form as liquids in pressure containers is followed by their advantageous utilization as true gases.

TABLE 1 PRINCIPAL PHYSICAL AND CHEMICAL PROPERTIES OF COMMERCIAL PROPANE AND BUTANE

	Lb. per sq. in. gage	
Vapor pressure	Propane	Butane
at 70 deg. fahr	120	33
at 90 deg. fahr	165	53
at 100 deg. fahr	195	65

B.t.u. per lb	186	170
B.t.u. per gal.	788	830

Properties. Chemically speaking, propane and the butanes (normal and iso-butane) constitute the predominant compounds in all of the definitely established grades of liquefied petroleum gas. Practical consideration of their properties has divided these products into two classes, the "propane" and the "butane" grades. There are shown in Table 1 the important properties of these two commercial grades of liquefied petroleum gas referred to as "propane" and "butane."

The properties shown in the table are those found by actual determination and careful research of these two products. For all practical purposes these grades can be considered as commercially pure propane and commercially pure butanes. Each of them is exceptionally uniform in composition and quality. The study of the properties of the products has been so complete that the behavior of either of the grades under the wide variety of conditions encountered in actual usage can be predetermined with a degree of accuracy much higher than that found in usual

[1] Vice-President and General Manager, Philfuels Company.

Presented at the Third National Fuels Meeting of the A.S.M.E. at Philadelphia, Pa., Oct. 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

engineering calculations. Fig. 1 shows graphically the temperature-pressure relations of several commercial grades.

Potential Supply. Propane and butanes are found abundantly in natural gases from gas wells and oil wells and are, of course, also present in large quantities in refinery gases resulting from oil-distillation processes. The natural-gasoline industry, however, constitutes the only source of liquefied petroleum gases worthy of consideration at present. This is due to the fact that the natural-gasoline industry has always disposed of the major portion of the volatile fractions, suitable for liquefied petroleum-gas manufacture, in motor fuel. There is a definite limit to the percentage of this volatile material which can be absorbed by motor fuel.

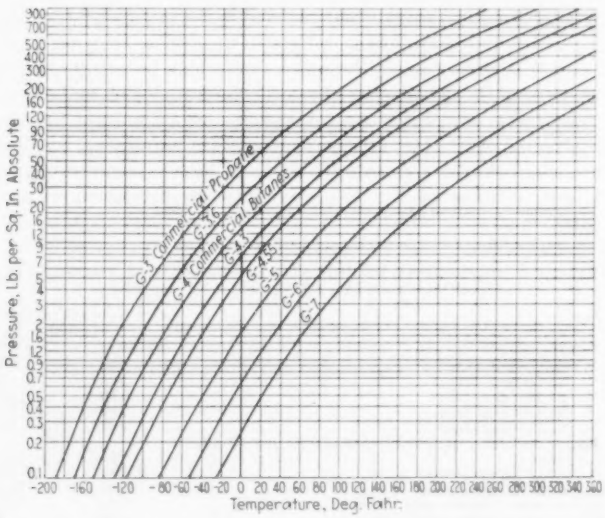

FIG. 1 VAPOR-PRESSURE-TEMPERATURE RELATION OF LIQUEFIED PETROLEUM GAS

The increased use of oil-cracking processes by the refiners is known to favor a demand for still more stable grades of natural gasoline, thereby augmenting the supply of liquefied petroleum gases available from the natural-gasoline industry. The average motor fuel contains 0.4 per cent of propane and 4.0 per cent of butanes. The average daily consumption of motor fuel during 1928 was approximately 38,500,000 gal. This means that the motoring public last year daily consumed about 1,700,000 gal. of liquefied petroleum gas in its motor fuel. Statistics indicate that as a very conservative estimate there is a daily potential production of at least 13,000,000 gal. of liquefied petroleum gases from the natural-gasoline industry. However, this large supply is not immediately available. To begin with, the design and operation of the average natural-gasoline plant are such that only a portion of the potential supply is extracted along with the raw natural gasoline. Another consideration in regard to the availability of liquefied petroleum gas lies in the fact that its production is accomplished more economically at the larger natural-gasoline plants. The amount of liquefied petroleum gas removed from the raw natural gasoline in preparing it for the market is about 1,500,000 gal. daily, of which about 50 per cent is propane. Probably 50 per cent of this immediately available supply exist at plants too small economically to justify equipment necesssary for the further separation of the liquefied petroleum-gas products. This means, then, that there is available a supply of about 750,000 gal. daily which will undoubtedly find markets at existing competitive prices. When economic conditions justify, the supply of liquefied petroleum gases will be increased in proportion to the price level of the commodity. Table 2 presents some pertinent data covering the growth of the natural-gasoline industry, and gives a picture of the rapidly increasing supply of the raw material from which the liquefied-petroleum gases are segregated.

Manufacture. Liquefied-petroleum gases are manufactured from the "wild" raw natural-gasoline feed stock by the application of the well-known principles of rectification to large-scale production, resulting in accurate separation of the original components. Fig. 2 shows three liquefied-gas rectifying columns.

Uses. The known commercially practical uses of liquefied petroleum gases can be briefly summarized as follows:[2]

1 Domestic fuel transported in cylinders, thus supplying gas to districts not having that service. This use is a valuable ally to the gas companies as outlying districts can be serviced and held against encroachment by electricity or other fuels, pending gas main extensions. Commercial propane, being self-vaporizing at all temperatures above minus 40 deg. fahr., is the most applicable and most widely used fuel for this "bottled gas" service.

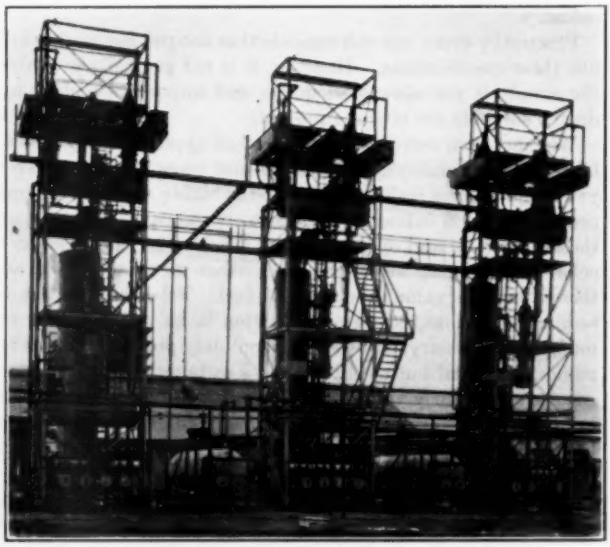

FIG. 2 RECTIFICATION COLUMNS MANUFACTURING LIQUEFIED PETROLEUM GAS

2 Industrial gas for various heating operations when the fuel consumption is large, and where an economical but clean and easily controlled fuel is necessary. This phase of utili-

[2] R. W. Thomas and O. M. Setrum, "Commercial Propane and Butanes in the Manufactured Gas Industry," p. 1284, American Gas Association, 1928 Proceedings.

zation, unless the marketing is controlled by the utilities themselves, is in direct competition with the industrial-fuel sales efforts of the gas companies. Commercial butanes are best adapted to this exacting large-scale use.

3 Enricher for manufactured gas in place of gas oil to carburet producer gas, blue-water gas, or other gases of relatively low thermal value to the required calorific standard. The efficiency of "cold carburetion" is 100 per cent. Commercial butanes are most applicable here, due to their favorable physical characteristics.

4 Base material for manufactured gas.

a Carbureting gases of little or no calorific value, these acting as diluents or carrying mediums. Exhaust or flue gases, or air are the materials commonly used

b Reforming or cracking high-calorific-value liquefied petroleum-gas vapors to produce low-density gaseous fuel of the desired B.t.u. content. Although the use of any of the standard grades is practical for either of the foregoing operations, nevertheless the commercial butanes offer outstanding advantages and economies.

5 Commercial solvents.

6 Raw materials for the manufacture of chemical compounds.

Industrial Fuel Uses

Grade. Consideration of the physical properties of commercial butane indicates that this grade is better adapted for economical transportation, storage, handling, and use than is the case with the more volatile propane fractions. Butane is favored with a low vapor pressure, averaging from 10 to 50 lb. gage within the usual atmospheric temperature range, and likewise has an advantage over propane in a higher concentration of heating value per gallon of liquid or per cubic foot of vapor. Only the butane grade will be considered herein, and the word "butane" will describe the commercial grade rather than the chemically pure compound.

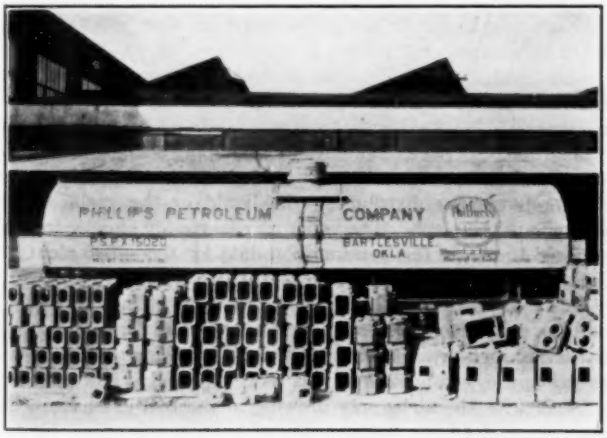

Fig. 3 Class 104-A Tank Car for Butane Transportation

Transportation. Butanes are shipped in class No. 104-A tank cars of special heavy construction to withstand the specified 100-lb. test pressure. The safety valves are set at 75 lb., and the cars are insulated with 4 in. of cork lagging covered by a metal jacket. Fig. 3 shows such a car. It will be noted that no bottom outlet connection, no dome, and no removable dome cover are provided. All fittings are mounted inside a protective housing on a cover plate bolted to a nozzle at the top of the car. Outage or expansion space is left in the tank when the car is loaded. The ordinary shell capacity is 10,500 gal., and about 10,000 gal. or 48,000 lb. are actually shipped. Unloading is provided for by eduction pipes extending from the valves on the top cover plate to sumps in the bottom of the shell. All outlets are equipped with upward-seating check valves which close when the rate of flow exceeds a safe point, thereby insuring against loss of contents in case the dome valves or fittings are damaged or unloading connections accidentally broken. As the contents are at practically all times under pressure, the liquid level in these cars is determined by a graduated tube passing into the tank through a stuffing box, equipped with a needle valve at the upper end, and provided with an accurate vertical adjusting device.

Liquefied petroleum gases are shipped in tank cars under the

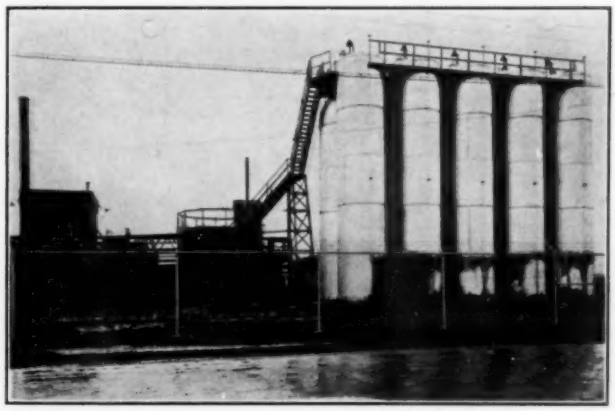

Fig. 5 Recent Installation for Butane Storage

refined-petroleum-products freight rates, which are based on the arbitrary weight of 6.6 lb. per gal. irrespective of the actual weight of the commodity. Table 3 gives the present rates from shipping points in Oklahoma, Group III, to various localities.

Butane is easily and economically unloaded from tank cars to storage tanks by the most convenient of the following methods: (*a*) Temperature differential, (*b*) pressuring with gas or air, and (*c*) pumping. Cars can be unloaded in slightly over one hour, and the cost is negligible, ordinarily being less than $0.0005 per gallon.

Storage. Storage tanks are usually of the horizontal cylindrical type, either riveted and hammer calked, riveted and electrically calked, or fusion welded. It is recommended that these tanks be designed in accordance with section VIII of the A.S.M.E. Boiler Code, and made for a working pressure equivalent to the vapor pressure of commercial butane at 100 deg. fahr. or about 65 lb. Tanks should preferably be installed above ground for convenience, but may be placed underground to satisfy special or local conditions. They are equipped with safety valves, drains, thermometers, gage glasses, or slip-tube gaging devices, and sometimes heating-tube bundles, in addition to the inlet

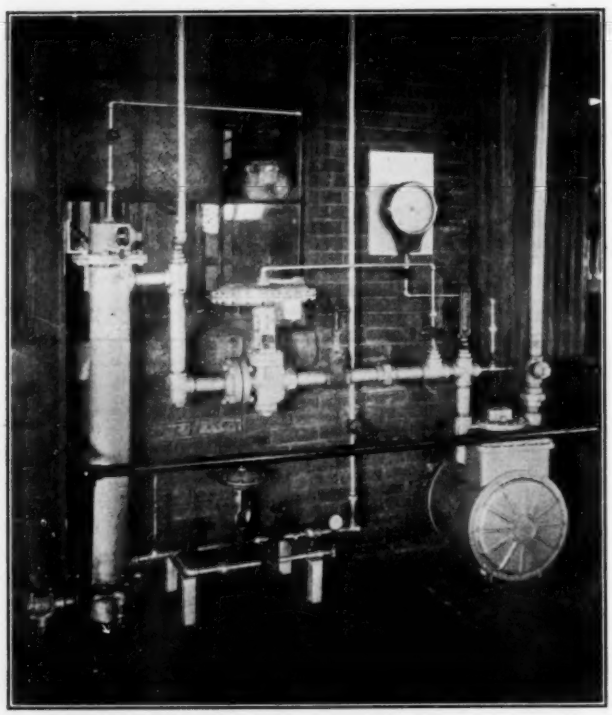

FIG. 6 BUTANE VAPORIZER AND REGULATORS

and outlet liquid and vapor lines, etc. Figs. 4 and 5 depict some recent butane storage installations.

Vaporization. Liquid butane must be provided with its latent heat of vaporization of 170 B.t.u. per lb. before it will evaporate. The level at which this heat is supplied can be as low as 32 deg. fahr. if vaporization takes place at atmospheric pressures. A multitubular vaporizer is ordinarily used, and the heat is supplied by hot or cold water or by exhaust steam. Fig. 6 illustrates a typical vaporizer and regulator installation. It will be noted that the pressure on the liquid from the storage is stepped down to a few pounds by means of a regulator ahead of the vaporizer, and that the uniform butane vapors resulting from the flash vaporization of the liquid are further reduced to gasoline or burner pressure by a final pressure governor. The vapor

TABLE 4 APPROXIMATE LIMITS OF INFLAMMABILITY OF GASES AND VAPORS IN AIR AT ORDINARY TEMPERATURES AND PRESSURES[1]

Gas	Lower limit by volume per cent	Higher limit by volume per cent

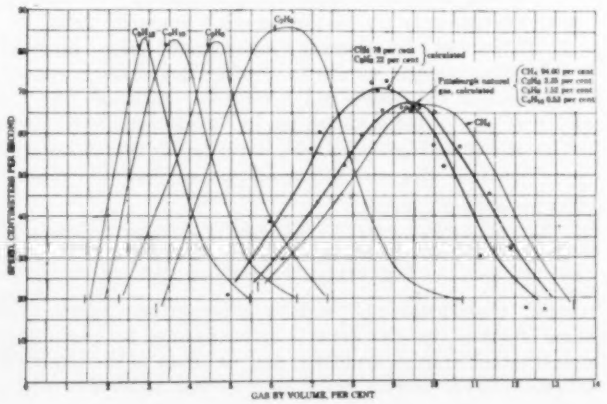

FIG. 7 SPEED OF UNIFORM MOVEMENT OF FLAMES IN A 2.5 CM. TUBE

(Taken from U. S. Bureau of Mines bulletin No. 294, "Carburetion of Combustible Gas With Butane and Propane-Butane Mixtures," by W. W. Odell, page 17.)

(3200 B.t.u. per cu. ft.) may be piped any distance at moderate pressure provided it is not cooled below its dew point (26 deg. fahr. at atmospheric pressure). The cost of vaporization is nominal and obviously depends on the heating medium used, but in any event is much less than the expense of heating and pumping fuel oil. With exhaust steam at $0.0008 per pound, the cost is about $0.0007 per gallon. No fuel-pumping charges are necessary as the vapor pressure of the liquid butane provides the motive power for distributing the liquid or the gasified fuel throughout the plant. The vapor may be readily and accurately metered to obtain fuel-consumption data for the entire plant or for tests on individual furnaces.

Burners. Owing to the high calorific value of butane vapors, and the consequent large amount of air required for combustion, the use of high-pressure burners where the flowing stream of gas entrains the combustion air is not practical. Low-pressure burners with the air supply drawing in the fuel gas have been very successful for a large variety of heating operations. Automatic premix types and hand-controlled premix-burning equipment have likewise shown their adaptability to handle this high calorific value fuel.

The combustion equation for butane is $C_4H_{10} + 6.5\ O_2 = 4\ CO_2 + 5\ H_2O$. It is apparent that 31.1 parts of air (O_2 = 20.9 per cent) are necessary to afford complete combustion of one volume of butane vapor, and that five volumes of water vapor are given off per unit volume of butane.

The inflammability limits of various gases mixed with air at atmospheric temperatures and pressures in large vessels are given in Table 4. The rates of flame propagation of several industrial gases mixed with air are shown in Fig. 7. It will be noted that the inflammability limits of butane in air are somewhat narrower than those of methane or natural gas, and very

much less than the limits on any of the manufactured gases. The maximum rate of flame propagation of butane in air (32 in. per sec.) is slightly greater than that of an average natural gas, but only one-half as much as the rate on typical carbureted water gas (64 in. per sec.). These factors make for safety in the handling and use of butane vapors, and permit combustion conditions and furnace design to be almost identical with natural-gas practice. On burners adapted for manufactured gases butane vapors

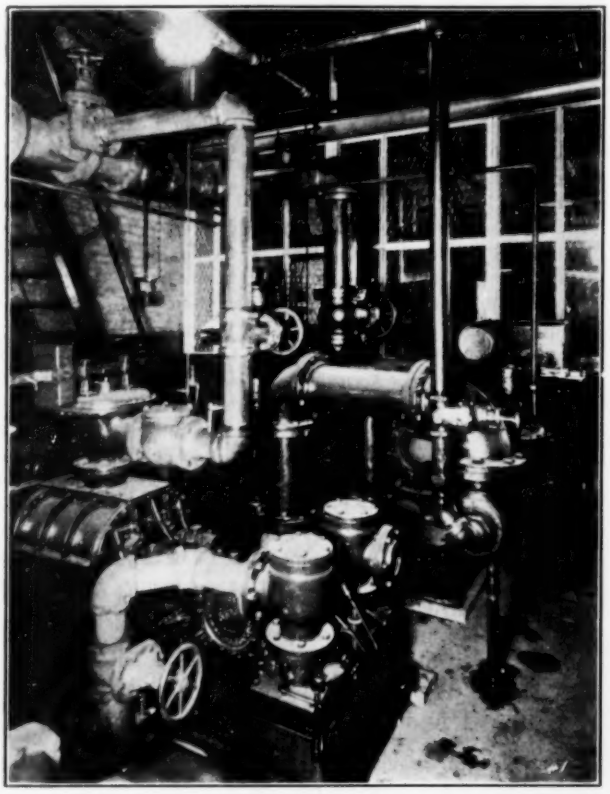

FIG. 8 AUTOMATIC BUTANE-AIR PREMIX MACHINES

will blow off the nozzles or tips owing to the lower rate of flame propagation. However, no difficulty is encountered in purchasing excellent butane-air mixing devices and burners from any of the prominent manufacturers, or in adapting practically any existing low-pressure or premix burners for proper combustion of butane.

Advantages. The unexcelled uniformity of composition of commercial butane liquid, and of the gas resulting from the flash vaporization thereof, coupled with the available gas-air proportioning devices and burners, results in an unparalleled ease of temperature regulation and furnace atmosphere control. These advantages plus the absence of sulphur compounds, dust, water, tar, gums, or other fuel contaminations insure constant furnace conditions, and make possible a hitherto commercially unattainable regularity of production with a minimum of interruptions and a negligible number of rejections or damaged stock.

The fact that each user of butane has in effect a private gas plant, insures against interruptions to the fuel supply and avoids periods of low pressure or insufficient quantity. Peak fuel loads can be carried without the penalty of a demand charge, and without pumping or boosting the gas.

Gas-piping sizes are much smaller when the high calorific value butane is used than is the case with manufactured or even natural gas. Fig. 8 illustrates this point. The 3-in. line carries

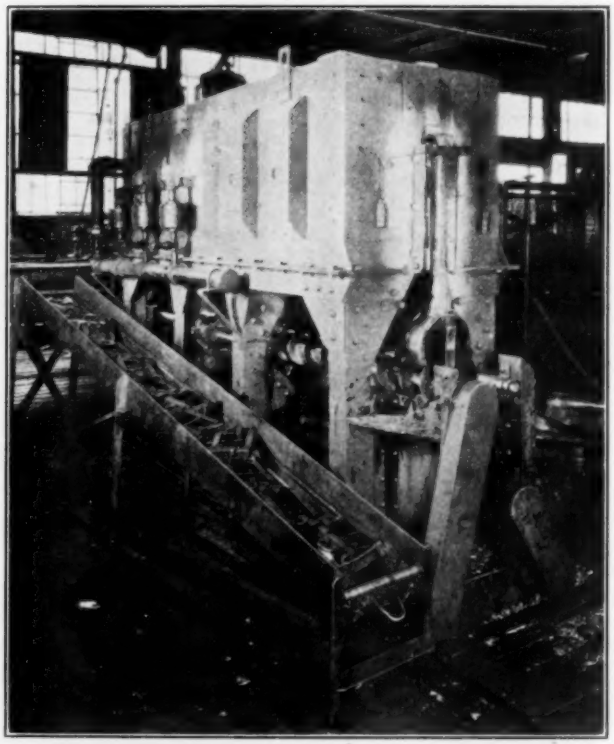

FIG. 9 CONTINUOUS BUTANE-FIRED FORGE FURNACE

butane vapors to a premixing machine formerly used on city gas. The old 8-in. manufactured gas main connected to the same machine can be seen and contrasted.

A tremendous gas reserve can be cheaply maintained in storage. One 15,000-gal. tank costing $2500 installed will ordinarily be filled to 14,500 gal. or 1,484,800,000 B.t.u. This is equivalent to 2,800,000 cu. ft. of 530 B.t.u. gas. The cost of a conventional low-pressure holder for this amount of gas would run in the neighborhood of $200,000. Any gas-fuel user would consider himself fortunate were he formerly able to afford such a fuel reserve.

Industries where refined heating operations are conducted, and where gas fuel is practically a necessity, can now locate their plants to take advantage of low labor costs, better employee living conditions, low real estate values, and other allied advantages, when they were formerly forced to operate in the congested territories already served with gas.

Butane manufacturers are offering long-term flat-price contracts with commitments up to five years. Other agreements are entered into at a fixed differential above gas or fuel-oil markets with minimum price stipulations. Continued execution of such contracts indicates the stability of the liquefied petroleum-gas industry and implies its vigorous growth and long life.

The application of butane to industrial uses sometimes builds up a competitive fuel-buying situation that is often used to advantage by the gas, butane, or oil purchaser, and tends to force each fuel into its natural field of activity where its value in terms

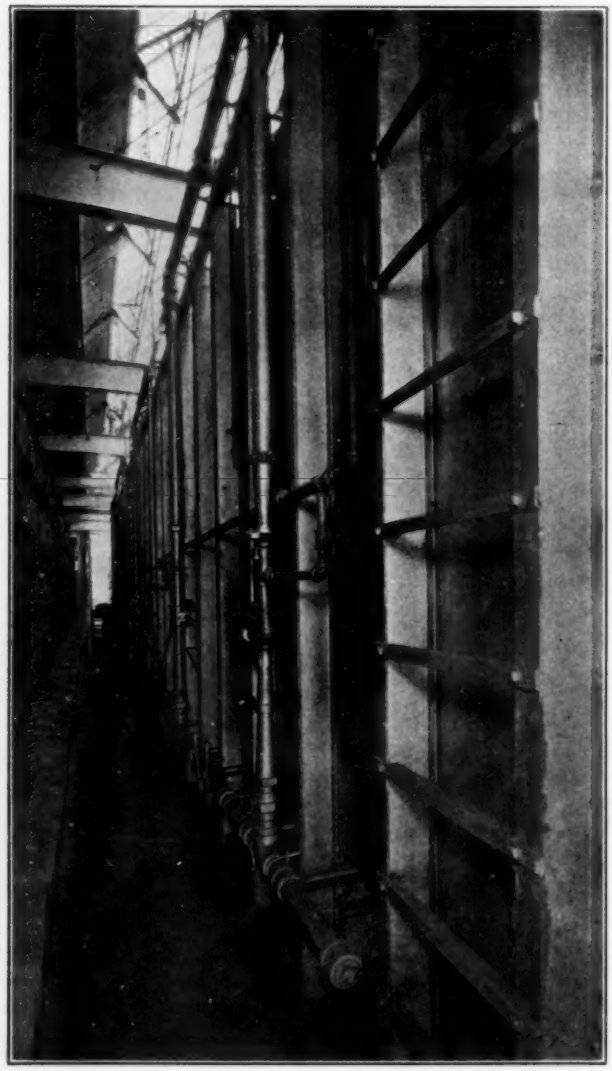

FIG. 10 BUTANE-FIRED TUNNEL KILN MALLEABILIZING CASTINGS

of finished production is greatest, and its economies most pronounced.

Fuel Cost. Butane is ordinarily sold in tank-car lots in the manufacturer's cars f.o.b. the shipping points, which are practically all at present located in Oklahoma and Texas. The price ranges from $0.04 to $0.07 per gallon in cars, or from $0.39 to $0.69 per therm, depending on the quantity contracted for. It is obvious that the freight rates to destination are a controlling factor in the economies of butane use. The freight rates (see Table 3) vary between $0.02 and $0.05 per gallon, with an average of perhaps $0.035 per gallon to points of use in the Mississippi valley and Great Lakes industrial districts. Adding a storage and handling charge of $0.002 per gallon, which is ordinarily found to be ample, a total average addition of $0.037 per gallon may be used. A strictly thermal comparison between butane and 530 B.t.u. manufactured gas results in the cost relations shown in Table 5. Needless to say, the purchase of manufactured gas for industrial use at 30 to 60 cents per thousand is ordinarily considered attractive. The use of butane, with its several advantages over other gaseous fuels and at the indicated delivered costs, presents an even more attractive picture, and will command increasingly greater attention from large-scale users of clean, high-grade, economical, and easily controlled fuels.

Disadvantages. The primary disadvantage encountered in the use of butane lies in the necessity for making a capital expenditure for liquid storage. A minimum 15-day fuel supply is ordinarily recommended. The cost of completed storage will average $0.18 per gal. exclusive of real estate, but including the vaporizer and regulator equipment. If this storage is filled and emptied 18 times per year (each 20 days) the storage cost is $0.0015 per gal. based on a 15 per cent annual capital charge. The lack of available space for storage tanks in a congested manufacturing district is sometimes a factor, but is usually overcome by burying the tanks below the surface. If the tanks are installed properly according to local fire ordinances, state regulations, and insurance company rules, the vaporizers located outside plant building, and the gas piping run as usual, no objections are encountered from the regulatory bodies, and no increase in insurance premiums results. Liquid butane is considered to carry the same fire or explosion hazard as gasoline or motor fuels. The butane vapor in low-pressure piping has the same relative classification as piped natural or manufactured gas.

Butane manufacturers have a large and adequate fleet of tank cars. Fuel deliveries are therefore prompt, and present no problems different from the rail delivery of fuel oils.

Uses. Present successful industrial uses of butane include: Heat treating and hardening, annealing and normalizing, carburizing, forging, malleabilizing, enameling, japanning, core baking and mold drying, metal cutting, galvanizing, glass-machine forehearths, glass annealing, ceramic ware, textile singeing, and internal-combustion engines.

CONCLUSIONS

1 Butane is transported economically and handled as easily as liquid, and also has all the advantages of other gaseous fuels.

2 Butane is uniform in composition and is uncontaminated with deleterious substances. Precise temperature and atmosphere control is easily obtained.

3 Butane can be burned economically with standard combustion appliances and in standard furnaces.

4 Butane can only be used industrially where freight rates permit economical delivery. For this reason it will be utilized primarily in the Middle West, the Mississippi Valley, and Great Lakes industrial regions. It will not invade New England or the far South.

5 Butane is competitive with manufactured city gas for practically all large-scale industrial uses in the territories to which it can be economically transported. It is not competitive in any event with natural gas.

6 Butane is not competitive with fuel oil on a thermal basis, but will win many an industrial load from oil because of its cleanliness, ease of control, and lower cost per unit of finished product.

7 The supply of butane is adequate to justify almost unlimited industrial use without fear of depletion of raw material supply.

8 Butane is swiftly becoming a factor in industrial fuel markets, and its use and importance are destined to increase.

FSP-52-22a

Carbonization-Plant "Lurgi" Process of Lehigh (N. D.) Briquetting Company

By MAX TOLTZ,[1] ST. PAUL, MINN.

The first operating installation of the German "Lurgi" process for treating low-grade fuel is described. The process is particularly adapted to North Dakota lignite; and the carbonized-coal residue, with pitch by-product as a binder, is pressed into merchantable briquets, which burn as a smokeless fuel with high recoverable heat value.

THE carbonization-plant "Lurgi" process of the Lehigh Briquetting Company is located about one mile south of the Northern Pacific Railway's main track at Lehigh, N. D., and about 3½ miles east of Dickinson, N. D. It is the first completed American installation of the German process for treating low-grade fuel now in operation.

The process is adapted to North Dakota lignite only and produces a carbonized-coal residue which, when bound together with one of the by-products, pitch, and pressed into briquets delivers a smokeless, sootless, clinkerless fuel of high recoverable heat value and which can compete successfully in the market with anthracite and all intermediate grades of natural and briquetted raw coal.

This process was invented by Dr. F. A. Oetken and Dr. O. Hubmann, of Germany, and was developed under their patents by the Lurgi Corporation of Frankfort-on-the-Main, Germany.

The lignite tar recovered by this process is of a high grade, from which many by-products of value such as creosote and paraffin are recovered.

The result of the carbonization of the lignite is a residue called carbon char, which when not briquetted can be used with high efficiency, especially in pulverized form for firing boilers and also for smelting purposes. This latter will probably influence the production of iron and steel from the great mines of northern Minnesota, due to the fact that the char not alone can stand the pressure in the cupola, but having no impurities such as sulphur, will produce a better and cleaner pig iron than that made with common coke.

There are in the region of these lignite deposits some of the finest clays of the United States for the manufacture of face-brick, paving brick, firebrick (good for 4200 deg. fahr.), hollow tile, terra cotta, etc., which excel in quality. Some of the clays can be used in the manufacture of pottery and white porcelain, also of white cement. There are also immense deposits of alumina and other minerals, all of which await suitable cheap fuel to become commercially profitable.

The plant is built on top of the coal mine, the lignite of which lies about 70 ft. below the surface and has a thickness of from 12 to 18 ft. The coal is mined according to the room-and-pillar system, the rooms being 20 ft. wide and about 100 ft. long, and the pillars or walls between the rooms are 8 ft. thick. The supporting roof is 4 ft. thick coal.

The buildings are of substantial fireproof construction, consisting of a steel structure (see Fig. 1), with brick curtain walls and steel windows. The floors are of reinforced concrete. The layout of the plant is shown in the diagram, Fig. 2.

The accomplishment at Lehigh has shown that through this new process of chemical change and from the vast lignite resources of North and South Dakota and eastern Montana can now be made available for commercial and domestic use.

The process of carbonization of this lignite is as follows:

The lignite comes from the mine in chunks of from 12 to 20 in., and is deposited in a hopper, from where it is belted to the magnetic separator and then into the crusher. The flow sheet is shown in elevation and in plan in Fig. 3. On the belt, coal which contains clay matter is thrown out. The crusher reduces the size to 4 in. or less. The coal is then raised by a bucket

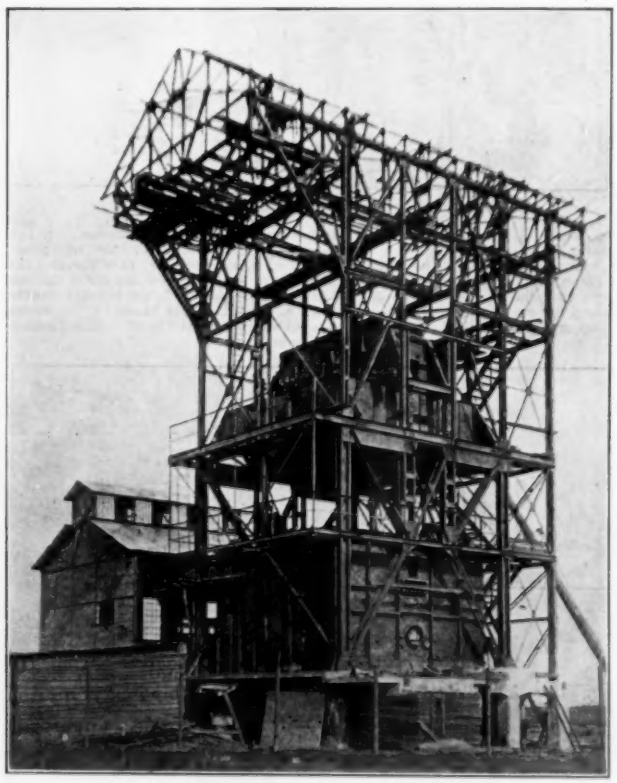

FIG. 1 CARBONIZER BUILDING UNDER CONSTRUCTION

elevator and goes over a vibration screen, which takes out the sizes of ¾ in. and under. This fine coal is conveyed to the power house and is used on the chain grates under the boilers. The coal ¾ in. and over falls into hoppers, from which it is conveyed by a belt to another bucket elevator to the top of the carbonizer building, where an automatic loader delivers it to the two raw-lignite bunkers of the carbonizer. (See Fig. 4.)

From here the coal falls into the dryer, which is heated by gas generated in the drying chamber, and which is circulated by a fan after it is heated by the combustion of gas from the scrubber in a specially built combustion chamber. The temperature

---

[1] Engineer. Mem. A.S.M.E.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., October 7 to 10, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

in the dryer is kept at about 230 deg. cent. (446 deg. fahr.). The dried coal falls then by gravity into the carbonization chamber, to which heat from the cooling zone as well as from the combustion of the generated gas, similar to that in the dryer, is supplied. (See Fig. 5.)

The temperature of carbonization for this lignite was established after experiments and must not be lower than 600 deg. cent. (1112 deg. fahr.) and not higher than 620 deg. cent. (1148 deg. fahr.). This temperature is checked by a set of pyrometers and is regulated from a board located in the gas-cleaning room. If

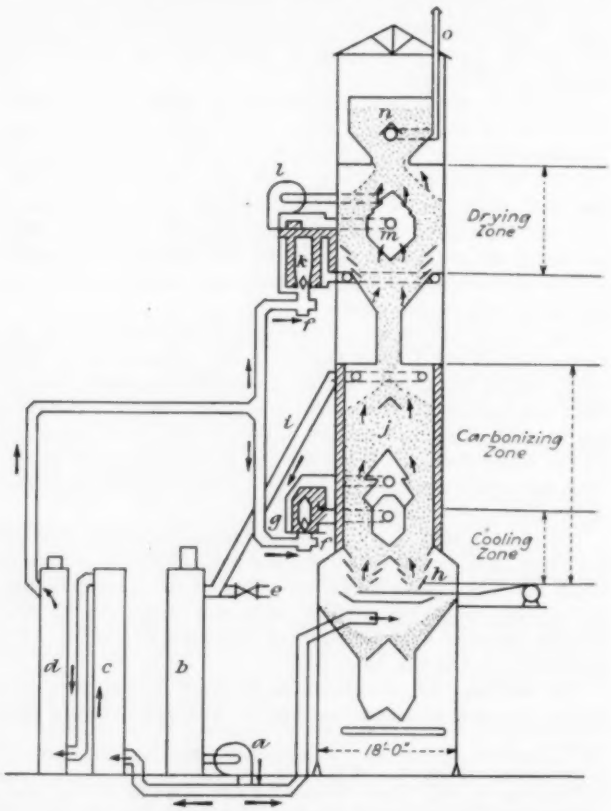

FIG. 5 SECTION OF CARBONIZER AND GAS DISTRIBUTION

(*a*, blower; *b*, Theissen tar disintegrator; *c*, cooler; *d*, Raschig scrubber; *e*, producer gas; *f*, air; *g*, heater for carbonization chamber; *h*, cooling hopper for char; *i*, air; *j*, carbonization chamber; *k*, heater for dryer; *l*, blower; *m*, dryer; *n*, raw-lignite bunker; *o*, ventilator.)

the temperature is too low, the heat created in the heater is increased, but when the temperature is too high, cooling is effected by supplying cooled air and gases from the cooling hopper.

The reason why the "Lurgi" carbonizer was selected was that it had no moving parts except the two gates in bottom of the char hopper.

It has been found by daily operation that if the lignite contains less than 38 per cent of moisture the gas generated in the carbonization zone is sufficient for heating the lignite particles to change them into carbon char. If the moisture exceeds 38 per cent, then producer gas has to be added.

The gas generated in the carbonization zone is drawn off at the top of that zone into a Theissen disintegrator in which the tar is extracted. The gases from here are used partly for cooling the carbon char in the hopper below the carbonization zone, and partly are drawn through a cooler and washer or scrubber and are then conducted to the heaters for the dryer and for the carbonization chambers. This process converts the lignite into carbon char of the size of pea coal. (See Fig. 6.)

After this char has gone through the cooling zone, still having a temperature of 120 deg. cent. (248 deg. fahr.), it falls into the cooling hopper, from where it is elevated by another bucket elevator to the char crusher. This is a special machine imported from Germany. The rolls of high-tempered hard-steel alloy have recently been replaced by carborundum rolls, also made in Germany, and the result of crushing the char to $^1/_8$ in. size has been considerably improved, so much so that the finished briquets have the appearance of anthracite coal. The crushed char is hoppered and goes to a table, which feeds the right amount into the mixing drum, into which at the same time pitch in atomized form is introduced. The mass from the mixer is elevated to a fluxer, where if necessary superheated steam is added to make the mixture pliable, and from thence is taken by a screw conveyor to the briquetting press. (See Fig. 7.)

The finished hot briquets, in the shape and size of an egg (see Fig. 6), are then sent over a cooling belt of wire mesh to the storage bin.

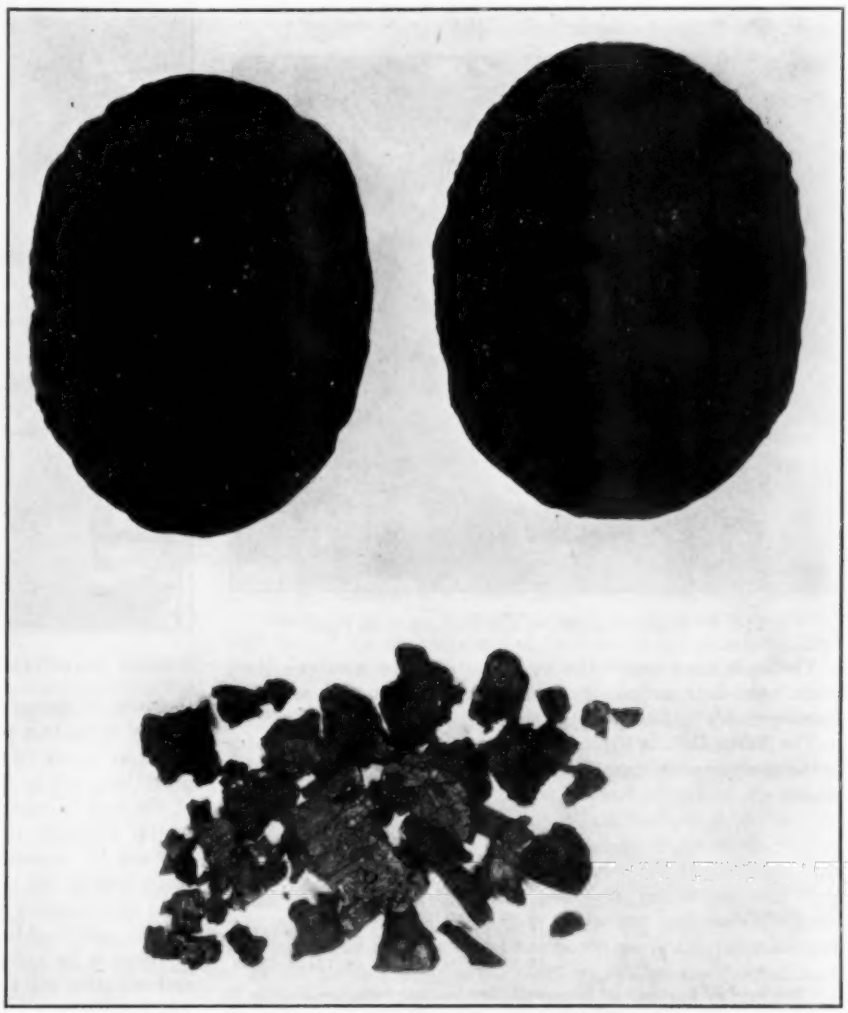

FIG. 6 BRIQUETS, NATURAL SIZE, SHOWN ABOVE; LIGNITE CARBON CHAR, NATURAL SIZE, SHOWN BELOW

From the tar the tar water or ammonia liquor is separated, which latter is wasted at present, although by-products of ammonia sulphates and acetate of lime can be procured from it. (See Fig. 8.)

The tar is then pumped by compressed air in superheated steam-jacketed pipes, a novel installation, to the distillation plant, in which from a still heated to a temperature of about 320 deg. fahr., the pitch is drawn off. The remainder of the tar, on account of being dust free, has therefore a good market value or can be converted into light and heavy oils, creosote, and paraffin.

The apparatus used in this process is of standard type as to rubber belt conveyors, bucket elevators, magnetic separator, coal crusher, char crusher, mixer, fluxer, screw conveyor, and briquetting press. The belt which conveys the hot briquets is of wire mesh. The new features are the carbonizer, the Theissen disintegrator, and the Raschig scrubber, all of which are patented.

The carbonizer is open on top and closed by two gates at the bottom of the char hopper. It has no moving parts and consists of the drying zone, carbonizing zone, and cooling zone. It is built of steel throughout, 18 ft. square at the bottom and about 80 ft. high. The sides of the carbonization chamber are lined with firebrick. (See Fig. 5.) The automatic loader in connection with the carbonizer is almost human, and also can be handled by remote control.

The Theissen disintegrator is really a separator of the centrifugal type to separate the tar and tar water. It is a vertical machine. Of the Raschig scrubber no details could be obtained.

The capacity of the plant at present is not balanced; that is, the carbonizer can produce only 100 tons of char per 24 hours while the briquetting plant is able to make 400 tons in 24 hours, or in other words, three more carbonizers will have to be installed to balance the output of the briquetting plant, and at the same time the distillation plant will have to be doubled to balance with this future output.

The power house contains two 300-hp. longitudinal water boilers and one 375-kva. turbine at 80 per cent power factor, 175-lb. initial pressure, running condensing. Water for condensation and boilers is furnished by a spray pond. The boilers are equipped with chain-grate stokers

The power used in the different parts of the plant is as follows:

Coal crushing	30 hp for 4 hours per day
Carbonization	120 hp. for 24 hours per day
Briquetting	120 hp. for 6 hours per day
Mine operation	100 hp. for 24 hours per day
Pumping tar and pitch with compressed air	20 hp. for 8 hours per day
Lighting, etc	10 hp. for 24 hours per day

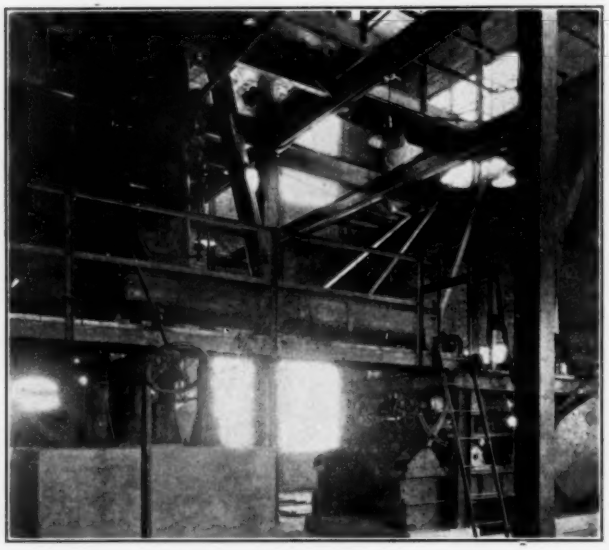

FIG. 7 SCREW CONVEYOR AND BRIQUETTING PRESS

The carbonizer needs the attention of three men per shift, while when four carbonizers are installed, the attendance will be increased only to four men per shift.

The North Dakota lignite is a non-coking coal. The following is the analysis of the raw lignite, char, and briquets of the Lehigh plant:

		Moisture	Volatiles	Fixed carbon	Ash	Sulphur	B.t.u.	B.t.u., combustible[1]
Lignite	wet	40.40	26.35	26.45	6.80	0.86	6380	
	dry		44.35	44.30	11.45	1.44	10704	12088
Char (600° C.)	wet	1.15	10.90	73.80	14.15	2.24	12759	
	dry		11.00	74.50	14.30	2.26	12778	15177
Briquets	wet	1.30	15.95	70.05	12.70	1.98	12942	
	dry		16.65	71.00	12.85	2.04	13112	15048

[1] The sulphur in char and briquets is combustible to approximately 25 per cent; the rest is ash-sulphur and non-combustible.

It takes 2 1/3 tons of lignite of the foregoing quality to make one ton of char. The amount of tar extracted is 2.8 to 3.2 per cent in weight, of which 42 per cent is pitch, and which, as stated, is used for binder in the briquets. The balance of 58 per cent of tar consists of 8 per cent water, 5 per cent gas, 19 per cent creosote, 26 per cent paraffin fractions (8 per cent paraffin).

To briquet the char 6 to 6 1/2 per cent pitch in weight is necessary for a binder. From this it can be seen that the lignite does not produce enough pitch for all the manufactured char to be briquetted. It is therefore necessary to procure pitch from other sources for over 50 per cent of the char, unless this part of the char is marketed, which can be done readily.

The author is not able to give exact expenditures and cost of operation, but the following will give a fair picture of the financial side of this plant:

The total cost of the plant as it stands today, not including

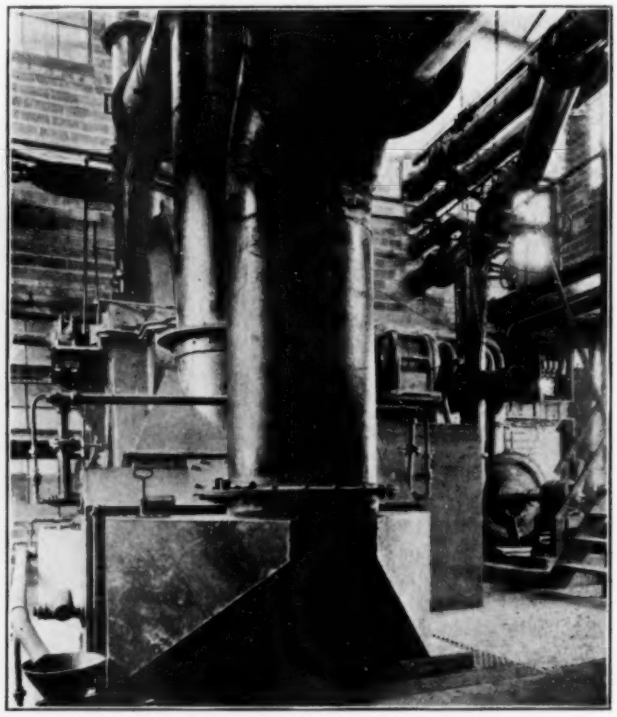

FIG. 8 GAS CLEANING AND TAR AND TAR WATER SEPARATION

the mine, is approximately $550,000. Having a capacity of 100 tons of briquets a day, the cost per ton output would be $5500, which is excessively high. If the plant is extended so that everything will be balanced, which would give a daily capacity of 400 tons of briquets, the total expenditure would be approximately $700,000, or $1750 per ton output. This is also high, but can be accounted for by the reason that this is the first plant built in this country. The author's estimate of cost of an eight-unit plant, or 800 tons daily capacity, is $900,000, or $1125 per ton output of briquets.

There is no question that the processes of low-temperature carbonization will be improved and simplified in the near future, which will reduce initial investment and also manufacturing costs.

So far as could be ascertained, the cost of manufacturing one ton of briquets at the Lehigh plant is a little more than $6, but the author has estimated, and quite conservatively, that with an eight-unit plant and a strip mine in which coal can be produced for less than one-half of the present cost of operation, one ton of briquets can be manufactured for $3.30 or less.

The plant has been in operation since December, 1928, and has given the results promised by the Lurgi Corporation.

In conclusion the author acknowledges with thanks the cooperation of Dr. Hubmann, Mr. K. Loven, manager, and Mr. R. E. Brewer, superintendent, of the Lehigh Briquetting Company.

[Discussion of this paper follows the paper by J. D. McQuade.]

FSP-52-22b

The Hayes Process Low-Temperature Carbonization Plant at Moundsville, W. Va.

By J. D. McQUADE,[1] PITTSBURGH, PA.

Low-temperature carbonization was adopted at Moundsville so that the large percentage of slack and screenings could be converted into a merchantable fuel and sold at a profit, clearing the way for the prepared coal at a price that would enable it to enter the open market and justify the continued operation of the mine. The process adopted had to meet the requirements of being operated over long periods and be free from carbon formation when working high-volatile bituminous coal; the retorts must be of a design to allow of easy repair with a minimum of time and labor; the process must be automatic; it must yield tar and gas as by-products; the investment must be so low as to yield an operating profit. Operating costs and returns have been such that the unit will be expanded for a much larger output.

THE primary reason for undertaking the development of a low-temperature carbonization process at Moundsville was to provide a means whereby the slack coal or screenings, which constitute from 30 to 40 per cent of the output of the mine, could be changed into a fuel that could be sold at a profit.

It is unnecessary to go into detail regarding the troubles which for the last five years have beset the coal industry, as they are generally known. However, the company became convinced that if it had an outlet for the screenings, through which they could be sold at a price above the cost of production, the prepared sizes of coal could be sold on the open market at a price that would justify the continued operation of the mine.

With this object in view, a thorough investigation was begun of the different processes having for their object the utilization of low form value screenings. Many schemes were investigated, which ranged from various methods of cleaning and preparing the coal to the various methods of carbonizing the coal at low temperatures. Some of these processes were installed and operated on a small scale, only to be discarded because of high installation and operating costs or because the finished product was not in a suitable form for domestic use.

As a result of these investigations, the company was thoroughly convinced that low-temperature carbonization offered the most satisfactory and most profitable means of changing the form value of bituminous-coal screenings, provided a process could be found that met with the following requirements:

1 It must be a machine capable of continuous operation over reasonably long periods and without difficulties due to carbon formation and sticking when using high-volatile bituminous coals.

2 The retorts must be of such design that permit necessary replacement and repairs to be effected in the shortest possible time and with a minimum of labor.

3 The process must be automatic or nearly so in its operation so as to reduce the amount of labor and supervision to the lowest possible figure.

4 The process must be of such a type that the entire solid product could be recovered in a form suitable for use as a high-grade domestic fuel and in such form that it would stand the abuse of handling and shipping with the least amount of degradation.

5 It must yield a large amount of tar oils of such characteristics that have the highest market value and at the same time yield a gas of high heating value.

6 The initial investment cost per ton day input of coal must be sufficiently low to allow the fuel product to be sold in competition with existing fuels and at the same time realize a substantial return on the investment.

With these objectives in mind, and after many tests on small scale retorts, the patent rights for the Hayes process were purchased in 1926. In 1927 the first full-scale unit was built, having a capacity of 50 tons of coal input per 24 hours.

With the operating experience and data obtained from this unit as a basis to work on, a second unit of 50 tons capacity was constructed in which many improvements were incorporated. This unit has been in successful commercial operation up to date.

The Hayes process retort consists of an alloy steel tube 17 in. inside diameter by 20 ft. long. This tube is placed in a furnace setting and supported by rollers on each end. Stationary feed and discharge castings are located at either end of the retort and are connected to it by special packing rings. The tube is rotated at a speed of $1^1/_2$ revolutions per minute.

Within the retort is a specially constructed screw conveyor. This screw is driven by a train of gears which gives it a progressive oscillating motion. The motion is such that the screw moves the coal toward the discharge end of the retort a given distance, and on the reverse oscillation it is returned a distance slightly less than the forward motion. Due to this forward and backward motion, the coal has a theoretical travel of 240 ft. in passing through the length of the retort.

The problem of coal carbonization resolves itself into a question of heat transfer. In low-temperature carbonization, due to the relatively low heat head available, it is difficult to raise the temperature of a layer of coal to the point where complete distillation is effected in a reasonable length of time. In this process, due to the motion of the retort screw, every particle of coal is brought into contact with the hot walls of the retort, and the carbonization is completely effected in the short time of 25 minutes.

In the present unit, seven of these retorts are located in a battery type of furnace. Each retort is heated externally by means of gas burners located on the under side of the furnace, and each retort is entirely independent in the operation of the other six. Removable one-piece covers form the top of the furnace, and any retort can be removed for inspection or repairs without interfering with the operation of the other six.

Coal is fed to each of the retorts by a screw feeder located on the feed end casting. The rate of feed is 700 lb. per hour for each retort.

The char is discharged from each retort into a main collecting conveyor, which runs the length of the retort setting, thence being discharged into a quenching conveyor, where it is cooled by water sprays. From this conveyor the char discharges through a rotary seal valve and is conveyed to a crusher, where it is ground to the proper size for briquetting.

The coal gas and tar vapors are removed from the retorts through offtake connections located at either the feed or discharge

[1] Coal Carbonization Company.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., October 7 to 10, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

end of the retorts and are conducted through standard condensing and cleaning apparatus, where the tar is removed and the gas is sent to the holder.

In this installation the gas produced is returned to the furnaces and is used for heating the retorts, and the excess gas is used for steam raising.

The coal processed is the $^3/_4$-in. screenings produced by the Ben Franklin Coal Company and has the following average analysis: Moisture, 2.25 per cent; volatile, 39.40 per cent; fixed carbon, 51.04 per cent; ash, 7.31 per cent. B.t.u. per pound, 13,500.

This coal is rescreened over a $^1/_2$-in. bar screen, and the coarser sizes are crushed to pass a screen of the same size.

The average yield of products derived from one ton of this coal is as follows: Char (12 per cent volatile), 1326 lb.; tar, 30 gal.; gas (800 B.t.u. per cu. ft.), 5000 cu. ft.

The char after being ground is passed through a standard briquetting machine of the Belgian roll type where about 10 per cent of coal tar pitch is used as a binder. The briquets are pillow-shaped and weigh about $2^1/_2$ ounces.

This type of fuel is ideal for domestic use. It is readily controlled in a heating furnace or stove, will hold the fire for long periods, and retains its shape in the fire until entirely consumed. It will withstand the roughest abuse in handling and shipping, is not affected by weather conditions, and is remarkably free from broken pieces or dust when delivered in the consumer's bin.

As is the case with nearly every machine, the success of its operation is mainly dependent on the method of control and its ability to maintain uniform conditions throughout the entire system.

The heating of the retorts is controlled in accordance with temperature readings taken in the furnace chamber at the feed and discharge end of the retort. All the firing is done at the feed end, where a temperature of 1400 to 1600 deg. fahr. is maintained dependent on the nature of the products desired and the nature of the coal being processed. This produces a furnace temperature of 1100 to 1300 deg. fahr. at the discharge end of the retort. This method of firing has the effect of removing the moisture from the coal and raising it to the distillation temperature before it passes the middle of the retort. All that is then required is to maintain this temperature until complete distillation is effected. The heat required for carbonization is approximately 1200 B.t.u. per pound of coal, or about 60 per cent of the total gas made.

Automatic governors regulate the vapor pressure on the retorts, and uniform temperature conditions are maintained by automatic valves at various points through the gas-handling equipment.

This unit has now been operated over a sufficiently long period of time to demonstrate its ability to produce the required type of products and to prove the reliability of its operation.

The products have been marketed in different localities, and their reception has been such as to leave no doubt as to the prospects for selling large quantities of both the tar products and fuel briquets.

There has been much speculation as to the value of low-temperature tars, and the general impression has been that their only immediate use would be as a fuel and that their value could only be rated as such. Recently, however, there has been shown a remarkable interest in the distillates from low-temperature tars by the manufacturers of synthetic-resin compounds. Due to their high tar-acid content and other peculiar characteristics, these distillates are beginning to find favor in this industry, and their value is indicated by the willingness of several manufacturers to contract for large amounts at a very good price.

As is the case with every new industrial undertaking, the question arises if it is commercially profitable. The answer to this question is that plans are now under way for the erection of a plant having a coal input of 400 tons per day. The carbonizing units of this plant will be merely a multiplication of the unit now operating, and there will be no untried schemes incorporated in its design. Provision is being made to distil all the tar produced in order to recover a suitable pitch to be used as a binder for the briquets, and only the distillate oils will be marketed.

The estimated operating cost and returns on this plant are as follows:

Labor

	Cost per day	Cost per ton input
General: 1 superintendent at $12 per day, 1 chemist at $6, 6 general laborers at $4	$42.00	$0.105
Carbonizing plant: 3 foremen at $6 per day, 12 men at $4	66.00	0.165
Steam plant: 3 firemen at $4 per day	12.00	0.030
Briquetting plant: 1 foreman at $6 per day, 2 men at $4	14.00	0.035
Tar distillation: 9 men at $4 per day	36.00	0.090
Total	$170.00	$0.425

Operating Cost per Day

	Daily cost	Cost per ton input
400 tons slack coal at $1 per ton	$400.00	$1.000
Labor	170.00	0.425
Interest on $600,000 at 7% per annum	116.66	0.290
Depreciation at 10% per annum	166.66	0.411
Royalty at $0.30 per ton	120.00	0.300
Repairs and supplies	75.00	0.187
Power and water	50.00	0.125
Office and laboratory	25.00	0.062
Total cost	$1123.32	$2.800

Income per Day

	Daily income	Income per ton input
300 tons briquets at $5	$1500.00	$3.75
4000 gal. distillate oils at $0.13	520.00	1.30
Total income	$2020.00	$5.05
Operating costs	1123.32	2.80
Profit	$ 896.68	$2.25

From the foregoing, it would seem reasonable to conclude that within a comparatively short time the larger producers of bituminous coal will, by the low-temperature carbonization of the coal they produce, place their business, which is now unprofitable, on a profitable basis.

It would also seem probable that the time cannot be far distant when bituminous coal will not be in general use in its raw state as a fuel, but its place will be taken by a smokeless fuel, the product or result of low-temperature carbonization of bituminous coal.

From the present trend in the value of low-temperature tar products, it would appear that by the use of a low-temperature distillation process the coal producer will be able to sell the smokeless fuel resulting from such a process at a price to bring it within the reach of the average domestic consumer.

In addition, when such smokeless fuel can be thus had by domestic consumers, it is reasonable to suppose that the municipal authorities in the cities and larger towns, in order to eliminate smoke, will prohibit by law the use of raw bituminous coal as a fuel.

From all these considerations, it may be possible that low-temperature distillation of bituminous coal will prove to be the remedy for the "smoke nuisance" about which so much is heard in the cities today.

Discussion

HORACE C. PORTER.[2] Low-temperature carbonization of coal has, in most cases where it has been tried commercially, proved uneconomical due to high costs of plant and operation. The author presents figures of estimated costs and returns on a plant that has been tried out on a smaller scale. These figures, if they work out in practice as indicated, show a substantial profit.

[2] Consulting Chemical Engineer, Philadelphia, Pa.

The coal is charged at $1 per ton, which, with a profit of $2.25 per ton from the carbonizing process, totals $3.25 net return to the mine owners on their slack coal.

There are two sets of conditions under which low-temperature carbonization is likely to find its best prospect of success. One is as outlined in this paper—the conversion of low-value screenings at the mine into an improved fuel product commanding an enhanced value. The other is pretreatment of sticky and smoky coals as an auxiliary in steam-power-plant practice.

In both of these cases the profit will depend on the market for the oils and gas produced. It is a question whether the demand for low-temperature tar oils at the figure of 13 cents per gallon, as given in the paper, can be maintained indefinitely as production is increased.

It is a waste of a valuable by-product to burn rich gas as is done at this plant for heating the retorts. This gas (800 B.t.u. per cu. ft.) would have a very much higher value if applied to enrichment of blue water-gas for distribution as a public supply. When large installations of this type of plant are built, the possibilities should be well considered of placing them where they can contribute to a public gas supply, perhaps through long-distance transmission, and thereby add to the profits obtained through by-products.

The success of low-temperature carbonization will depend to a large degree on the relative future market returns from tar oils and gas. High-temperature carbonization gives high gas yields; low-temperature carbonization gives high tar yields. Future economic conditions affecting the demand for these products will have a large influence on the progress of low-temperature carbonization.

ALBERT L. KLEES.[3] In a study of the possibilities and economics of low-temperature carbonization processes, the one factor which will perhaps be of the greatest importance in determining the economies of this method of carbonization over standard methods will be the relative values of low-temperature tar and high-temperature tar. While this may not be particularly true in connection with the manufacture of prepared domestic fuel from bituminous coals, it is undoubtedly of prime importance in connection with the low-temperature carbonization of coal for gas-making purposes or for power development.

While considerable time and money have been spent during the last eight years in this country in investigating the possibilities of low-temperature tar, it is only during the last 18 months that one has been able to visualize a tangible relative value of this material in comparison with high-temperature tar. A few years ago, in setting up a budget analysis of a low-temperature carbonization process, it was even difficult to substantiate a price for low-temperature tar comparable to that of high-temperature tar. Today, because of the great progress that has been made during the past 18 months, one can conservatively estimate a considerably higher price for low-temperature tar.

Of course there is considerable discussion as to the present and potential value of low-temperature tar products, but the writer feels confident that any one who is thoroughly familiar with the laboratory and semi-commercial and commercial tests that are being made with products of low-temperature tar and familiar with the viewpoints of the manufacturers that are using this material and the success that they are having, can no longer be in any doubt or have any question as to the basic value of low-temperature tar in comparison with high-temperature tar.

While it is always difficult and dangerous to mention specific prices, it may be helpful to have some tangible indication of the relative prices of low-temperature tar and high-temperature tar in accordance with the way this situation looks to men who have been studying this problem for several years.

There is a sound basis for believing that low-temperature tar in comparison with 6-cent high-temperature tar is worth and will be worth a minimum of 10 cents per gallon. This figure is based not only on the present value of low-temperature tar in small quantities, but takes into consideration the tremendous production and consumption of low-temperature tar and the probable reduction in price that will have to be made when this material is used for large-quantity purposes.

The picture today of low-temperature carbonization is rather clean-cut. We can definitely see a price of 10 cents a gallon or better for low-temperature tar, and on this basis the processing of coal by low-temperature carbonization methods can be economically projected for the three major divisions—namely, domestic fuel, gasification of coal, and the production of char in the power plant.

At this time the picture is economically sound for the application of low-temperature carbonization to the manufacturer of domestic fuel. In the near future it should be applicable to the processing of coal prior to gasification, and in the not-distant future it should become economically feasible in connection with the processing of coal before such fuel is burned under the power-plant boiler.

FSP-52-23

Smoke-Abatement Methods in Knoxville

By F. L. WILKINSON, JR.,[1] KNOXVILLE, TENN.

Classed as one of the smokiest cities in the Southeast, Knoxville has been making a determined effort to clear its smoke-laden atmosphere. Methods used to enlist the cooperation and support of the public, to establish a bureau for smoke regulation, and to enact necessary measures to carry out recommendations are discussed in this paper.

KNOXVILLE has for many years been classed as one of the smokiest cities in the Southeast. Its rapid growth from a city of 36,000 people in 1910 to approximately 135,000 in 1928, with little or no control over the direction or class of its expansion, has augmented the atmospheric pollution due to smoke.

The city is located on the banks of the Tennessee River, is surrounded on all sides by the foothills of two ranges of the Southern Appalachian Mountains, and is within easy freight haul of the rich Southern Appalachian bituminous-coal fields. The city is built on a series of ridges and valleys, and its streets are narrow and crooked, as is common among old cities that have expanded rapidly with little or no attention to city planning. Its proximity to the Eastern Kentucky and Eastern Tennessee coal fields has made bituminous coal almost the only fuel for the generation of heat and power. The cheapness of coal has constituted a decided incentive to almost a total disregard of efficiency in its use, resulting in a marked fuel wastage and a decidedly smoky atmosphere. The locality has an average yearly wind velocity of only six miles per hour, making it difficult to dissipate the river fogs so prevalent during the winter months.

The agitation for smoke abatement in Knoxville began in 1911, when pressure was brought to bear on the city council to pass an ordinance prohibiting "the emission of dense-gray or dense-black smoke" within the city limits. After a futile attempt to enforce this ordinance on the citizens by the building inspector, who was also the smoke inspector by virtue of the ordinance passed, the city council remitted all fines that had been adjudged under the act and let it lie dormant, but still on the books, hoping that some day it would gain new life under different auspices.

At the time of the passage of this early ordinance, there were many good citizens who were anxious to comply with its provisions. These fell dupes to the salesmanship of a group of men who found Knoxville a "happy hunting ground." They found eager purchasers for everything from water tanks for washing the smoke, at several thousand dollars, to patent salts that when thrown upon the fire were guaranteed to cleanse the smoke of all evil. The results of this early and undirected effort at smoke abatement could be expected to leave a very bad taste in the mouths of many people, and smoke abatement would seemingly have a very hard path ahead of it. This short history of the early efforts of Knoxville to clean its atmosphere is only given here as a contrast to the situation as it appears at present.

The agitation for the passage of the present ordinance covered a period of approximately five years. A Smoke Abatement League was formed by a group of earnest and hard-working women a short time prior to the advent of the city manager-council form of government in 1923. These women, drawn largely from the women's clubs of the city, finally enlisted the aid of every representative group of citizens in the city. The civic clubs, Technical Society, Manufacturers' Association, Retail Merchants' Association, local section of the A.S.M.E., local chapter of the N.A.P.E., and other organizations gave active and financial support to their efforts.

The chemistry department of the University of Tennessee conducted a soot-fall determination that awakened the public to the immense loss attributed to a smoke-laden atmosphere. The monetary loss due to smoke was variously estimated at from $15 to $17.50 per person annually.

The Smoke Abatement League had its "ups and downs" for several years until, with perseverance, the entire public was aroused to the necessity of doing something in an attempt to abate the smoke nuisance. Mass meetings were held at which doctors outlined the effect of smoke on health, merchants gave data concerning the yearly loss due to damaged stock, housewives testified to the drudgery of housekeeping within the city limits, representatives of modern industrial plants assured other industrial managers of the benefits to be derived from modernizing power-plant equipment, and engineers advised the public at mass meetings and through the press of the best way in which smoke reduction could be accomplished.

As a result of the concerted efforts of all agencies lasting over a period of approximately five years, the city council was moved to action and appointed a committee composed of councilmen, laymen, and engineers to study the problem, and to suggest legislation and a course of action for the municipality to follow. This committee recommended the adoption of the standard ordinance of the A.S.M.E. with slight changes to meet local needs. This ordinance was passed in March, 1928, and active work started by the Bureau of Smoke Regulation in May of the same year.

Some of the distinctive features of the ordinance are as follows:

1 It provides for a Bureau of Smoke Regulation under the Department of Public Welfare with a technically trained man at its head.

2 It provides for an advisory board to serve without pay, of not less than five members, three of whom shall be mechanical engineers, who shall act as advisors to the chief engineer.

3 It provides that the ordinance shall apply, in substance, to all fuel-burning equipment except in a private residence.

4 It prohibits the emission of smoke equal to or greater than No. 3 Ringelmann chart for a period in excess of two minutes in any fifteen, except for a sufficient period of time necessary for starting and cleaning fires. The time limit is reduced to one minute in any eight for locomotives, steamboats, steam rollers, etc.

5 It provides that a permit be obtained for the installation of new fuel-burning equipment or for alterations and repairs to existing equipment.

6 It provides penalties for owners or contractors installing equipment without obtaining a permit from the chief engineer of the Bureau of Smoke Regulation. No charge is made for these permits.

7 It provides that owners shall make changes recommended by the chief engineer, looking toward the reduction or elimination of smoke, within thirty days of the date the recommendations are made.

8 It provides that the owner or contractor shall have the right to appeal to the advisory board from the decisions of the

---

[1] Chief Engineer, Bureau of Smoke Regulation. Mem. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Fuels Division, Philadelphia, Pa., October 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

chief engineer, and further provides that the ruling of the advisory board shall be binding on the chief engineer.

9 One long section of the ordinance contains recommendations as to new installations concerning setting heights of boilers, etc.; in fact, it establishes a code that shall serve as a guide to the purchasers and manufacturers of equipment. This code was first proposed as a requirement, but was wisely changed by the council to act only as a guide. The wisdom of this change has been brought out even in the short time of the ordinance's existence due to the constant advance in the design of heating boilers and furnaces.

10 The ordinance further provides that no prosecutions can be made unless instituted by the chief engineer of the Bureau of Smoke Regulation.

The outline of the preliminary campaign for smoke abatement in the city of Knoxville is given merely as an illustration of the necessity of arousing public sentiment for the undertaking. Unless the residents of a community want smoke abatement and are made to be willing to do their part, the engineers and the municipality can do very little, no matter how many ordinances are passed nor how many enforcement officers are appointed. The public of Knoxville were ready to lend their aid, and were awaiting the word from some authoritative source when Mr. John Hunter arrived in June, 1928, to act as consulting engineer for a period of three months, and to train an engineer to fill the office of chief engineer of the bureau.

A survey of industrial plants had been made prior to the arrival of the consulting engineer, and work was commenced immediately with a view to eliminating smoke. No expensive surveys were made to determine how much smoke was being emitted. Every chimney and smoke stack was considered a potential offender, and investigated. Recommendations were made based on sound engineering knowledge and practice. The work of educating the public was continued, and still continues through newspaper articles, talks before clubs and group meetings, firing schools, and radio.

The municipality was made to realize that the first move would be that of "cleaning its own front porch," with the result that today no soft coal is burned in the city's boilers except in underfeed stokers and on downdraft grates. Coke is used in all other heating and power boilers, with the result that the city itself does not own a single smoking stack. This municipal cooperation is considered very essential in obtaining the cooperation of the general public.

The following methods have been used largely in the operation of the campaign in the city of Knoxville. The first year has been devoted to recommending changes in equipment or to existing equipment and to changes in fuel, with little attention paid to ordinance violations. The different classes of offenders will be taken up separately and suggested methods of insuring smoke reduction in each class discussed.

Industrial and Commercial High-Pressure Plants

The first summer was devoted to the industrial and commercial plants operating boilers at a steam pressure in excess of 50 lb. This group included all types and sizes of boilers, from the small vertical boiler so common in the small dry-cleaning plants, to the largest water-tube boiler. The majority of the industrial-plant boilers, however, were of the horizontal-return tubular type of approximately 150 hp. Of these, it is safe to say that fully 75 per cent had been installed with little regard for furnace efficiency, their settings being characterized by a seeming attempt to bring the boiler shell as close to the firebox as possible. It seems to have been the practice in industrial plants, where little or no engineering supervision was had in the design and installation of the boilers, to require a setting height that allowed only 30 in. from the dead plate to the boiler shell, and in many cases older installations have been found as low as 24 in.

The author feels that this state of affairs has been brought about by some of the boiler manufacturers themselves, as they have been entirely willing to set a return tubular boiler at any height that the customer desired. This practice might be condoned where boilers were installed about twenty years ago, but many of the low settings found in Knoxville were of recent construction and their heights seemed inexcusable. It was found in many cases that the small-plant owner had trusted the boiler manufacturer to give him the setting height he needed. The need for sufficient furnace volume for the combustion of high-volatile coal has been very difficult to impress upon many of the managers of small plants. The answer has been invariably, "If we needed more furnace volume, why didn't the boiler manufacturer give it to us?"

Space limitations prevented increasing furnace volume in many cases, but a simple form of steam-air jet was used to bring over-fire air into the boiler furnace at high velocities to accelerate mixing at times of stoking. The jets consist simply of $2^1/_2$-in. cast-iron or steel pipes carried through the front wall of the boiler, and inclined at an angle to make the stream of air strike the bridgewall at about eight inches above the rear of the grate. Into each pipe was inserted a $^3/_8$-in. nipple connected to a $^3/_8$-in. header to which was admitted steam at full boiler pressure from a $^1/_2$-in. connection to the main steam line. The nipples were capped with a simple pipe cap into which a $^1/_8$- or $^3/_{16}$-in. hole had been drilled. The position of the nipple in the air pipe depends upon the amount of air necessary to insure combustion of volatiles distilled off at the period of firing. Steam is used only as an agent for carrying the air into the furnace and giving it necessary velocity and turbulence. No claims for great economies have been made in their use, but in several cases slight reductions in coal consumption have resulted.

The main difficulty met with in air-jet installations has been the difficulty in getting the firemen to use them, as there is no denying the fact that, unless muffled, the noise is objectionable. There is no license law for operators in the state of Tennessee, and as a result, the average small-plant manager has considered that the cheapest man that he can obtain as an operator is the most economical. This idea is rapidly being overcome, and managers are beginning to realize the economies that can be obtained in the boiler room from efficient personnel.

Many of the larger plants are installing underfeed stokers, and others are planning to do so as time and money permit. Smoke abatement in Knoxville has resulted in fifteen underfeed stokers being installed in industrial plants during the past year, and two of the largest plants have completely scrapped their boiler equipment, and are now installing new boilers and stokers at a cost of approximately $90,000. The installation of jets is considered merely as a temporary expedient to abate smoke immediately, and they are proving to be the forerunners of more modern fuel-burning equipment.

In the smaller vertical and firebox boilers, coke is resorted to as a fuel, and in some cases where the steam pressure is above 50 lb., a jet is introduced to the firebox through the furnace door, with holes cut in the door to admit over-fire air. Where coke is used, the engineers of the Bureau of Smoke Regulation have given advice and assistance in its use, and it is becoming a popular fuel for the vertical and firebox boiler, especially where the fireman has other duties to perform around the plant.

In making the recommendations to the plant owners, the bureau engineers try to drop useful hints to the management with a view to effecting fuel economies beyond those incident to the elimination of smoke. This tends to make the bureau popular and to increase the desire of the management to cooperate.

At the present time, it is safe to say that virtually every industrial plant in the city is capable of operating within the ordinance requirements. The author does not mean by this statement to convey the impression that there is no smoke from industrial plants. The fact that there is smoke means that the operating personnel is not using the necessary precaution. At the present time, the bureau does not have sufficient personnel to insure proper operation at all times, but it is hoped that this condition will be remedied during the coming year, and more pressure can be brought to bear on the operating personnel.

Large Heating Plants

The heating plants of Knoxville's business sections have been the dumping grounds for any and all boilers, the straight-draft cast-iron boiler predominating. In comparison with other cities of its size and larger, coal is the cheapest commodity by comparison on the local market. As a result of its very low price per ton, the cheapest coal has been the rule for use in the downtown business houses and office buildings. The result of smoke emission can be realized easily when run-of-mine bituminous coal, running as high as 40 per cent volatile, is burned in anthracite heating boilers. That this class of fuel user has been quite a problem during the past heating season is evident.

Many experiments were tried with the use of better grades of coal, repairs to boilers, changes in grate area, improved firing conditions, and better draft control, and it has been found that while in many cases conditions have been improved and operation can be maintained within ordinance limits, satisfactory results from the standpoint of smoke elimination cannot be had in the straight-draft low-pressure heating boiler unless a smokeless fuel is used or an oil burner or small stoker installed.

It was found that the majority of the owners of heating plants were willing and anxious to do their part. They knew better than any one else the cost to them of a smoke-laden atmosphere filtering through their doors and windows, spoiling stocks, and adding to building cleaning costs. Many changes of fuel were made during the winter, coke being used extensively. Particular attention was paid to instructing janitors in the use of coke, and with careful firing under the supervision of the bureau's engineers, it was shown that coke could be used as economically as the better grades of bituminous coal. Fortunately for smoke abatement there is only a price differential of approximately 20 per cent between coke and the better grades of bituminous coal on the local market.

Sixteen motor-driven unit stokers have been installed, or are being installed in the larger store and office buildings, and the saving resulting from their use this past winter is expected to result in many future installations. One department store alone reports a saving of 45 per cent in fuel costs during the past season with an underfeed unit stoker installed under a cast-iron boiler.

Many of the older buildings in the downtown section are small two- or three-story structures, overtopped by large office buildings. Even should these buildings operate within the limits prescribed by city ordinance, their low stacks, augmented by fog and low wind velocities, would make them quite objectionable in the congested areas. As a remedy for this condition, a block heating system has been proposed and designed by the bureau, several units of which are now under way.

Six of the worst offending city blocks are commanded by large office buildings, department stores, or hotels. Each of these buildings is equipped with duplicate boilers, each of sufficient capacity to carry the load of the entire building. It has been proposed to connect them with the smaller buildings in their blocks, and have them supply steam for heating purposes. This system when completed, and if entirely carried out as planned, will eliminate 34 chimneys within the congested downtown section. The owners of the supplying agencies have been shown that even if their equipment is operated at a loss, the returns from reduced cleaning costs and stock losses will more than pay for the trouble and expenditure. The cooperation of the supplying agencies has been freely given, and it is believed at the present time (July) that three of these units will be in operation by November, and the others will fall in line as soon as enough customers can be assured to make the plan operative.

Financial organizations are being interested in the establishment of a central heating plant for the entire congested area, and the lines for the block systems are being laid so that they can be connected to the low-pressure mains of a large central-heating system. It is hoped that the block-system units will be a nucleus for the larger system.

A record has been made of all the larger and offending heating plants. Letters were sent in the early spring to all owners, making recommendations covering fuel, furnace changes, and repairs that should be made during the summer months in order to bring their plants within the ordinance limits during the next heating season. Although these recommendations had been made previously, by getting them on record in the early spring and before the winter's fuel was purchased, the bureau will be able to bring concrete evidence before the court, should occasion arise, that the owners had been sufficiently warned well in advance of the heating season. Answers to many of these letters have been received assuring the bureau of the owners' desire and entire willingness to cooperate by carrying out its recommendations.

Procedure With Railroads

Knoxville has a very decided smoke menace from the two railroads serving the community. Both lines enter the heart of the city, traversing its full length and cutting it almost in half. As industrial plants line the railroads, switching operations are carried on day and night within the heart of the city. Most of the through freight has been shunted around the city within recent years, relieving the smoke nuisance somewhat from that source. Nevertheless, the highest soot-fall records have been recorded within the business districts adjacent to the railroad lines.

Little was done in the early months by the Bureau of Smoke Regulation to combat the smoke nuisance from this source. The cooperation of the railroad officials was requested, with the result that each road appointed a supervisor to look after smoke abatement in its own organization. Air jets and refractory arches were installed by both railroads in all switching locomotives. These have been effective in reducing smoke emission, but again the operating personnel has been careless in the use of the equipment supplied them. The bureau attempted during the past winter to send each week to the different roads records of smoke-density readings taken as time permitted. Each case has been handled by the road, and penalties invoked on the crews where carelessness and failure to use the jets have been shown.

With the coming of spring and the release of an assistant engineer from heating-plant work, a new system has been adopted. The assistant engineer spends several days with the railroads observing firing methods and working conditions of the locomotives and recording smoke densities. The records obtained, both good and bad, are sent to the officials as before, but a monthly grade sheet is made of the records taken during the month, and each locomotive is given a standing in smoke emission for that month. These grade sheets are presented at a monthly meeting between representatives of the bureau and the railroads. Problems relating to smoke abatement and fuel economy are discussed at these meetings. The locomotive crews are given the opportunity to attend, and a spirit of rivalry among the crews is being fostered. Although this system has been in operation for only a short time, it is believed that it will bring beneficial results to the railroads

and to the bureau. Nothing is said about ordinance violations, and locomotive crews are endeavoring to keep their grades low, which means, in effect, a minimum of smoke emission.

Residence Educational Work

Although the smoke-abatement ordinance exercises no control over the smoke from residences, as much if not more educational work has been done among this class of smoke maker than any other. It is, in the author's opinion, useless to say that the smoke from domestic furnaces and boilers can be eliminated unless a smokeless fuel is burned or soft coal burned in one of the successful automatic underfeed stokers now appearing on the market.

Of course, any reduction of smoke is thankfully received and strived for, but it is almost impossible to fire bituminous coal by hand in the average domestic boiler or furnace without objectionable smoke emission. The author understands that furnaces and boilers are now appearing on the market for domestic use, designed to accomplish this purpose, but as yet they have not been found in any of the homes under his jurisdiction, nor has he ever seen such a unit in operation.

In the effort to obtain as much smoke reduction as possible, and smoke elimination when possible, an intensive educational campaign was carried on during the past heating season. Talks were given for a few minutes over the radio each week for several months. Articles were printed in the local papers urging the individual responsibility of each citizen to effect smoke abatement and recommending effective means to bring this about. Articles have been continued in the press during the past summer, keeping smoke abatement alive when fires were dead. Instruction cards were placed in the homes of the city by Boy Scouts, illustrating most successful methods of firing coal and coke to bring about smokeless or near smokeless combustion. Pamphlets entitled "The Smoke Nuisance and Its Abatement," prepared by John Hunter, were placed in all public places with placards asking that one be taken. Large cards were placed on the front and rear of all street cars impressing on each individual his responsibility in the work for cleaner air. Home owners were urged through the press to call on the Bureau of Smoke Regulation for individual assistance in helping with their fuel and heating problems.

The above methods are believed to have brought results. Coke which had previously been a drug on the local market has been used extensively. Coke sales increased over 300 per cent and the local gas company has reported that a very large amount of their coke output has been contracted for the coming winter. By-product coke has been shipped in from Birmingham and Chattanooga, and sold at a price in competition with the local product. The gas company has installed many gas burners in the homes of the wealthier class, and oil-burning equipment has gained a strong foothold.

The retail coal merchants have been called upon to assist in the domestic campaign, and while a few of the less prominent dealers have not been won over to smoke abatement, the larger and more important ones are assisting admirably by recommending, and making an earnest effort to see the right kind and size of fuel go into the home. One large company has employed a fuel advisor to give free service to the home owner, and two others have assumed the agencies for approved types of domestic stokers, and are waging an effective campaign for their use.

The campaign in the home has brought encouraging results, but there is still a menace to combat within the residential area. Plans have been laid to intensify efforts in this direction during the next winter. A school for home owners has been projected for the early fall to be conducted through the afternoon paper. Citizens will be asked to enroll in this school. Lessons or lectures will be published daily and questions submitted will be answered each day. Following this educational week, there will be a city-wide "Clean Your Chimney Week" sponsored by the Citizens' Smoke Abatement League. Prizes will be offered school children for essays on smoke abatement, and for posters calling attention to the evils of a smoke-laden atmosphere. Smoke-abatement programs will be requested of all organizations, and radio talks made by leading citizens. The effort will be made to intensify public opinion, and make them smoke abatement conscious.

The cooperation of the press has been splendid during the entire campaign and requests for copy sometimes have been more urgent than it has been possible to comply with.

New Construction Improved

New construction and alterations to old installations have been handled by the permit system. All heating units, large and small, except in private residences, must pass the approval of the Bureau of Smoke Regulation before installation is started. No charge is made for this permit, but the ordinance provision requiring that it be obtained is enforced rigidly. The only case brought to court during the past year was due to a violation of this provision. A contractor was brought before the municipal court for failure to obtain the necessary permit, after having been warned. He was given a fine and appealed his case to circuit court, where the fine was upheld. Some difficulty was met with at first in getting the contractors to obtain the necessary permits, but since the above court case, their cooperation has been improved greatly.

The bureau makes no attempt to specify the make of boiler or furnace that can be installed, but it does assume the authority of specifying types. The bureau has taken the stand that no boiler or furnace will be permitted until it has proved its ability to function within the limits prescribed by city ordinance. Where a permit is requested for a boiler that is not known to the engineers of the bureau, and the manufacturer claims smokeless operation, its installation is permitted subject to test. If it cannot be fired under average operation within ordinance limits, it must be removed and permission for its future installation will not be granted.

The architects have been informed of the bureau's requirements, and their cooperation in specifying accepted types has been evidenced in all new construction. During the past summer the construction of three large buildings has been begun, the plans and specifications having been made by three different local architects. It is significant that the heating boilers of each of these buildings will be equipped with motor-driven underfeed stokers.

Experience in Knoxville with high-volatile bituminous coal has led the bureau to disregard the claims of manufacturers that their equipment has met the approval of smoke-abatement organizations in other cities. This is not meant as a reflection on either the manufacturers making such claims or on the engineers engaged in smoke-abatement work elsewhere. The author simply believes that the conditions in Knoxville are not enough like those in other cities to take the approval of smokeless operation in other cities as a criterion for smokeless operation in Knoxville. For that reason the Bureau of Smoke Regulation has its own list of approved types and adheres to it strictly, permitting no others unless the installation is made subject to test or the owner makes a written agreement to burn a smokeless fuel.

Types of Smokeless Boilers and Combustion Equipment

The experiences of the Knoxville bureau with different types of boilers and combustion equipment are given here as a matter of information.

1 *Straight-Draft Boilers.* (*Cast Iron and Steel.*) This type of boiler is not permitted in the sizes where approved boilers will apply. When permitted, the owner must burn a smokeless fuel.

2 *Smokeless Boilers With Refractory Arch.* It has been found that it is possible for this type of boiler to be operated within ordinance limits only with the most careful of fireman and the very best grade of coal. It is certain to smoke with local coals when operated at low ratings and low firebox temperatures. For these reasons permission for its installation is not granted.

3 *Smokeless Boilers With Air Admission Through Arch.* The later designs of this type of boiler are being operated within ordinance limits with a clean grade of coal and careful firing. Permits are issued for its installation, but particular attention is always given to instructing the fireman in the proper methods of operation to produce smokeless results.

4 *Downdraft Boilers.* The downdraft boiler has proved itself the best type of hand-fired boiler for smokeless operation. It is essential, however, to insure sufficient draft and a clean coal, even if the boiler is fired continually on the upper grates. The author knows of a number of cases where run-of-mine coal is used with considerable success in this type of boiler, but in each case the fireman is superior to the average, and works his upper grate in a manner to insure freedom of holes through which the fines can fall to the lower grate.

5 *Underfeed Stokers.* By far the greatest boon to the smoke-abatement engineer is the motor-driven underfeed stoker for low-pressure work with bituminous coals. The cheaper fuel and the smaller sizes used make them popular with the owner and the smoke-abatement authorities. They are gradually being reduced in size until their application is bringing splendid results in all sizes of boiler furnaces from the smallest to the largest. Some very great claims were made for these appliances in the early days of their appearance, and dissatisfaction was experienced due to salesmen's claims. The author was called by a new stoker owner, and requested to tell him what was the matter with his unit as it was giving considerable trouble. It was found that the stoker had been sold with the assurance that coal would be burned with "no smoke and no ash." As a result the ash and clinker had accumulated all the way from the grate surface to the boiler shell, and the owner was very much disturbed because his ashes had not burned up completely as he had been led to believe.

With a reasonable amount of care, proper setting height and average intelligent operation, the unit underfeed stoker will prove itself quite useful in smoke abatement.

Fines and Penalties

The provisions of the ordinance invoking fines and penalties on offenders have not been enforced during the first year except in the one case noted.

It has been thought that the public needed educating more than it did penalizing, and all efforts were made to that end. Some harsh warnings have of course been necessary to bring unwilling owners to make necessary changes in equipment, but with the exception noted, no court cases have resulted.

Up until the present time the bureau has not had sufficient personnel to exercise a constant supervision over smoking stacks. During the past summer a closer supervision has been kept over industrial stacks. When a violation is noted an immediate inspection is made of the boiler room, and the owner is given a notice containing an exact record of the smoke density and period of violation with a recommendation for improvement. Three notices will be given before court action is taken. Each notice seems to bring a decided improvement in conditions, and it is believed that the necessity of court action will be infrequent. The Bureau of Smoke Regulation is completely divorced from the police department and no prosecutions can be made except by the chief engineer.

Conclusion

The author has tried to refrain from discussing the question of smoke abatement from a technical standpoint. It has been his object to outline the work of the Bureau of Smoke Regulation in Knoxville, and submit their methods as a suggested means of approach in other cities confronted with a similar problem.

It is realized that Knoxville is not a very large city, and that a closer contact can be maintained with its citizens than in a city of much larger size. He does believe, however, that as close a contact as possible with the general public should be maintained in order to bring about worth-while results.

The small budget requested for the first year curtailed the activities of the bureau somewhat. An expansion is planned for the coming budget year, commencing in October, with a decided increase in personnel and a corresponding budget increase. Whether this will be allowed is not yet known. It is known, however, that in the face of a 20 per cent budget reduction ordered for the next year, smoke abatement will not be touched, unless the incoming council upsets the plans of the city manager. The chances of a decided increase are excellent.

While Knoxville is still classed as a smoky city, it cannot be denied that progress has been made. There are people that can see no improvement, and there always will be, but it is believed that the general public has been won for smoke abatement, and it is daily growing in favour.

A new soot-fall survey was started by the University of Tennessee in February, but due to the summer vacation data for only three months are at hand. While this survey has not been conducted for a long enough period to give an exact comparison, the total soot fall measured in tons per square mile per year shows an appreciable reduction over the 1927 survey.

The author, in conclusion, wishes to submit the following essentials for a successful smoke-abatement campaign:

1 A well-directed preliminary campaign designed to make the public want smoke abatement.

2 The passage of a complete ordinance that can be enforced without necessary hardships on those concerned.

3 The complete removal of smoke abatement from the police department.

4 The necessity of appointing an experienced engineer, not only to carry out the provisions of the ordinance, but to gain the respect and confidence of the public.

5 Reduce prosecutions to the minimum and prosecute only when other methods fail.

6 Start the work with a small budget and personnel, increasing it only after the work of smoke abatement has proved itself in the minds of the public.

7 Enlist the aid and support of the press. Without its aid little can be accomplished.

8 Most essential of all, keep smoke abatement free from political influences.

Coal Pretreatment

By CLARENCE B. WISNER,[1] NEW YORK, N. Y.

PRETREATMENT of coal must offer financial profits or economic advantages, or both, in order to function under present-day conditions. Assuming a sound business basis, important economic considerations include health, sunlight, and cleanliness. The health commissioner of Chicago is quoted as stating that 16 per cent of the deaths in his city are caused by smoke, and that its elimination would reduce the death rate from the present figure of 12 per thousand to 10 per thousand. It has been estimated that smoke cuts off one-third of the sunlight of New York City, and the annual damage to buildings, house furnishings, and decorations, added to the cost of cleaning, is said to total one hundred million dollars in New York City alone.

Loss of Fuel

The combustion of bituminous coal includes three separate and distinct actions, each centered about a different fuel. The fuels are tar, gas, and carbonized residue. Tar eduction is a distillation process with a time element in burning much longer than the gas or carbonized residue. When the tar molecule is released it is covered with a gas envelope requiring turbulence to bring it into intimate contact with oxygen. This often does not take place until the gases are in the chimney or until they have passed out of it. Thus smoke is caused by the breaking up of the gas unit at a reduced temperature releasing the carbon.

The gas contains a large portion of methane burning under about the same conditions as natural gas. Carbonized residue carrying volatile is free burning with rapid combustion. One of the products obtained from carbonizing coal is oil. Many large bodies of bituminous coal contain three-fourths of a barrel per ton. Next to petroleum this oil is believed to offer the cheapest raw stock for motor fuel. Petroleum derivatives occupy such an important place among the necessities and luxuries of life that the maintenance of a future supply is a serious matter.

Increased demand for petroleum products is such that the present consumption will be doubled in less than four years. Therefore, a pretreatment of coal, which will provide oil as one of the products, will unquestionably be found essential. This is on the assumption that the production of petroleum will not double in the next four years. In some quarters it is felt that the cleaning of coal meets present requirements. A study of the matter, however, indicates that this is not the case.

Coal Cleaning

In keeping with modern industrial progress, the operation of mining is performed with mechanical undercutters and loaders. Mining machines have no means of differentiating between coal and rock handled, and although the coal in place may be low in ash, more or less wall rock will be included with the loaded coal. The rock usually breaks finer than the coal when sized, thus throwing the highest ash content into the slack, which ordinarily means all that will go through a $^3/_8$-in. screen.

Slack coal, as burned in the big steam plants, on an average carries from 11 to 16 per cent ash. It is worthless as domestic fuel. If, as is claimed, 40 per cent of all coal mined breaks to slack, the need of processes for turning this enormous tonnage into an improved fuel is obvious.

The geologically older coals have been the first to be cleaned; the volatile content is quite stable, and spontaneous combustion is not a troublesome factor when stored. This is not true of the younger and higher-oxygen coals mined in the greater part of Ohio and the states west.

Operators complain that cleaning does not go far enough; that coal pretreatment must give a product strong and shipable to be attractive. With this understanding it will be seen

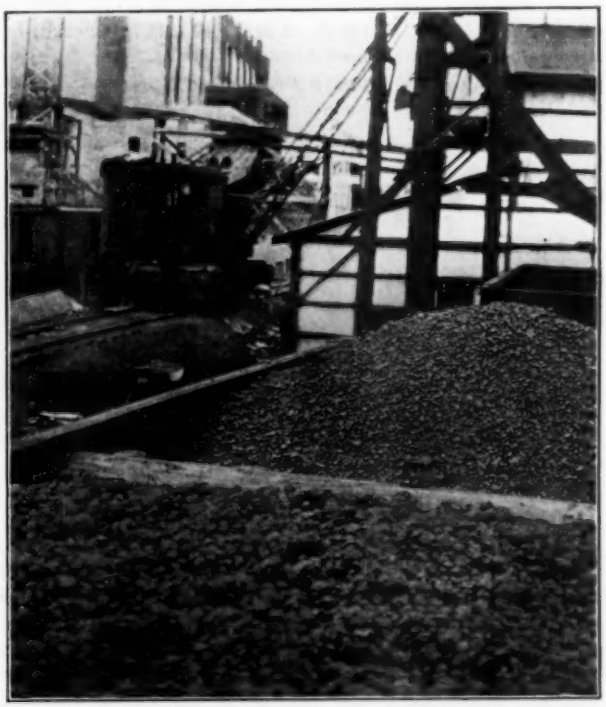

Fig. 1 A Carload of Coal Balls; Half Are Stove Size, Half Nut

that although coal cleaning is essential to the best use of coal for any pretreatment program, it does not play a major part, because it only reduces high-ash coals to a par with low-ash coals, of which there is not enough to go around. It has accomplished nothing toward reducing smoke or conserving by-products.

Low-Temperature Carbonization

It is not the purpose of this paper to discuss a process that has already been carefully covered,[2] further than to say that the coal-ball process is a two-stage continuous method of low-temperature carbonization founded upon two basically new principles.

Presented at the Third National Fuels Meeting, Philadelphia, Pa., October 7 to 10, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

1 *Thermodizing*, modifying, and conditioning the coal in a thermal pretreatment in which oxygen may be brought into intimate contact

[2] Proceedings of the First International Coal Conference on Bituminous Coal, Carnegie Institute of Technology, 1926. These contain a description of the Carbocite process by which coal balls are made.

with heated coal while it is tumbling through an indirectly heated closed rotating container.

It prevents sticking to the retort during the plastic stage.

It controls the swelling, the density, and weight of the fuel.

It makes possible an ideal domestic fuel, coal balls.

It controls the maximum size of coal balls.

It carries into the coal two-thirds of the carbonizing heat required in the next step of carbonization, utilizing the waste heat from the carbonizer.

2 *High velocity of heating medium*, a double-shell retort, the space between the coal container and the outer wall forming the heating flue, limited in depth to draw the heating medium around the coal container at a velocity of 75–100 ft. per sec.

The demonstration plant at Philo, Ohio, has convincingly taught that capacity is in direct proportion to the velocity of the heating medium drawn over the wall of the container.

In these two methods, steps exclusively parts of the coal-ball process, lies the key to successful low-cost processing of all solid fuels giving off hydrocarbons at critical temperatures.

The gross fuel used in the process operating at 100 tons per day has been 700 B.t.u. per lb. of raw coal. It is believed that the fuel used will be reduced to under 500 B.t.u. per lb., when operating a 250-unit, bringing the efficiency up from 55.5 per cent to 78 per cent.

TABLE 1 RELATIVE SUPERIORITY OF SMOKELESS FUELS

Requirements	Anthracite, per cent	By-product coke, per cent	Pocahontas, per cent	Coal balls, per cent
Smokeless	100	100	75	100
Cleanliness	100	100	25	100
Low ash	25	50	75	50
Clinker	75	25	75	100
Fire control	75	25	100	75
Firing periods	100	50	75	75
Value to consumer, total points.	475	350	425	500

TABLE 2 SALES OF SMOKELESS DOMESTIC FUEL IN CLEVELAND, OHIO

	Anthracite	By-product coke	Pocahontas	Coal balls
Annual sales, 256,500 tons	60,000	20,000	175,000	1,500
Price in buyers' bin	$14.50	$11.25	$10.85	$12.00
Dealers' gross margin	3.25	4.00	4.50	4.00
F. o. b. dealers' siding	11.25	7.25	6.35	8.00

FIG. 2 STOVE-SIZE COAL BALLS MADE FROM PITTSBURGH VEIN COAL

FIG. 3 NUT-SIZE PRODUCT MADE FROM PITTSBURGH VEIN COAL

FIG. 4 A SUPERPOWER COAL-HANDLING UNIT (This plant cost in excess of $500,000. It has an unloading capacity of 500 tons or more per hour and distributes to storage or to the boilers. A car of coal is over the unloading hopper at the left. There is a duplicate unit to the right.)

It is now proposed to take up the practical use of such a product, and outline the experiences encountered. Sufficient sale and use has taken place so that definite trends have been established.

The prepared fuel known as coal balls is a smokeless product of bituminous coal. It has been produced in considerable quantity, and distributed to the consumer in competition with other smokeless fuels. The selling price was next to anthracite, but in spite of that it was very popular and the demand exceeded the amount which it was possible to supply.

COAL BALLS

In character the fuel is strong and dense. It has the same weight as by-product coke of equal size and made from the same coal. It has stood the test of being loaded with a clamshell bucket, of being dumped into the coal pockets of dealers, and of being delivered by truck, without complaint of degradation loss.

Coal balls are formed during the plastic stage of carbonization, while tumbling through a rotating container, and because of their oval shape they do not offer rough edges to crumble and form breeze. Of the product, 85 to 100 per cent may be shipped in perfect form as domestic fuel.

Table 1 was made by a mine operator and representatives of wholesale and retail distributors.

A preliminary test of this fuel for steam raising on chain-grate stokers indicates economies that may make it as useful for this purpose as for domestic fuel.

With 85 per cent to 100 per cent of the solid product in suitable state for sale as domestic fuel in competition with other smokeless fuels, the sale value of the by-products is not the impelling factor which it becomes when the coal is to be carbonized for the power house, because of the wide margin between the cost of slack and the sale price of smokeless domestic fuels.

When considering the latter the value of low-temperature oil becomes of major importance, because there must be delivered to the power house the same number of heat units in the carbonized fuel and surplus gas as were contained in the raw coal, to make it attractive. Whatever saving is made in decreased upkeep cost, extending to firing and degradation loss in stored reserves, will be accepted as a profit and reason for adopting processed fuel.

Following this basis of reasoning there is thrown upon the by-products the duty of producing a revenue equal to or exceeding (1) loss of B.t.u., extracted in the volatile hydrocarbons, (2) cost of processing, and (3) interest and amortization of capital.

Power-station fuel in Ohio, Indiana, and Illinois is generally noncoking, high in volatile hydrocarbons, and quite liable to catch fire in storage. Although these coals do not make a good carbonized domestic fuel without mixing with some coking coal, they do produce an excellent steam fuel when carbonized alone.

These coals are greatly improved as steam fuel by carbonizing, and as now mined with mechanical undercutters they produce a high-ash slack with an average heat unit content as burned of, approximately, 25,000,000 B.t.u. per ton. There will remain in the carbonized fuel 17,500,000 B.t.u.; in surplus gas, 1,125,000 B.t.u., and charged to process 25 per cent of the cost of the coal, 6,375,000 B.t.u. per ton. The cost of raw coal delivered to boilers in Ohio is $2.25, and in Indiana $3.35.

It is assumed that at the power plant no market will exist for the gas and that the surplus over processing requirements will be burned as fuel. There will be no need of duplicating the coal-handling and storage plants, so that it is believed that the cost of the carbonizing plant can be kept within $2 per ton of annual capacity.

TABLE 3 CHARGES THAT MUST BE BORNE BY THE RECOVERED OIL PRODUCT

25 per cent of the raw cost		$0.57	$0.84
Operating labor	$0.18		
All other operating expense	0.27		
Capital charges, 15 per cent on $2 ton	0.30	0.75	0.75
Cost of oil per ton of coal processed		$1.32	$1.59

The oil content will approximate 30 gallons per ton, and 2½ to 3 gallons of light oil from the gas.

The place for the power-house processing plant is at the unloading station. The coal passes through it with as little difficulty as over a belt conveyor. The carbonized fuel, positively cooled, is put back on the belt for delivery to boilers or storage.

It is believed that the true future market for the oil is as a cracking and hydrogenation stock for motor fuel, and that it will follow the price of petroleum for crude stocks of similar gravities. Additional research is of great importance at this point as indicated by the increased recovery of motor fuel from petroleum from 30 per cent to 45 per cent by means of cracking.

Low-temperature oil, by cracking, has produced 22 per cent water-white motor fuel of a superior anti-knock quality, and 13 per cent of tar acids. This is exclusive of the light oil recovered from the gas. The development of hydrogenation at atmospheric pressure applicable to this oil is well on toward

FIG. 5 DISTRIBUTING BELT WITH TRIPPER DISCHARGING STREAM OF COAL TO THE STORAGE WHARF

FIG. 6 END OF DISTRIBUTING BELT AWAY FROM THE POWER HOUSE WITH TRIPPER DISCHARGING TO STORAGE

FIG. 7 METHOD USED TO KEEP STORED COAL SAFE FROM SPONTANEOUS FIRING

For superpower steam fuel it has been shown that there must be assured at least $1.32 in Ohio and $1.59 in Indiana from the oil by-products before the cost of processing is justified. If 30 cents be taken as the value of the light oil recovered from the gas, then the 30 gallons of heavy oil must sell for $1.03 for Ohio coal and $1.29 for Indiana coal; in other words, for from 4 cents to 5 cents per gallon.

Time contracts have been made at a higher price than this, but the supply has been small, and this may not represent a permanent price for unlimited supply.

This low cost of operation is made possible by operating as a department of a going business with an engineer-superintendent in charge and includes:

Working shift bosses
One extra chemist in laboratory
One control room with one operator for each 1000 tons capacity
Eight men on shift
Ordinary repairs handled by shift crews
Major repairs by power station machine-shop crew on hourly basis
No hand labor in the flow sheet from raw coal to finished products

This cost estimate is based on actual operation.

commercial use. It may open a highly profitable outlet for these oils.

Another point to be borne in mind is that the preferable location for carbonizing plants will be in communities of considerable size, which require large quantities of motor fuel. To make use of motor fuel produced from low-temperature distillation and refined at the plant would therefore save freight on the crude out and the refined in; the price approaching closely filling station prices.

As regards the domestic market there is little reason to doubt the permanency of demand. Experience has shown that the domestic uses will absorb a large volume of carbonized fuel, and that this is possible with relatively little comeback or dissatisfaction.

The margin between the price for slack coal and the selling price of smokeless fuels is great enough to warrant large production. The fact that about 40 per cent of all bituminous coal breaks to slack size, provides material for large production at reasonable figures. Much of this slack is not utilized at the present time, but it is beyond question that as the tonnage of processed fuel increases, the price to the consumer will decrease, and this in turn will expand the demand for the product, provided these manufacturing advantages result in greater quantity production.

FSP-52-25

A Graphic Method for Determining Expansion Stresses in Pipe Lines

By C. T. MITCHELL,[1] NEW YORK, N. Y.

The modern engineer recognizes an expansion problem in every pipe that carries steam. Increasing temperatures and pressures may compel the labeling of every important joint in the piping of a power plant with the bending stress allotted to it, the same as the stress diagram of a truss. The paper describes a serviceable method for determining the stresses. The claimed advantages are that it is graphic and thus free of tables and formulas; it is concerned only with the entire pipe structure from one anchor point to another; it is a standardized method applicable to any pipe structure in one or more planes; it involves less work with greater accuracy.

AN expanding pipe line gives no visible evidence of the terrific bending strain that it may be exerting on a certain joint—no evidence but the sudden escape of steam. The blame for failure of a joint is frequently laid to the gasket or to the bolts or to the pipe fitter.

If a pipe joint could be furnished with a guarantee as to the amount of bending strain it would stand before beginning to leak, due care would be exercised to see that it was not overstressed. But since no such guarantee is available is it not logical to treat the joint with all the more consideration?

The practice of installing large loops on the steam headers and allowing the rest of the piping to take care of itself is nearly obsolete. The modern engineer recognizes an expansion problem in every pipe that carries steam, whether he takes the time to analyze it or not. Increasing temperatures and pressures may soon force him to label every important joint in the power plant with the bending stress allotted to it, in similar fashion to the stress diagram of a truss. There is a tendency in this direction now, but very little system in carrying it out, partly because of the lack of a serviceable method for determining the stresses.

In this paper an attempt has been made to supply this deficiency. The method to be described is recommended as having the following advantages:

(1) It is almost entirely graphic and is thus independent of tables and complicated formulas.

(2) It is concerned only with the entire pipe structure from anchor point to anchor point, and thus avoids the uncertainty of trying to piece together the supposed deflections of individual bends.

(3) It is a standardized method, applicable to any independent pipe structure, whether in one or more planes.

(4) It involves less work than any other known method for the same degree of accuracy.

(5) It has been in active use for two years by the author and thus has been proved out as a practical working method.

Two broad assumptions are made in every problem covered by this method: first, the ends or anchor points of a structure are assumed to be 100 per cent fixed—that is to say, the direction of the axis of the pipe where it passes through the anchor does not change; second, the moment of inertia of the pipe is assumed to be constant, whether the section be taken in a bend or elsewhere.

It has been found that any assumptions other than these involve an amount of labor that is entirely out of proportion to its value. Furthermore, there is no means for determining the degree to which a pipe end is fixed nor the amount of flattening of a pipe section in bending. The very uncertainty regarding these matters makes it superfluous to aim at high accuracy. It is better to maintain a good average in all problems than to hit the bullseye in one problem and be wide of the mark in the next. A structure proportioned on the foregoing assumptions will be conservatively designed. The cost of such conservatism is believed to be negligible.

Two other features of this graphic method deserve comment, since they are at variance with the usual practice: first, no attempt is made to determine the horizontal and vertical reactions at the anchor points, for that only complicates the analysis, the only force dealt with being the one which passes through both anchors, whether the anchors are on the same elevation or otherwise; second, all bends are eliminated from the structure during the analysis, and square corners are substituted in their place, a correction being subsequently made to allow for the influence of the bends. This procedure does away with the most laborious element of these problems. Its justification will be demonstrated at the conclusion of the paper.

For the benefit of those who are willing to accept the method on its face value a few typical problems will first be worked out in detail. These will be followed by the theoretical derivation. There is nothing new in the theory. It is as old as the equation of the elastic curve. It should be accepted as a necessary adjunct of this paper, however, since those who are conversant with the theory will make the most intelligent use of the graphic method.

Notation

- P = thrust between anchors, lb.
- Δ = expansion of pipe between anchors, in.
- E = modulus of elasticity, lb. per sq. in.
- I = moment of inertia of pipe, in.[4]
- M = sum of moment areas times distance of center of gravity of each to neutral axis, cu. ft.
- S = stress in outside fiber of pipe, lb. per sq. in.
- P_c = thrust corrected for bends on pipe, lb.
- R = shortest distance from neutral axis to point of greatest bending moment, ft.
- D = outside diameter of pipe, in.
- d = inside diameter of pipe, in.
- T = total length of pipe with square corner bends, ft.
- t = total length of pipe with full radius bends, ft.

[1] Allied Engineers, Inc. Mr. Mitchell was born in August, 1878. He was graduated from Sheffield Scientific School, Yale, 1901, in mechanical engineering, and then was associated for several years with Western copper mines and smelters in general engineering work. Since 1916 he has specialized on power-plant engineering with J. G. White Engineering Corporation, Electric Bond and Share, and Allied Engineers, Inc.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

A, B, C, D, E, F, G = moment areas, sq. ft.
$a, b, c, d, e, f, g, l, m, n, o$ = distances on sketches, ft.

ASSUMPTIONS

All pipe ends 100 per cent fixed.
Moment of inertia of pipe constant at all sections.

FORMULAS

$$I = \frac{\pi}{64}(D^4 - d^4)$$

$$P = \frac{\Delta EI}{1728\,M}$$

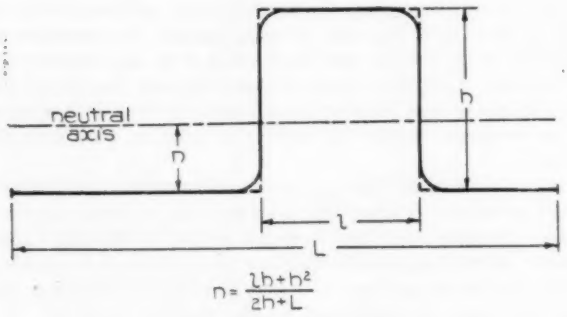

FIG. 1

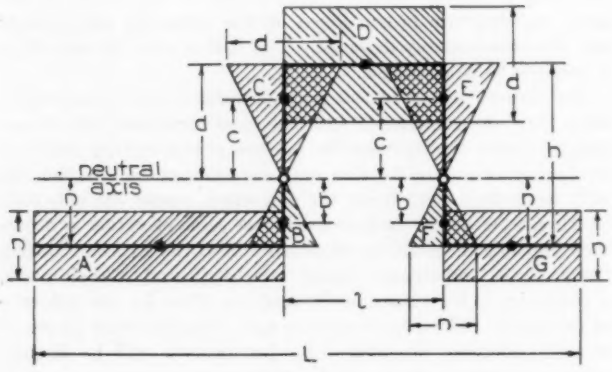

FIG. 2

For determination of M, see cases below.

$$P_c = \frac{PT}{t}$$

$$S = \frac{6P_cRD}{I}$$

DETERMINATION OF M

Case I, Figs. 1 and 2.

(A) Locate neutral axis. The neutral axis passes through center of gravity of shape and is always parallel to the line connecting the end or anchor points, as shown in Fig. 1.

(B) Draw moment areas A, B, C, D, E, F, and G, as shown in Fig. 2. These areas should be drawn about the member to which they apply, the member bisecting the area.

(C) Compute square feet in moment areas.

(D) Compute M by multiplying each moment area by its respective moment arm. The moment arm is the perpendicular distance from the center of gravity of the area to the neutral axis.

$$M = An + Bb + Cc + Dd + Ec + Fb + Gn$$

Case II, Figs. 3, 4, and 5.

(A) Locate neutral axis parallel to line connecting pipe ends, as shown in Fig. 3.

(B) Draw moment areas A, B, C, D, and E, as shown in Fig. 4.

(C) Compute square feet in areas A, B, C, D, and E.

(D) Locate center of gravity of each area.

(E) Compute M.

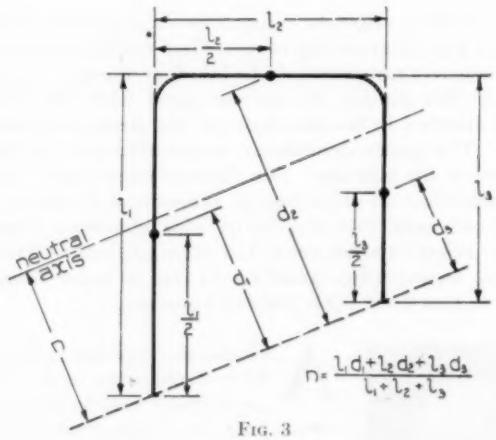

FIG. 3

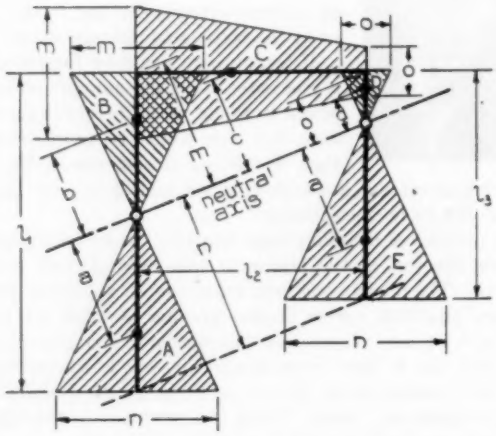

FIG. 4

$$M = Aa + Bb + Cc + Dd + Ea$$

Note: For convenience in locating center of gravity of a trapezoid, the graphic method suggested by Fig. 5 may be used.

Case III, Figs. 6 and 7.

(A) Locate neutral axis, as shown in Fig. 6, through the mid-points of lengths l_1 and l_2.

(B) Draw moment areas A, B, C, and D, as shown in Fig. 7.

(C) Compute square feet in areas A, B, C, and D.

(D) Locate center of gravity of each area.

(E) Compute M.

$$M = Aa + Ba + Ca + Da$$

To Plot the Moment Areas Correctly.

(1) Draw a line at the end of each pipe member perpendicular to the pipe.

(2) The length of this line is equal to the perpendicular dis-

tance from the pipe end to the neutral axis. The pipe member bisects this line.

(3) Complete the figure to obtain closed area.

TYPICAL SINGLE-PLANE PROBLEM (FIGS. 8, 9, AND 10)

Conditions.

12-in. pipe-wall thickness = 1.219 in.

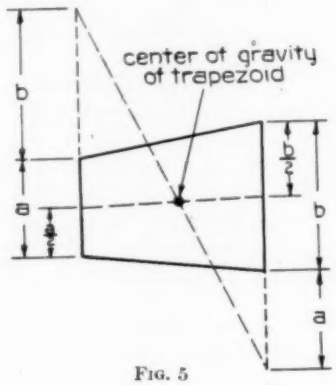

FIG. 5

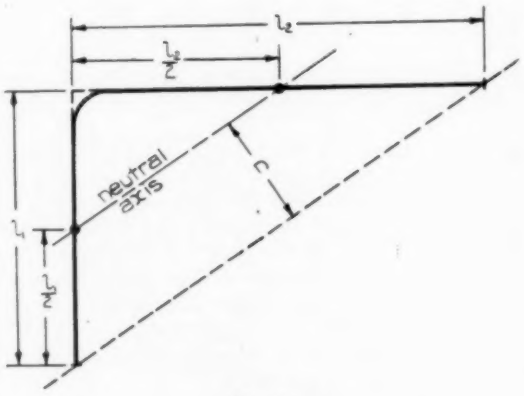

FIG. 6

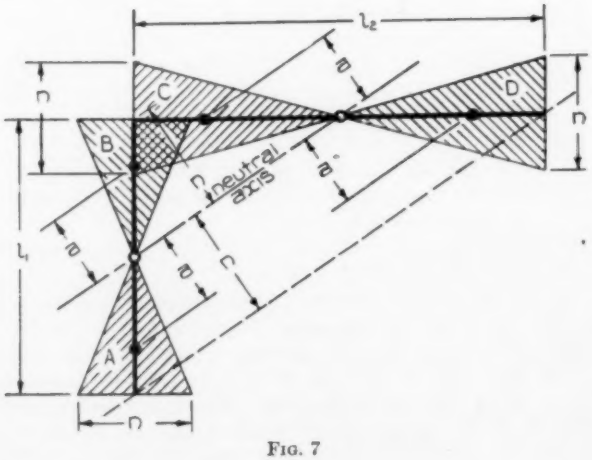

FIG. 7

I = 740.0 in.^{4}
Temperature of steam = 750 deg. fahr.
Room temperature = 70 deg. fahr.
Expansion of steel pipe at 680 deg. fahr. = 7.20 in. per 100 ft.
Fig. 8 shows the piping arrangement.

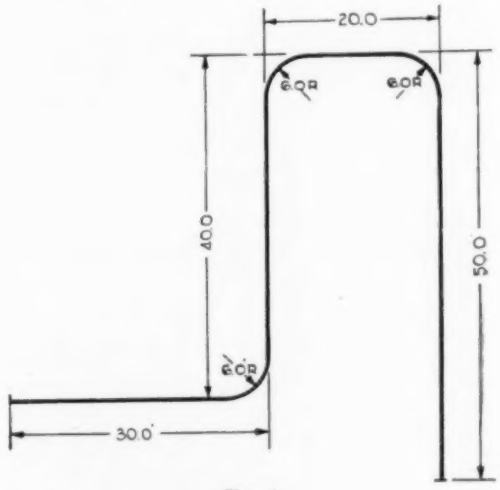
Procedure.

(A) Redraw arrangement at a convenient scale and make all bends in pipe square corners.

(B) Locate neutral axis, as shown in Fig. 9.

(C) Draw moment areas A, B, C, D, E, and F, as shown in Fig. 10.

(D) Compute square feet in areas A, B, C, D, E, and F.



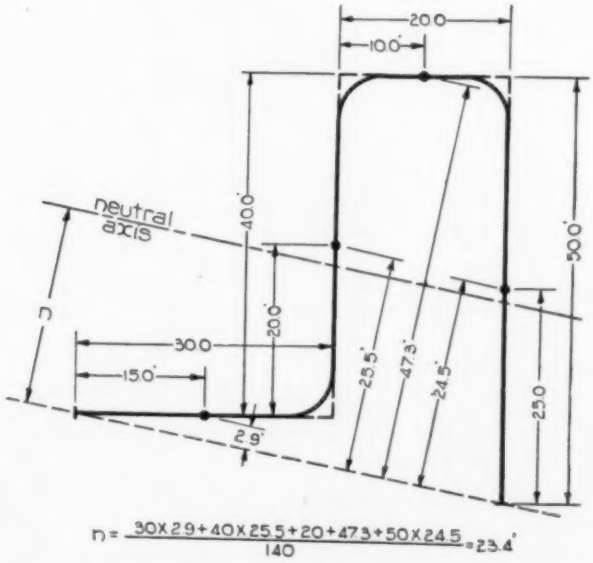


FIG. 8

$$n = \frac{30 \times 2.9 + 40 \times 25.5 + 20 + 47.3 + 50 \times 24.5}{140} = 23.4'$$

FIG. 9

$A = \frac{1}{2}(23.4 + 17.6)\,(30) = 615$
$B = \frac{1}{2}(17.6)\,(17.9) = 158$
$C = \frac{1}{2}(21.9)\,(22.1) = 242$
$D = \frac{1}{2}(21.9 + 25.6)\,(20) = 475$
$E = \frac{1}{2}(25.6)\,(26.2) = 335$
$F = \frac{1}{2}(23.4)\,(23.8) = 279$

Note: A check on the work may be made at this point. The sum of the areas on each side of the neutral axis should be equal.

(E) Compute M.

$M = Aa + Bb + Cc + Dd + Ee + Ff$

$= (615)(20.8) + (158)(11.7) + (242)(14.4) + (475)(24.0) + (335)(16.8) + (279)(15.7)$
$= 39{,}545$ cu. ft.

(F) Compute P.

Distance between anchors = 51.0 ft.

consequently, $\Delta = \dfrac{7.20 \times 51.00}{100} = 3.68$ in.

therefore, $P = \dfrac{\Delta EI}{1728M} = \dfrac{3.68 \times 29{,}000{,}000 \times 740.0}{1728 \times 39{,}545} = 1160$ lb.

and, $P_c = \dfrac{PT}{t} = \dfrac{1160 \times 140}{132.2} = 1230$ lb.

(G) Compute S.

The greatest stress in the pipe line is located at a point farthest from the neutral axis. From Fig. 10 this distance R is found to be equal to 25.6 ft.

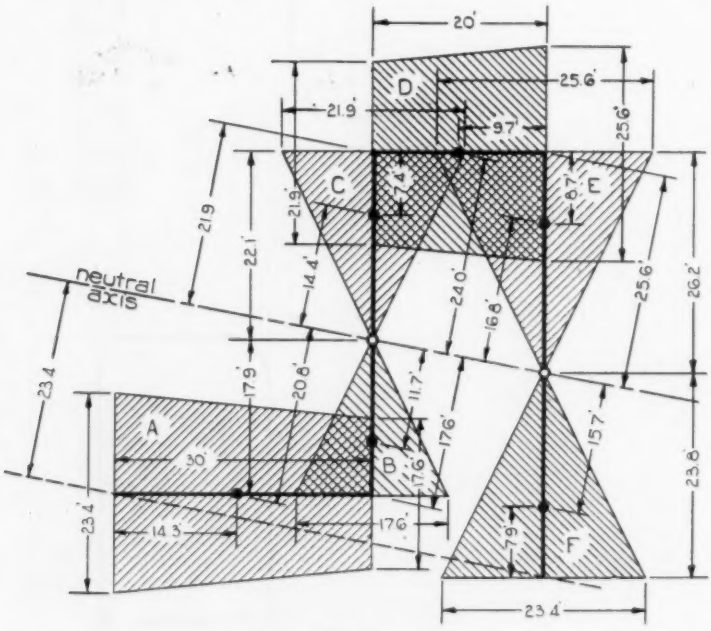

Fig. 10

Then, substituting in formula $S = \dfrac{6P_cRD}{I}$

$S = \dfrac{6 \times 1230 \times 25.6 \times 12.750}{740.0} = 3250$ lb. per sq. in.

The stress may be calculated at any point along the pipe line by scaling the perpendicular distance from this point to the neutral axis and substituting it for R in the foregoing stress formula.

Typical Two-Plane Problem (Figs. 11, 12, 13, 14, and 15)

Conditions.

6-in. pipe-wall thickness = 0.5 in.
$I = 45.4$ in.^{4}
Temperature of steam = 750 deg. fahr.
Room temperature = 70 deg. fahr.
Expansion of steel pipe at 680 deg. fahr. = 7.20 in. per 100 ft.
Fig. 11 shows the piping arrangement.

Procedure.

(A) Preliminary drawing.

(1) Lay out plan view to scale, with line X–X connecting anchors parallel to top edge of paper and all bends changed to square corners, as in Fig. 12.

(2) Draw elevation, as in Fig. 13, which shows the line X–X in its true length.

(3) Project another plan, as in Fig. 14. This view also shows line X–X in its true length.

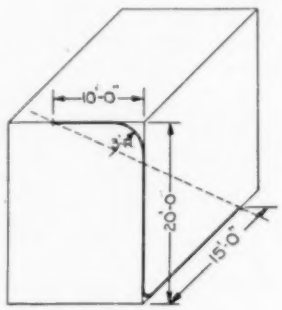

Fig. 11

(B) Locate neutral axis.

(1) Draw neutral axis through center of gravity of each view parallel to line X–X, taking care to use the true and not the projected length of each pipe member in the calculations, as follows:

$$n_1 = \frac{(10 \times 2.05) - (20 \times 2.60) - (15 \times 4.60)}{45} = -2.23 \text{ ft.}$$

$$n_2 = \frac{(10 \times 4.15) + (20 \times 8.35) + (15 \times 4.15)}{45} = 6.02 \text{ ft.}$$

(C) Draw moment areas A, B, C, D, E, F, and G, as shown in Fig. 15.

(1) To determine the moment areas it is necessary to know the perpendicular distance from the neutral axis to all parts of the piping arrangement. This distance for any point is the hypotenuse of a triangle, the legs of which are the ordinates to the neutral axis from the point in question. These ordinates may be scaled from Figs. 13 and 14.

(2) Draw the moment areas about the line Y–Y shown in Fig. 15. This line represents the total length of pipe with each member marked out to scale.

(*a*) Above line Y–Y and perpendicular to it, mark off the ordinates for the end of each member, as scaled from Fig. 13.

(*b*) Where the neutral axis crosses the middle member in Fig. 13, the ordinate with respect to line Y–Y is zero. Mark this point on line Y–Y in its relative location.

(*c*) Draw all ordinates *above* the line Y–Y irrespective of their position in Fig. 13.

(*d*) Connect the plotted points with straight lines.

(*e*) Draw the irregular line below line Y–Y in such a way that the vertical distance between the lines above and below Y–Y at any point is the bending moment at that point. This is conveniently done by laying off the required ordinate, scaled from Fig. 14, horizontally along line Y–Y, and by swinging the hypotenuse or true bending moment into position, as illustrated in Fig. 15.

(3) Divide the total moment area into a convenient number of trapezoids.

(D) Compute square feet in areas A, B, C, D, E, F, and G.

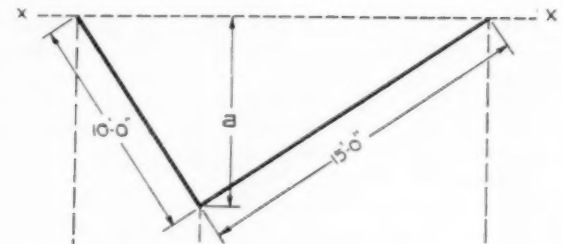

Fig. 12

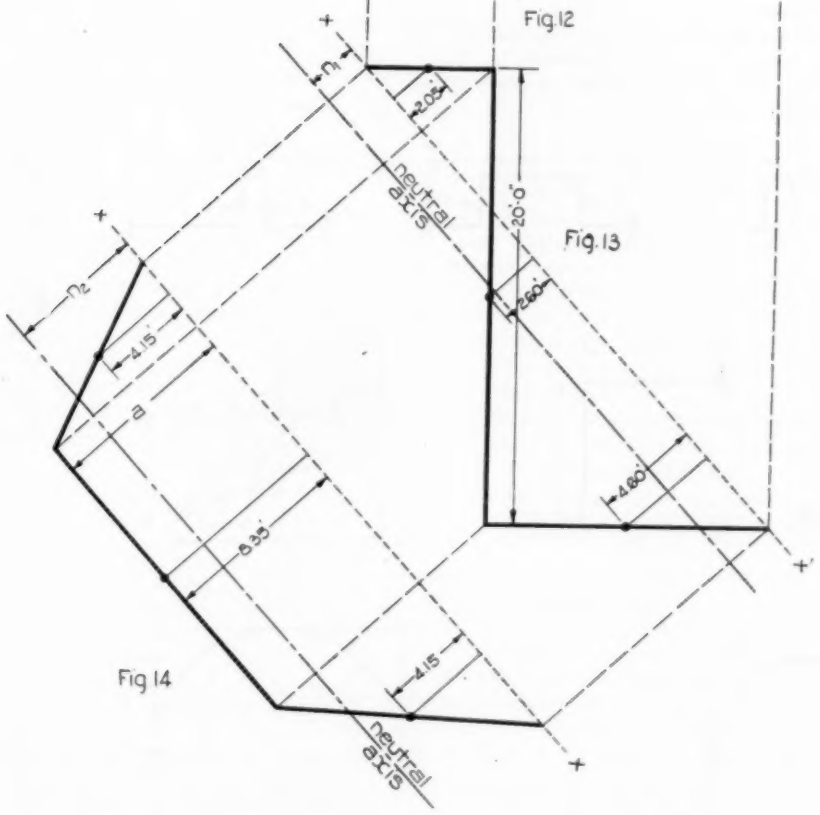

Fig. 13

Fig. 14

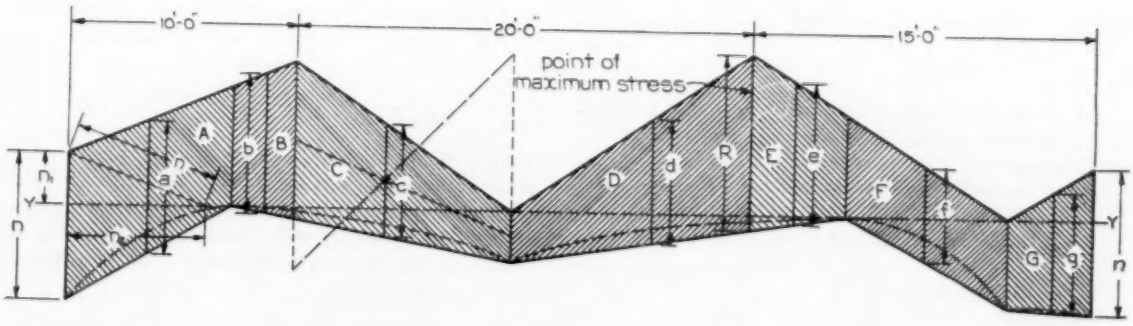

Fig. 15

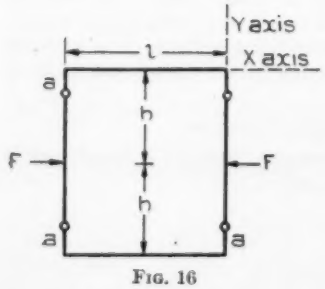

Fig. 16

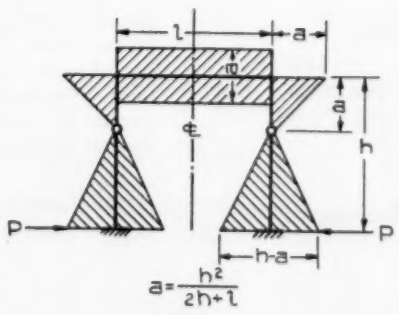

Fig. 17

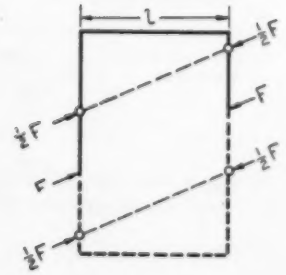

Fig. 18

$A = \frac{1}{2}(6.4 + 5.2) \times 7.2 = 41.7$
$B = \frac{1}{2}(5.2 + 6.9) \times 2.8 = 17.0$
$C = \frac{1}{2}(6.9 + 2.3) \times 9.5 = 43.7$
$D = \frac{1}{2}(2.3 + 7.7) \times 10.5 = 52.5$
$E = \frac{1}{2}(7.7 + 4.5) \times 4.2 = 25.6$
$F = \frac{1}{2}(4.5 + 4.0) \times 7.1 = 30.2$
$G = \frac{1}{2}(4.0 + 6.4) \times 3.7 = 19.3$

(E) Compute M.

(1) Determine distances a, b, c, d, e, f, and g.

(a) Locate center of gravity of each trapezoid by the graphical method previously described.

(b) Draw lines through each center of gravity and perpendicular to Y–Y.

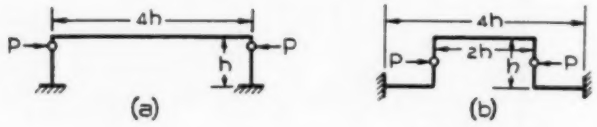

Fig. 19

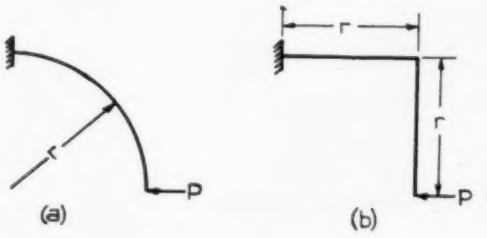

Fig. 21

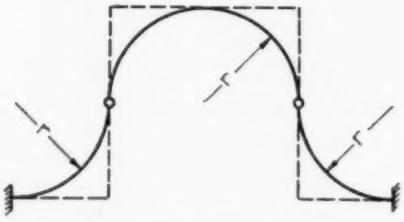

Fig. 22

(c) Scale the length of each line a, b, c, d, e, f, and g, as shown in Fig. 15.

(2) Compute M.

$$M = Aa + Bb + Cc + Dd + Ee + Ff + Gg$$
$$= (41.7)(5.8) + (17.0)(6.1) + (43.7)(5.0) + (52.5)(5.4) + (25.6)(6.2) + (30.2)(4.1) + (19.3)(5.2)$$
$$= 1237 \text{ cu. ft.}$$

(F) Compute P.

Distance between anchors = 26.9 ft.

$$\text{consequently, } \Delta = \frac{7.20 \times 26.9}{100} = 1.94 \text{ in.}$$

$$\text{therefore, } P = \frac{\Delta EI}{1728\,M} = \frac{1.94 \times 29{,}000{,}000 \times 45.4}{1728 \times 1237} = 1195 \text{ lb.}$$

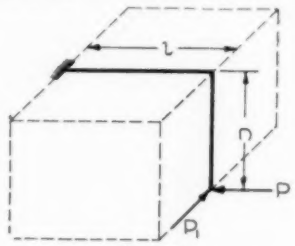
$$\text{and } P_e = \frac{PT}{t} = \frac{1195 \times 45}{42.6} = 1260 \text{ lb.}$$

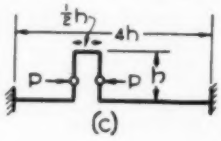
(G) Compute S.

The maximum stress occurs at the point of greatest bending moment. In the two-plane piping arrangement this stress may be due to a combination of torsion and bending. An explanation will be given later as to why it may be treated as though it were a simple bending stress.

The point of maximum stress is shown in Fig. 15, and the distance R is found to be equal to 7.7 ft.

Then, substituting in formula $S = \frac{6\,P_e\,RD}{I}$





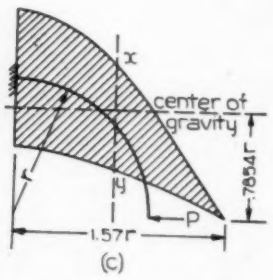


Fig. 20

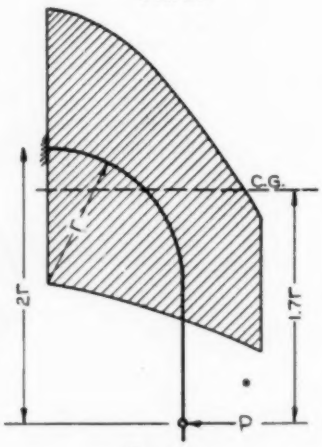

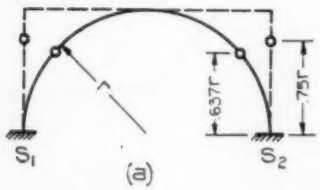

Fig. 23

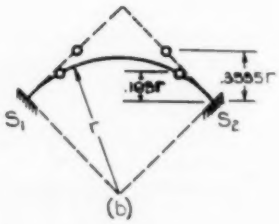

Fig. 24

$$S = \frac{6 \times 1260 \times 7.7 \times 6.625}{45.4} = 8500 \text{ lb. per sq. in.}$$

The stress may be calculated at any point along the pipe line by scaling the ordinate at this point on line Y–Y in Fig. 15, and substituting it for R in the foregoing stress formula.

Explanation of Dotted Curves in Moment Diagram

If all points on each member are plotted for the bending moment, it will be found that the lower line of the diagram, Fig. 15, is a series of curves instead of straight lines. The labor involved in plotting these curves is not considered worth while in view of the small amount of accuracy sacrificed. It is more important to avoid errors in plotting than to be too precise about the last decimal.

Theoretical Analysis

The theory upon which the graphic method is based may be demonstrated as indicated on page 7.

The first step is to eliminate all bends and to replace them with square rigid corners. Square corners are physically impossible, of course, but for the purpose of theoretical analysis they are excellent. Having computed the stresses in a square-cornered structure, a method will be indicated for correcting the results and applying them to an equivalent round-cornered structure.

Fig. 16 represents four lengths of pipe joined at angles of 90 deg. at the corners, each corner having the same rigidity as the pipe itself. At the middle of the vertical length a force F is acting, and is opposed by an equal force on the opposite side. It is evident that when flexure occurs four points of neutral bending moment are formed in the vertical members at a distance a from the corners. To determine the length a, follow the procedure used in mechanics in the analysis of continuous beams.

TABLE 1 MOMENTS OF INERTIA OF PIPE SECTIONS

Nominal size of pipe, in.	O.D.	250 Lb. Std. I.D.	250 Lb. Std. I	400 Lb. Std. I.D.	400 Lb. Std. I	600 Lb. Std. I.D.	600 Lb. Std. I	900 Lb. Std. I.D.	900 Lb. Std. I	1350 Lb. Std. I.D.	1350 Lb. Std. I
4	4.500	4.026	7.2	3.826	9.6	3.938	8.3	3.750	10.4	3.500	12.8
6	6.625	6.065	28.5	5.761	40.2	5.855	36.8	5.625	45.4	5.250	57.2

16	16.000	15.000	733.0	14.625	969.0	14.500	1045.0	13.938	1365.0	13.000	1812.0

Take an origin at the upper right-hand corner, with Y axis vertical and X axis horizontal. Clockwise moments will be considered positive. The moment of inertia of the pipe is I and the modulus of elasticity E. The bending moment at any point in the length immediately below the origin $= M =$

$$EI\frac{d^2x}{dy^2} = F(h-y) - \frac{F}{2}(2h-y-a) \quad \ldots\ldots [1]$$

integrating

$$EI\frac{dx}{dy} = Fhy - \frac{Fy^2}{2} - Fhy + \frac{Fy^2}{4} + \frac{Fay}{2} + C_1 \quad \ldots [2]$$

and

$$EIx = \frac{Fhy^2}{2} - \frac{Fy^3}{6} - \frac{Fhy^2}{2} + \frac{Fy^3}{12} + \frac{Fay^2}{4} + C_1y + C_2 \ldots [3]$$

As x, or the deflection, equals zero when y equals O, C_2 equals O. If $y = h$, $EI\frac{dx}{dy} = O$, since a tangent to the deflection curve at F is vertical. This gives the value of C_1. Substituting it in Equation [2], the tangent to the curve at the origin

$$EI\frac{dx}{dy} = \frac{Fh^2}{4} - \frac{Fah}{2}$$

To solve for a, an expression must be obtained for the tangent to the elastic curve at the right of the horizontal member. It is evident that there will be a reaction $P = F/2$, acting at distance a from the horizontal member, and since this force P is exerted parallel to this member, the bending moment at any point of it will be Pa, or $M = EI\frac{d^2y}{dx^2} = -Pa$, the minus sign being necessary since the moment is counter-clockwise with respect to the origin.

The tangent to the curve caused by this moment is

$$EI\frac{dx}{dy} = -Pax + C_3$$

But the tangent is O when x equals $\frac{l}{2}$, and consequently $C_3 = \frac{Pal}{2}$. Therefore, when x equals O, $EI\frac{dx}{dy}$ equals $\frac{Pal}{2}$.

Since the corner is rigid, $\frac{dy}{dx}$ may be considered equal to $\frac{dx}{dy}$, and consequently $\frac{Pal}{2} = \frac{Fh^2}{4} - \frac{Fah}{2}$.

whence a equals $\frac{h^2}{2h+l}$.

Now remove the lower half of the rectangle in Fig. 16, substituting fixed supports at the point of application of the force F. The result is a familiar expansion loop with the vertical members anchored at the bottom. Expansion of the length l causes horizontal reaction P at the base and also at the points of neutral bending moment. The tangents to the deflection curves at the base of h are zero. Having the length a, the bending moment at any point in the structure can be readily computed provided the value of the force P is known.

To determine P an expression must be developed for the total deflection of the structure at the point of application of P and equated to the actual expansion in the length l. It can be assumed, of course, that P causes the bases of the vertical members to approach each other an amount equal to the expansion in l. The deflection of the structure will evidently equal the sum of the deflections of each separate member. Each a and each $(h-a)$ is a cantilever with the force P acting at the free end. The deflections of a and $(h-a)$, for instance, are expressed by the familiar formulas $\Delta = \frac{Pa^3}{3EI}$ and $\Delta = \frac{P(h-a)^3}{3EI}$. If the top member l were inflexible, the deflection of the structure would equal the four deflections of the vertical members a and $(h-a)$. But the member l is not inflexible, and when it bows up slightly, due to the constant bending moment Pa it permits additional lateral deflection of the members a. To determine the total laterial deflection of the member a at its lower end, refer to Equation [2], which is an expression for the tangent to the deflection curve at any point of h below the origin. If $y = O$ in this equation, $EI\frac{dy}{dx} = C_1$.

But it has already been proved that $EI\frac{dy}{dx}$ and $EI\frac{dx}{dy}$ at the origin equal $\frac{Pal}{2}$. Therefore C_1 equals $\frac{Pal}{2}$.

It has also been proved that C_2 in Equation [3] equals zero. If $y = a$ in Equation [3], an expression is obtained for the total deflection of a at its lower end. For convenience convert F into its equivalent $2P$. Then

$$EIx = Pha^2 - \frac{Pa^3}{3} - Pha^2 + \frac{Pa^3}{6} + \frac{Pa^3}{2} + \frac{Pa^2l}{2}$$

or

$$x = \frac{Pa^3}{3EI} + \frac{Pa^2l}{2EI}$$

The value of P is now obtained from the following equation, in which Δ is the known expression of the horizontal member:

$$\Delta = \frac{2P}{EI}\left[\frac{a^3}{3} + \frac{(h-a)^3}{3} + \frac{a^2l}{2}\right]$$

Two very interesting discoveries manifest themselves at this point. The first has to do with the three items in the foregoing

brackets. In order to visualize them relatively, the moment diagrams have been sketched as shaded areas in Fig. 17.

The first two items are concerned with the triangular areas $a^2/2$ and $(h - a)^2/2$. The third item is concerned with the rectangle $al/2$ (only one-half of the structure being considered). The rectangular area is quite important, as it represents the sum of the bending moments along the length l. The relation of these areas to the deflection of the members on which they are superimposed is very simple. For example, the area $a^2/2$ only has to be multiplied by $2/3a$ to make it equal to the first item in the brackets, or $a^3/3$. The area $al/2$ becomes $a^2l/2$ by simply multiplying it by a. But $2/3a$ is the center of gravity of the upper triangle with respect to the line of force which passes through the point of neutral bending moment in h, while a is the distance of the center of gravity of the rectangle from the same point. From this is deduced the following important law: If the moment diagram be superimposed on a member, with the center of gravity of the diagram coinciding with the axis of the member, the deflection of the member will be proportional to the area of the diagram times the shortest distance from its center of gravity to the line of the force which causes the deflection. To avoid overlapping of areas in Fig. 17, the upper triangular diagrams have been drawn on either side of h instead of axially, which is permissible as long as it does not disturb the horizontal center of gravity of the areas.

This device of using moment diagrams to compute deflection is quite familiar to structural engineers. Fortunately it is peculiarly adapted to the problem of pipe expansion.

Now comes the second discovery. Equating the sum of the areas above the line of neutral bending moment to the areas below results in the following:

$$a^2 + al = (h - a)^2$$

Whence $a = \dfrac{h^2}{2h + l}$, the formula which has already been deduced. The sum of the moment diagram areas above the neutral line is therefore equal to the sum of the areas below the line. In other words, the neutral axis or "secondary force" passes through the center of gravity of the structure.

This necessarily holds true for any structure between two rigidly anchored supports, provided it is in one plane, consists of intersecting straight lines, and has no force acting on it other than the internal ones due to expansion. It is also true, for any similar structure, that the neutral axis is parallel to the line passing through the anchor points.

That these lines of force are parallel may be demonstrated as follows: Fig. 18 is a closed rectangle with rigid corners. The force F acts diagonally through the center of the rectangle. Since the structure is in equilibrium, the horizontal reaction along the members l must be equal and opposite. This, however, is an apparent anomaly, since the force F does not act at the center of either vertical member. The only way in which the force F can cause equal reaction at the corners is through the development of neutral axes on each side of the force at equal distances from its point of application. The vertical member then becomes a cantilever bridge, the suspended span supporting the load in the middle and transmitting half of it to each unequal cantilever arm. Since the suspended spans are of equal length on either side of the rectangle, it follows that the force $F/2$ which passes through the points of suspension must be parallel to F.

If the dotted half of the rectangle is removed, there remains a three-sided expansion bend with unequal legs, a common enough case in practice. Each leg is so anchored tha' tangents to the deflection curve at the base are vertical. Conditions are identical to those which prevail in the closed rectangle.

The graphic method of solving for M and the location of neutral axis for this shape has already been illustrated in Fig. 4. A similar method is applicable to any straight-sided plane shape whatever.

A further study of the method reveals the fact that expansion bends of the same overall dimensions will establish quite dissimilar values for P according to the arrangement of the horizontal and vertical members.

In Fig. 19 three expansion bends are shown, each having a length between anchors of $4h$ and a height of h. In order to illustrate clearly the effect of arrangement on the internal stresses, relative value for P and the maximum bending stresses have been worked out for each shape and assembled in the following table:

	Fig. 19(*a*)	Fig. 19(*b*)	Fig. 19(*c*)
Relative values of P	100	43	63
Relative bending stress, top	20	26	56
Relative bending stress, bottom	100	26	19

The discrepancy between these figures is quite surprising. A comparison indicates that, in general, the arrangement shown in Fig. 19 (*b*) is the best, especially as regards the value of the direct thrust P. It also indicates that the place to locate a valve or a flanged joint is certainly not at the top of arrangement Fig. 19 (*c*) or the bottom of arrangement Fig. 19 (*a*), provided they can be located elsewhere. The figures in this table must not be accepted too literally, as they are exact only for arrangements whose length is four times the height. They may be accepted as applying to round-cornered shapes as well as to the square-cornered ones shown in the illustration.

A word of caution should be inserted regarding the shape (*c*) in Fig. 19 in case the expansion loop is placed near the end of a very long horizontal line. Theoretically it does not matter how long the line is or at what part of it the expansion loop is located. This line is in effect a horizontal strut with an eccentric load which causes it to deflect slightly upward toward the expansion loop. If this upward deflection is prevented by external means, as is very apt to be the case in a long line (the weight of the pipe itself will resist it somewhat), a new arrangement of forces results. The expansion will be the same as before, but the length must now be taken from the point of application of this external force. The neutral axes will assume a higher position on the vertical members, and the structure will be less flexible. There are formulas in use which give the deflection of a similar expansion loop when anchored on one side and free or unattached on the other, the assumption being, apparently, that the free end is really part of a long length of pipe. There is actually no such thing as a "free end" in a steam line. Such an assumption makes it impossible to arrive at the correct stresses in the structure.

Pipe Structure in Two Planes

Before approaching the subject of bends, a brief discussion may be inserted of the method as applied to the two-plane structure. In general, it may be said that a pipe line which departs from a single plane does so with the primary purpose of getting from one point to another, rather than with the purpose of insuring flexibility. Such structures, as a rule, are more flexible than is really necessary, due to the introduction of torsion. Occasionally, however, this is not the case, and there are times when space requirements do not permit of sufficient flexibility in the plane structure.

In such cases the method already described in detail may be of assistance. In principle it is identical to the method used for single-plane structure. The development of projections in plan and elevation is merely a device to assist in locating the line passing through the center of gravity of the structure and in measuring the perpendicular distances from this line to the various members. It will be found that the "secondary force" usually does not intersect the structure at any point. In these

cases torsion is present in every member and is inextricably associated with direct bending. It is unnecessary to separate them, since the deflection in either case varies as the length of member acted upon times the sum of the squares of the bending moments.

This relationship is illustrated in Fig. 20, which represents a pipe of length l, fixed at one end and acted upon at the other by a force P or P_1 at the end of an inflexible lever arm of length n. Internal stresses in the pipe cause a deflection at the point of application of the force. The deflection due to P equals Pln^2/EI, while that due to P_1, considering the effect of torsion only, equals P_1ln^2/EJ.

Since the polar moment of inertia J for pipe sections equals $2I$ and since Es is about 11,200,000 lb. per sq. in. as against 29,000,000 lb. per sq. in. for E, the actual deflection due to P_1 is about 30 per cent greater than that due to P. This relative differential persists for all variations of l and n. It is considered permissible to disregard it in practical problems for the following reasons: First, since the torsional moments in a structure are usually less than half of the direct bending moments, the inaccuracy is thereby reduced in proportion. Second, disregarding the differential adds a slight increment to the factor of safety. This is offset to a certain extent by plotting the sides of the moment diagrams with straight lines. These lines are found to be slightly curved in some cases if plotted for all points along the length of the member. The straight line thus adds a small amount of area to the diagrams, while another small amount is subtracted by ignoring the constant differential between torsional and bending deflection.

In general, the graphic method, as described, is slightly less accurate for two-plane than for single-plane problems. Nevertheless, it makes possible the solution of problems which by any other known method are practically insoluble.

A word of explanation may be added regarding the determination of maximum pipe-wall stress in the two-plane problem. In the problem illustrated, the procedure is exactly the same as with the the single plane. It is obviously an unnecessary refinement to distinguish betwen torsional and bending stress. The polar moment of inertia equals $2I$; consequently, if the maximum moment happens to be all torsion, the resulting shear is $S/2$. If it happens to be all direct bending, the resulting stress is S. The allowable stresses for shear are roughly one-half those for bending. Where there is combined bending and torsion, the method of measuring the moment arm from the neutral axis to the point in question and computing the stress as though it were a simple bending stress is again on the side of conservatism. The net resultant stress is theoretically somewhat lower. To compute it accurately would be outside the field of practical engineering.

Pipe Bends

It is not the intention to develop any new ideas or formulas on the subject of expansion bends, but merely to apply the graphic methods outlined in the foregoing paragraphs with a view toward establishing a relationship between the bend and the theoretical square corner. Square corners are much easier to work with. A correction factor for the bends appears both feasible and desirable and will tend to clarify the whole subject.

Only one general assumption is made, which is that the moment of inertia of a section taken in the bend is the same as that for the straight pipe.

That many writers object to this assumption has no particular bearing on the following analysis: Fig. 21 shows a 90-deg. bend with radius r, fixed at one end and with a force P acting at the other. Alongside it is drawn an equivalent square corner with legs r, and the same force P acting at the free end. The horizontal deflection of the latter shape has been found to be:

$$\Delta = \frac{P}{EI}\left(r^3 + \frac{r^3}{3}\right) = \frac{4Pr^3}{3EI}$$

The deflection of the bend can also be obtained in the same manner by the exercise of a little patience. Divide the bend into any number of equal parts. Using intervals of 5 deg., for instance, will give 18 sections of the curve, each of which, for all practical purposes, is a straight line. From the center of each section drop an ordinate perpendicular to the line of force P. The length of these ordinates may be obtained from a table of sines. The sum of all the ordinates divided by 18 will be the average height of the moment diagram. The area of the diagram is its average height times the length of the member, or 1.57 r. Multiplying the two quantities results in r^2 as the area of the diagram. Now the deflection of the bend is proportional to the sum of the squares of the ordinate times the length of a single section of the curve. In the case of a straight member the deflection is more readily computed by the use of the moment diagram and its center of gravity. But the moment diagram of the curved member is irregular in shape, as illustrated in Fig. 21 (*c*). To determine its center of gravity would be only an added labor. The result by either method is the same, and is expressed as follows in terms of deflection:

$$\Delta = \frac{\pi}{4}\frac{Pr^3}{EI}$$

The deflection of the bend is therefore 59 per cent of that of the square corner when both are acted upon by the same force. Now in an expansion loop similar to that shown in Fig. 22, this ratio evidently applies to the structure as a whole. The neutral axes coincide with the change in direction of the curves, and the effect is that of four 90-deg. bends with a force acting at the free end of each. The neutral axes of the curved structure also coincide with those of the square-cornered one. In this one case, then, the deflection can be first determined for the square-cornered structure and corrected with the factor 0.59.

But the neutral axes do not always occur at the end of the curve, and there is usually a quantity of straight pipe to be accounted for. In Fig. 23 a case is shown where the neutral axis is below the end of the curve an amount equal to the radius of the curve. The distance r must be added to each ordinate in obtaining the area of the moment diagram. There is also a moment diagram to be considered for the straight length below the curve. Neglecting this (since it is the same for both bent and square corners), the deflection, for the bend only, is found to be proportional to the quantity 4.37 r^3. Similarly the deflection of a square corner with legs of r and r in the same relative position to the neutral axis proves to be 6.33 r^3. The ratio between the two equals 4.37/6.33 = 69 per cent.

Lowering the neutral axis has consequently affected somewhat the deflection ratio between the square and ·ound corners. Now move the neutral axis down to a point $5r$ below the end of the curve and repeat the calculation. The results for the two cases and the ratio between them is 50/66.3 = 75 per cent.

The accuracy of an analysis based on a square corner in place of a bend is therefore 59 per cent, 69 per cent, and 75 per cent for the three cases. But in the second and third cases straight pipe has been introduced whose deflection is obtained with a com parative accuracy of 100 per cent. Giving credit to the straight pipe according to its proportion of the total length of the shape, the foregoing percentages of accuracy become 59 per cent, 79 per cent, and 93 per cent, respectively.

These percentages can evidently be further increased. The simplest factor for this purpose is the length of the curve itself in

relation to the length of the square corner in which it is inscribed, or 0.7854. Experimenting with this factor, it is found that the percentages of accuracy increase to 75 per cent, 92 per cent, and 99 per cent, respectively.

Two more cases will bear investigation before the use of this factor can be thoroughly justified. They are those in which the neutral axis is located on the curve itself, as illustrated in Fig. 24 (*a*) and (*b*). The location of the neutral axis is shown for the square and round shape in each case. The deflections calculated in a straight line between supports S_1 and S_2 for a given force P are as follows:

$$(a) \quad \Delta = \frac{0.295\,Pr^3}{EI} \text{ for round shape}$$

$$= \frac{0.4167\,Pr^3}{EI} \text{ for square shape}$$

$$(b) \quad \Delta = \frac{0.0244\,Pr^3}{EI} \text{ for round shape}$$

$$= \frac{0.0833\,Pr^3}{EI} \text{ for square shape}$$

Multiplying the second equation in (*a*) by the ratio of round to straight lengths reduces the constant to 0.328. The accuracy is therefore 0.295/0.328, or 90 per cent.

By the same operation the constant in the second equation of (*b*) becomes 0.0655. The accuracy in this case is therefore 0.0244/0.0655, or only 37 per cent. This is due to the projection of the square corner above the top of the curve, with correspondingly longer lever arms about the neutral axes. But the curve in (*b*) is not a legitimate expansion bend. In practice the radius r would be reduced as much as possible with straight lengths inserted between the bend and the supports. If the length of this curve is not greater than one-third the total length, the accuracy by the method suggested will be over 90 per cent.

Summarizing, therefore, the square corner may safely be used in the analysis of practically all pipe-expansion problems, correcting the results for Δ with the factor:

$$\frac{\text{total length of actual structure}}{\text{total length of square-cornered structure}}$$

Results will be from 90 to 100 per cent accurate in theory for all structures having the usual amount of straight pipe between the bends. Greater accuracy than this is hardly possible in any event, in view of the various uncertainties always present in problems of this character.

If the designer wishes to make allowance for the flattening of the pipe cross-section in bending, he may of course use any correction factor he chooses or none at all, bearing in mind that in doing so he lowers the factor of safety of the structure. The point to be emphasized is the small influence of the bends in the average design. In a certain large and probably typical station there is hardly a single instance where the length of straight pipe does not greatly exceed the length of bent pipe between any two fixed points.

Allowable Stresses

In general it is recommended that for very high pressures and temperatures the maximum stress in the pipe wall due to expansion be limited to 5000 lb. per sq. in. at any point. In some cases it may be desirable to limit the direct thrust at the anchors to 1000 lb., and even less for small pipe. These conditions, though conservative, are usually not difficult nor expensive to meet.

Stresses are reduced in proportion to the amount of cold-springing employed. It is recommended, however, that no regard be paid to cold-springing in designing the structure, except in special cases where close check of the work is possible, to insure the pipe being installed as planned.

Heat Reaction in the Boiler Furnace

By W. J. WOHLENBERG,[1] NEW HAVEN, CONN.

This paper attempts to point out only a few of the angles from which the modern art of boiler design may be viewed. Each important case must be specially investigated, for there are no hard-and-fast rules that may be applied, and many empirical data must still be relied upon in determining proportions that will result in satisfactory operation. The future will require that students become acquainted with certain broad underlying principles reached through such methods of analysis as are hinted at in this paper.

THE boiler furnace may be defined as consisting of a cavity provided with attachments for introducing fuel and discharging ash and in which the progress of the combustion of the fuel should continue practically to completion. This definition is concerned with the first considerations in the art of furnace designing. If this were the only set of conditions to be met, we might say that there has been but small progress in the development of such furnaces since the time of Watt. Even in those days these conditions could be met if the fuel was the right one and the rate of combustion was maintained within certain limits.

Modern developments have been forced in the direction they have taken in order to enable operation under conditions of far greater rates of steam output per unit of floor space which is occupied by the steam-generating units. The end in view has been, of course, that reduction in the total cost per unit weight of steam which results from the attendant reduced requirements in labor, overhead, and maintenance when concentrating the total capacity for generating steam into fewer units. It should be noted, however, that an increase in the rate of energy release per steam-generating unit does not necessarily require a greater release of energy per cubic foot of furnace volume per hour. For large furnaces it may mean the employment of arrangements and methods which make it possible to utilize to greater advantage the increase in furnace volume which is provided by increasing the height of the furnace cavity. As an example, some of the largest modern pulverized-coal-fired units produce a large amount of steam per square foot of floor space, even though the rate of energy release per cubic foot of furnace volume may be low. In such furnaces a long flame path is provided along the vertical axis, and hence the fuel and air streams are carried through the furnace at a high velocity. The time element during which any particle is en route through the furnace cavity may actually be greater than it would be in a shorter furnace and one in which the velocity of gas travel is lower.

Difficulties Encountered in Operation

The difficulties which are encountered in the operation of either large or small furnaces, but in which the total amount of energy released per unit of time is large at full load, may usually be traced back to the existence, either in localized spots or throughout the furnace, of temperatures which are too low or too high. When the temperatures are too low, the combustion reaction may not progress as it should; or if a furnace is designed to operate slagging (that is, at temperatures sufficiently high to cause the ash particles to melt and run down the side walls), then wall temperatures below the slagging point may cause building up on the side walls of layers of freezing slag, assuming possibly a honeycomb type of structure. If the process continues in this way for some time, such slag formations may later have to be run down in a molten form by raising the furnace temperature, or they may have to be broken down. In the latter parts of the wall are usually broken down with the frozen slag.

If the temperature is too high at any part of the furnace, a wall may fail due to the inability, from some cause or other, to conduct energy as heat through it at a rate sufficient to keep the inner-wall surface temperatures below the softening point of the material composing this surface. In pulverized-coal-fired furnaces slag penetration of the refractory surfaces will occur under these conditions. This is often followed by a chemical action between certain ash and refractory constituents, and the new compounds then often have lower melting points than either of the combining constituents. The inner refractory surfaces now rapidly disintegrate, and the process will continue to destruction unless special provisions, such as indirect water cooling of the refractory, are resorted to in order to arrest the action while the wall is still thick enough to remain intact.

Some attempts have been made to solve the furnace-refractory problem by doing away with all of the refractory materials on the inner faces of the furnace cavity and replacing them with bare iron water-cooled surfaces in the form of tubes through which water is circulated. However, such arrangements have in many instances led to serious losses from incomplete combustion because at low rates of driving, particularly with pulverized-coal firing, maintenance of the proper progress of the reaction during the heating-up and ignition periods has been retarded. Highly preheated air and turbulent firing improve the conditions in this respect at the higher rates of driving the furnace. At the lower rates, however, both the air temperature and turbulence fall off, with the result just stated. On the other hand, at exceedingly high rates of driving with uneven flame distribution, which is bound to occur at times, the localized heating of the unprotected tube elements has led to tube failures.

Thus it appears as though in most cases the design of the structure of the furnace cavity must be for a compromise between the conditions which provide for good combustion at all rates of driving and those which provide for lowest cost of maintenance of this structure under the conditions of operation that will be met. This compromise may resolve itself into a structure in which there are some bare iron water-cooled walls and others of the uncooled refractory type. Or, in another case, a part or all of the inner faces of such walls may be of refractory backed by water-cooling means. Only for large furnaces, for small furnaces, or when the extra expense of extremely fine grinding of the coal may be incurred, should consideration be given to the structure composed almost entirely of bare iron water-cooled surfaces if pulverized coal is the fuel. Even with these special provisions it is in such cases desirable to carry in the air for combustion in a highly preheated state.

All of this leads up to the point of this discussion. The heat reaction in the boiler furnace, as distinguished from combustion or chemical reaction, plays an important part in the process, at least in so far as its practical operation is concerned. Under the term "heat reaction" may be included the effects on the several parts of the structure of the temperature heads, and of their differentials, in discharging energy between the vulnerable parts

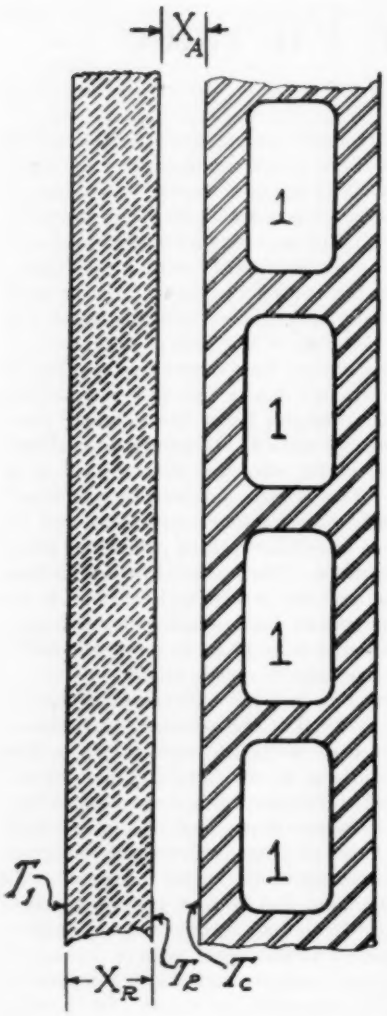

FIG. 1
(1, water circulating through channels in iron or steel water back.)

of the furnace cavity. A solution of this phase of the process thus involves a study of the energy distribution as heat within this cavity. A complete solution of the furnace reaction could, of course, be accomplished only by evaluating step by step the influence of the combustion reaction on the heat reaction and vice versa. Such a method of treating the problem is not within the limits of the possibilities of any analysis based on our rather meager knowledge of the details of the process. In dealing with this problem we are thus forced to separate the heat reaction from the combustion reaction. We assume a certain progress of the combustion reaction to determine the energy which has been released, and then make use of the principle of conservation of energy together with the available data and laws according to which energy as heat is distributed throughout cavity by radiation, conduction, convection, etc.

HEAT TRANSFER AND EQUILIBRIUM AT THE FURNACE WALLS

In discussing the heat reaction one should begin by a short analysis of the process which occurs at the walls of the furnace cavity. As an example, consider a wall such as is represented by Fig. 1.

Let K_R = conductivity of refractory
K_A = conductivity of air gap
T_1 = mean absolute temperature of furnace or hot face of refractory
T_2 = mean absolute temperature of cold face of refractory
T_c = mean absolute temperature of the iron face of structure forming channels for circulation. T_c will be practically equal to water temperature.
X_R = mean thickness of refractory in direction of heat flow by conduction
X_A = mean width of air gap.

The transfer of energy from the furnace face of the refractory through to the water occurs in several stages. First, by conduction through the refractory, and then by a combination of radiation, conduction, and convection from the cold face of the refractory across the air gap to the metal surface bounding the water passage. The quantity transferred by convection is, for obvious reasons, exceedingly small, and hence may be neglected. The equation of heat transfer thus assumes the form:

Heat transferred by conduction through the refractory must be equal to the total transferred across the air gap, or, for a square foot of wall front,

Conduction through refractory		Air-gap conduction		Air-gap radiation
$\frac{K_R (T_1 - T_2)}{X_R}$	=	$\frac{K_A}{X_A} (T_1 - T_c)$	+	$\alpha_o (T_2^4 - T_c^4)$. [1]

in which α_o is the net coefficient of radiation between the two surfaces bounding the air gap.

The particular structure shown in Fig. 1 was chosen for an illustration so that it should be at once obvious what the mean dimensions involved in the heat transfer are. For another type of structure these might have to be evaluated separately before substitution in Equation [1], or perhaps the process as a whole might have to be submitted to analyis by means of the differential calculus. This, however, is beside the point for this discussion.

Equation [1] may be applied to evaluate for given conditions as to T_1 and T_c the heat flow through any commonly used furnace-wall structure. In Fig. 2 it is shown how equilibrium is established for a given hot-surface temperature T_1. It is to be

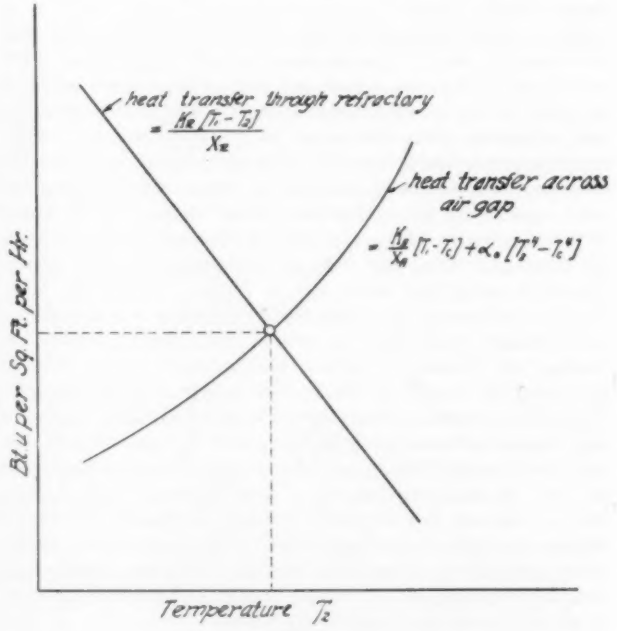

FIG. 2
(a, heat transfer through refractory $= K_R[T_1 - T_2/X_R]$; b, heat transfer across air gap $= K_A/X_A [T_1 - T_c] + \alpha_o[T_2^4 - T_c^4]$.)

noted that the energy conducted through the refractory falls off with an increase in the temperature T_2, whereas that transferred across the air gap increases. The point of intersection of the two curves shows the value of the temperature T_2 and rate of heat transfer at equilibrium.

Obviously now, the thinner the refractory the greater its conductivity, and the smaller the air gap the greater will be the rate of heat transfer through the wall to the water. At one limit the refractory has zero thickness, the rate of heat transfer is for practical purposes infinite, and the wall temperature T_2 remains constant at the value T_c of the water in circulation. At the other extreme the refractory is perfectly insulated, so that zero heat

flows through the wall by conduction and the temperature T_1 of the hot surface assumes an equilibrium value such that the energy received by radiation and convection from the flame mass is equal to the energy discharged by radiation to other parts of the furnace cavity from this surface.

The wall shown in Fig. 1 thus lies between the two limiting conditions described, from the point of view of its ability to receive radiant energy for a given surface temperature. The equilibrium magnitude of the temperature T_1 for this wall is the same time reducing the surface temperature, because now more energy as heat is conducted through the wall. This results in an increase in the total energy discharged to the wall from the flame, and in a comparatively small reduction in the mean flame temperature. The wall, under such conditions, will thus thin down until such an equilibrium state is reached. Let us suppose, for example, that this equilibrium thickness of refractory material is 2 in. A refractory of these dimensions may be maintained in the water-cooled structures, but for solid

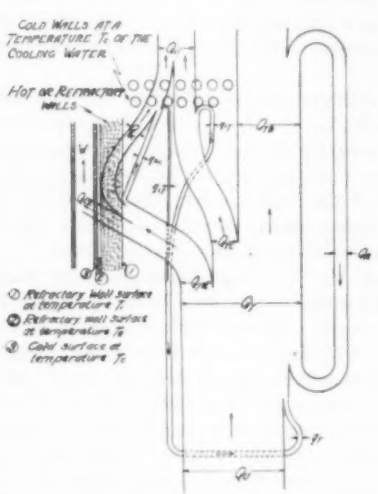

FIG. 3 ENERGY-FLOW DIAGRAM, FURNACE CAVITY

(1, refractory wall surface at temperature T_1; 2, refractory wall surface at temperature T_2; 3, cold surface at tempeature T_c.)

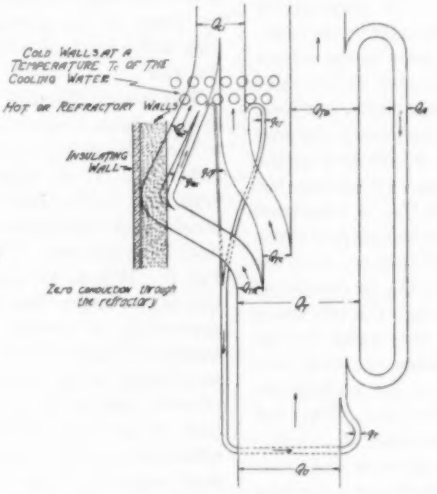

FIG. 4 ENERGY-FLOW DIAGRAM, FURNACE CAVITY

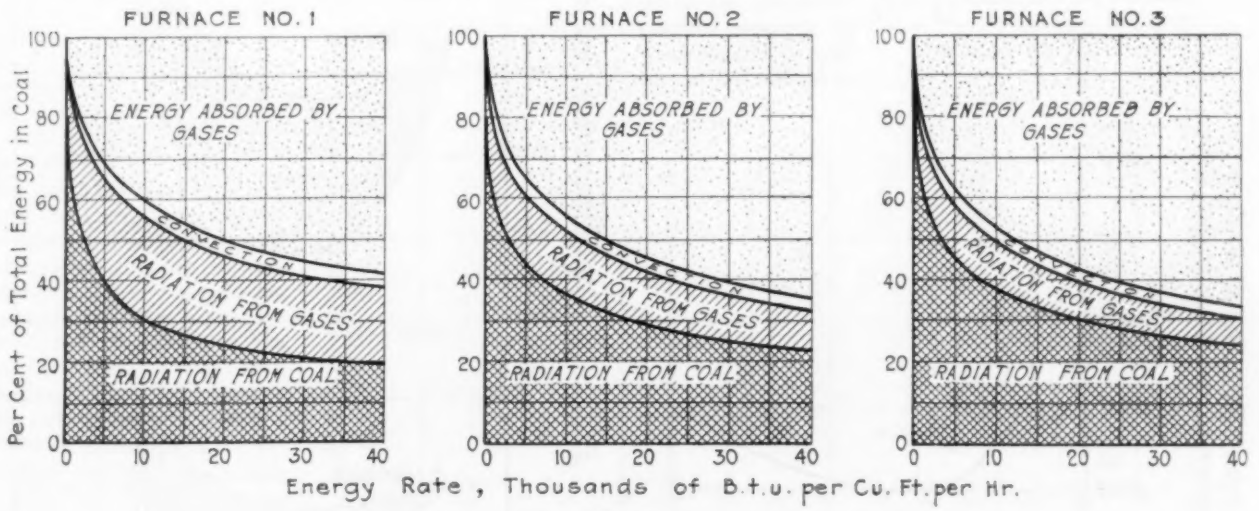

FIG. 6

that at which the energy received by radiation and convection at the wall surface from the flame mass is just equal to the rate at which energy is discharged by radiation from this surface to other parts of the furnace cavity plus the rate at which energy is conducted through the wall. The latter factor is large for this type of wall compared to its value for solid refractory wall, but less than would be the case for bare iron water-cooled walls.

If the equilibrium value of the wall temperature is so high that slag penetration occurs, the wall will obviously disintegrate at the surface and run down, thereby reducing its thickness and at refractory walls destruction is complete long before any such thinning down has occurred. Thus water cooling of refractory walls provides the conditions under which not only a thinner wall may be maintained but it also provides for the conditions for maintaining, as compared to solid refractory walls, a higher rate of energy release in the furnace for a given limiting wall temperature, which is of course an end in view. In addition to this it provides for a hot surface of such walls under all conditions. These are conducive to good combustion, which is another end in view.

Energy Distribution in the Furnace Cavity

Figs. 3, 4, and 5 are conventional diagrams representing the energy distribution throughout the furnace cavity for three different cases. In Fig. 3 refractory walls are represented at R as backed by some water-cooling means W. The bare iron cold walls are represented by circles to represent tubes. The total energy input Q_T is composed of that released by the fuel (Q_U), plus that recirculated by the preheated air (Q_A), plus that recirculated by reflection (q_T). The quantities of energy Q_{TR} and Q_{TC} are respectively radiated from the burning mass to the refractory and relatively colder iron surfaces. Of the former, the part q_{RC} is reflected at the refractory surface, the part Q_{RC} is reradiated from this surface to the cold surface, and the part Q_{c_2}, is conducted through the refractory to the water in the passage or tubes provided for cooling the refractory. The net absorption ($Q_{c_1} + Q_{c_2}$) by the water and steam in the boiler is less than the total discharge to it by the amounts q_{CT} of the reflection at the exposed cold surface C. The energy carried out by the gases escaping from the furnace cavity is represented by the width Q_{TB} of the stream passing straight through the furnace.

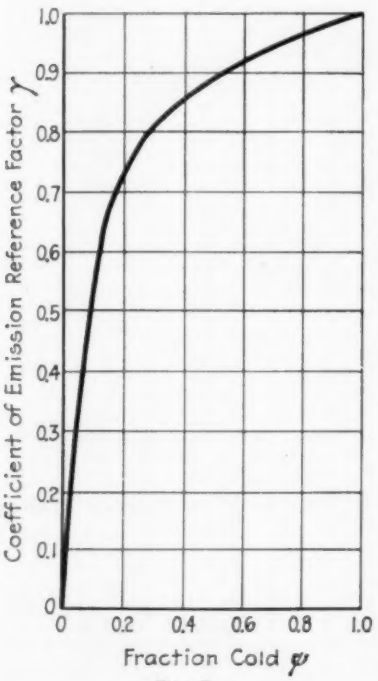

Fig. 7

It now appears as though the energy Q_{c_2} conducted through the refractory walls in effect enables an increase of the energy release rate by an amount just equal to this conduction factor. This, however, is not the case, because any reduction of the quantity Q_{c_2} will, for the same conditions otherwise, influence the width of the three streams Q_{TR}, Q_{TC}, and Q_{TB}, as shown in Fig. 4. The stream Q_{TB} will increase in width and the stream Q_{TR} will decrease, because the flame-temperature increase is now the result of the decreased radiation discharge to the walls by virtue of the increased wall surface temperature, which in turn is the result of a decrease of the energy conducted through the wall.

The stream Q_{TC} will increase somewhat, due to the increase in mean flame temperature, but it will not increase in proportion to the decrease in Q_{TR} caused by the reduction in the conduction factor Q_{c_2}. If all walls of the furnace are of the bare-cooled type, the conductivity of the wall material (iron or steel) is hundreds of times greater than for any refractory structure which may be employed. The resulting energy diagram is shown in Fig. 5. It is to be noted that the total discharge to the walls Q_{TC} is now larger than for either of the other cases, but there is apparently no simple relation between the conduction factor and the amount of energy Q_{TB} that leaves with the gases. Thus, any change in the conduction factor Q_{c_2} disturbs the equilibrium of every part of the heat reaction, or, in general, a change of any part of the heat reaction disturbs the equilibrium of every other part of this reaction. For the present, all that may be said about the influence of conduction on permissible rate of

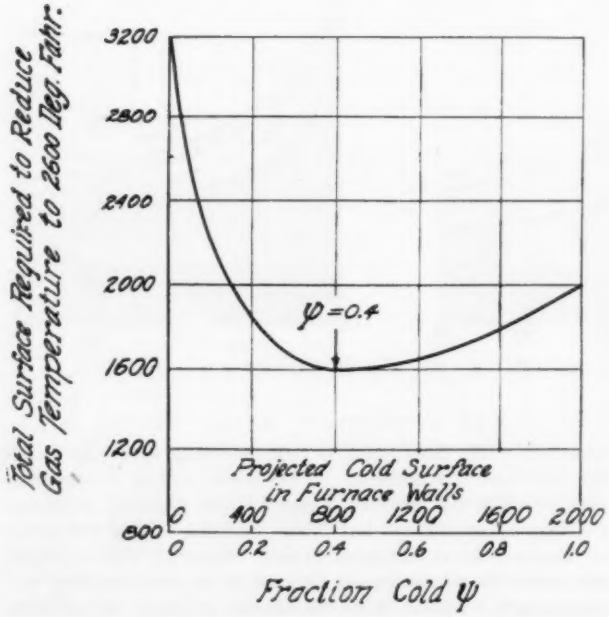

Fig. 8-A Influence of Fraction Cold on Total Surface Requirement

(Furnace No. 2, 8000 cu. ft.; 80,000 B.t.u. per cu. ft. per hr.; Illinois coal; excess air, 40 per cent; stoker fired.)

(k = coefficient of heat transfer.)

energy release is that an increase of the former will result in an increase of the latter, but the two changes are not proportional, and an evaluation of their relative magnitudes involves an evaluation of the resulting equilibrium variation for every part of the process.

The general influence of the wall structure itself on equilibrium has now been discussed to some extent. Let us next consider the influence of furnace-radiation symmetry on the heat reaction. That is, what is the influence on the heat reaction of changes in the proportional parts of the envelope of the cavity which present refractory and exposed bare iron water-cooled surfaces?

Equilibrium and Radiation Symmetry of the Furnace Cavity

To reduce this picture to its simplest terms, consider the energy diagram of Fig. 4, in which all of the refractory walls are shown as perfectly insulated. The energy Q_{ca} conducted through the walls R is now reduced to zero. A solution for the equilibrium conditions of this process involves the following things: for the determination of the energy released Q_U, the fuel weight and its calorific value; for a determination of the escaping energy Q_{TB}, a curve showing the relation between thermal capacity of the resulting gaseous mixture and the temperature of this mixture; and for the energy Q_A carried in by the preheated air, a similar curve. The radiation discharges Q_{TB} and Q_{TC} result from the sum total of radiation from the solid incandescent carbon surfaces and those from the radiating gaseous constituents like CO_2 and H_2O. The former require for their evaluation the solid angles subtended by the receiving surfaces from the radiating surfaces, and of course the extent of the radiating surfaces themselves. The latter depend on what are known as the "thickness concentration functions" of the gaseous constituents, and the radiation is evaluated per unit area of gas front facing the receiving walls. For the solid carbon surfaces the Stefan-Böltzmann law may be applied, but not so for the radiating gaseous constituents. A mathematical expression for these introduces the thickness concentration functions as exponentials. The reflection from the surfaces may, of course, be treated in the usual manner.

In Fig. 6[1] is shown the computed energy-discharge fraction as it appears for certain cases in furnace cavities having zero refractory surface in the envelope. All walls have been considered as bare exposed iron surfaces at the temperature of the cooling water, and therefore the discharge to the walls is the maximum possible for cavities of the size indicated and for the fuel and combustion conditions shown.

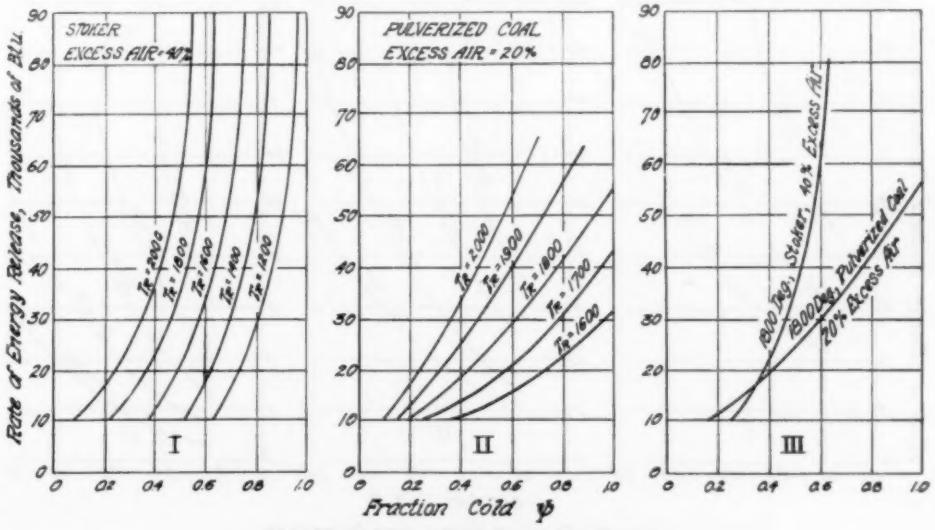

Fig. 10 Furnace-Refractory Isotherms
(Furnace No. 2; coal, No. 1 or No. 2; air temperature, 70 deg. fahr.)

The first solution for the energy distribution is, as seen, the result of a very involved procedure, and it might seem as though no simple way of viewing the sum total of the energy process in terms of furnace proportions were possible. Fortunately this is not the case. The result of a large amount of painstaking analysis shows that, for all practical purposes, the relativity of things, so far as the influence of variation of radiation symmetry on the net energy absorption is concerned, may be satisfactorily

[1] From Wohlenberg and Lindseth.

expressed in terms of a rather simple factor, called the "fraction cold."

The fraction cold is simply the fractional part of the furnace envelope which is occupied by bare iron water-cooled surfaces, the other portion of the envelope being assumed in such a case

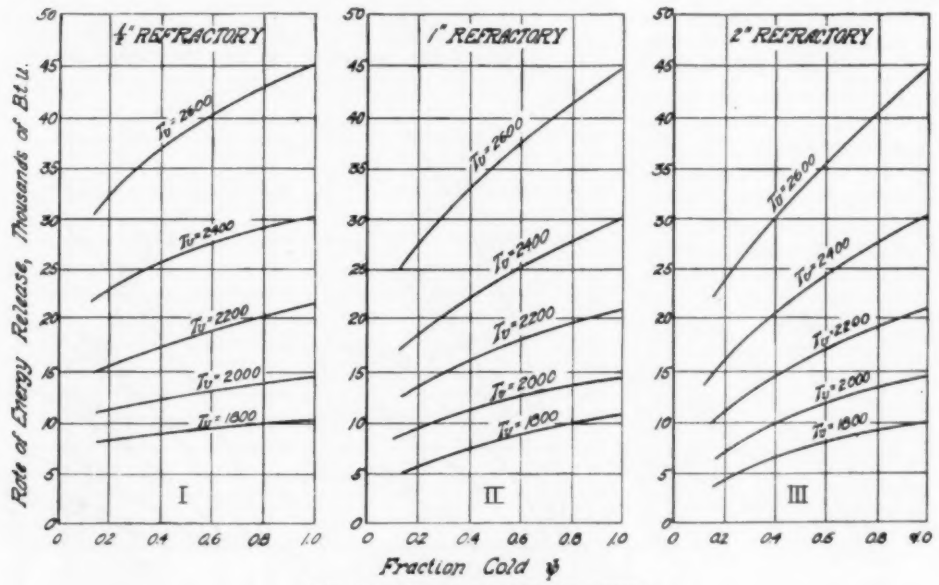

FIG. 11 FURNACE-FLAME ISOTHERMS

(Furnace No. 2; coal, No. 1 or No. 2, pulverized; excess air, 20 per cent; air temperature, 500 deg. fahr.; conductivity, $K = 10$; for any refractory conductivity multiply thickness shown by $K/10$.)

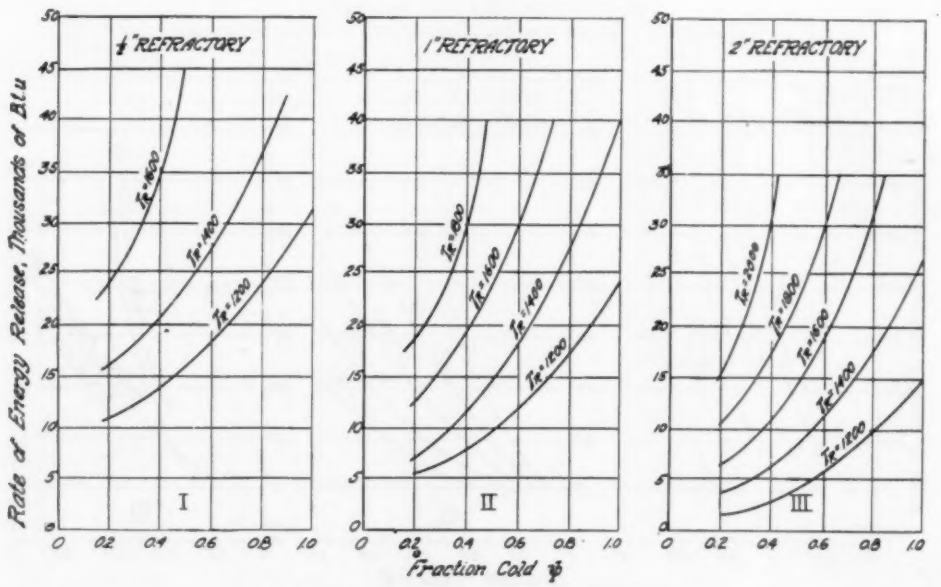

FIG. 12 FURNACE-REFRACTORY ISOTHERMS

(Furnace No. 2; coal, No. 1 or No. 2, pulverized; excess air, 20 per cent; air temperature, 500 deg. fahr.; conductivity, $K = 10$; for any refractory conductivity multiply thickness shown by $K/10$.)

to be occupied by solid refractory walls. In other cases, as will be shown later, such a factor may be used also if the part of the furnace envelope which presents refractory surfaces is backed by water or air cooling. The remaining part of this discussion will be occupied with an attempt to show to what extent a variation in the radiation symmetry of a furnace cavity influences the energy distribution, furnace performance, and steam-generator performance.

THE FRACTION COLD AND ITS INFLUENCE

The questions in the mind of the boiler-furnace designer with respect to fraction cold are these: How much does an increase in the extent of cold surface in a furnace envelope influence the temperature of the gases escaping from the furnace? And how much does it affect the rate at which energy as heat is absorbed by these cold walls? Also, how much is the final temperature of the gases escaping from the steam generator influenced by these conditions? Finally, how much does an increase in fraction cold relieve the conditions at the hotter refractory surfaces, or how much does an increase in the fraction cold permit of increasing the energy-release rate for the same wall maintenance costs? These questions, as stated, are not concerned with the extent to which the progress of combustion may be interfered with, which condition will, of course, have to be investigated separately for each case.

To indicate what the answer may be to the first two questions the curve of Fig. 7 is shown. The ordinate γ is the relation of the energy absorbed by the walls for any fraction cold ψ to the absorption at the walls when the fraction cold ψ is unity. Inspection of this curve shows that beyond a fraction cold of two-tenths the increase in absorption by increase in fraction cold is nowhere near in proportion to the increase in fraction cold. This means that as more and more surface is added, less and less energy is absorbed by each square foot of surface. Therefore, the mean temperature of the gases is influenced far less by an increase in fraction cold, from, say, 0.3 to 1.0, than it would be by an increase from 0 to 0.3.

To answer the second question the curves of Figs. 8-A and 8-B are shown. Fig. 8-A shows how the total surface requirements of the steam generator for a given escaping-gas temperature are influenced by an increase in fraction cold. Inspection shows that for the conditions illustrated there is no advantage from this point of view in going beyond a fraction cold of about four-tenths. The curves of Fig. 8-B show in another way how Münzinger has attacked this problem. The abscissa here represents the fractional part of the total boiler surface which is exposed to furnace radiation, and it is to be noted that the lowest final temperature results when approximately 12 per cent is exposed to radiation.

Both Figs. 7 and 8 indicate that a large fraction cold may never be the means of greatly improving the overall absorption efficiency of a steam generator. Its purpose, then, is, as before stated, either to reduce the cost of maintaining a wall at a given rate of energy release or permit a higher rate of energy release for a given maintenance.

Mean temperatures of wall and flame are of course, as before mentioned, good indicators of what the destructive effect of the combustion process will be for a given fuel. With this in view, the isotherms of Figs. 9 and 10 are shown. They are flame and refractory isotherms plotted between axes of energy-release rate and fraction cold. It is to be noted that an increase of fraction cold from two to four-tenths permits of doubling the energy-release rate for a given flame temperature. For refractory surface temperatures of 1800 to 2000 deg., roughly the same proportions hold as shown in Fig. 10.

The curves of Fig. 11 and 12 represent the same conditions for a furnace in which the refractory portions of the wall are backed by water cooling. The air gap between the refractory and water-cooled iron back is considered as zero. It is to be noted that for such cases fraction-cold variation has less and less influence as the refractory thickness is reduced. This should, of course, be the case, because as the refractory is approaching zero thickness the furnace envelope is approaching one in which the fraction cold is unity.

Conclusion

In concluding this discussion of heat reaction it may be said that it has been attempted to point out only several of the angles from which the modern art of boiler-furnace design may be viewed. No hard-and-fast rules may be applied. Each important case must be the subject of special investigation, and as yet many empirical data must still be relied on in arriving at proportions which it is hoped will prove satisfactory in operation.

It is very important, however, that those of the coming generation of engineers who may enter this field should begin to think of this process in other than purely empirical terms. Methods of analysis such as are hinted at in this discussion will acquaint the student with the broad underlying principles which are involved, and in addition may help to give them some sense of the relativity of things. This is of greater permanent value than, for instance, a table of values which shows what has been accomplished in certain furnace cavities.

FSP-52-27

Some Economic Considerations of Water-Wall Installations

By OLLISON CRAIG,[1] WORCESTER, MASS.

THE walls of boiler furnaces, on an increasing number of power plants, are being covered, in whole or in part, by water-cooled surfaces. These surfaces may be bare tubes or they may be tubes covered by metal blocks or by refractory material. In some cases metal is arranged to present a continuous surface by interposition of metal strips between bare tubes. The purpose of installing such surface depends on individual conditions. If the furnace is fired by powdered coal, it may be for protection of the walls, prevention of slag, increased capacity, or increased boiler efficiency. If the furnace is stoker fired, it may be for protection of the walls, prevention of slag formation on side walls or tubes, prevention of clinker in the fuel bed, protection of metal parts of the stoker, increased capacity, or increased efficiency. Usually, however, such an installation is made, not on account of one of these factors alone, but because of some combination of them, since no one is independent of all the others.

In most boiler-furnace installations a limiting factor is temperature, and this factor influences the others referred to. First the effect of temperature in furnaces fired by powdered coal will be discussed. In this case refractory walls are affected by high temperature in a number of ways. Softening of the wall material may occur. Undue expansion may be experienced, demanding special construction. High furnaces may cause undue compression loads that can result in failure of the softened brick. Slag formation may erode the walls by the action of fluid ash flowing over the softened surface. Certain combinations of ash and fireclay result in chemical reactions at high temperature, which cause deterioration of the brick. In any of these cases furnace-wall maintenance is affected.

Slag formation in the bottom of a furnace is expensive to remove, unless the ash is at all times kept so molten as to permit removal by tapping. Tapping in general is not practical except in cases of special design, and even then is not desirable except with low-fusion ash. Under certain conditions molten-ash particles may slag over the openings between tubes in the first boiler pass.

Refractory walls of stoker-fired furnaces are affected in the same way as walls in powdered-coal furnaces, except that in addition erosion may occur through the rubbing of the fuel bed adjacent to the wall. This form of erosion is increased with increased furnace temperature and increased softening of the refractory-wall surfaces. Slagging of the boiler tubes by molten-ash particles also occurs in stoker operation. This may be even more pronounced than in the case of powdered-coal firing, as the ash particles rising from the fuel bed will be larger and may not be chilled below the softening point before coming in contact with the tubes. High furnace temperatures tend to the formation of clinker in the fuel bed, reducing fuel-burning area, causing holes which admit excess air, and interfering with the mechanical action of the stoker parts. Stoker metal parts are affected by high furnace temperature, particularly if liquid slag comes in contact with the metal. Molten slag may act as a flux, and serious burning of metal parts occurs.

Attempts to secure higher capacity or higher efficiency in either a powdered-coal fired furnace or in a stoker-fired furnace usually result in higher furnace temperatures. Higher capacity demands a higher fuel-burning rate and a higher rate of heat release, resulting in higher temperature in a given furnace. Increase in efficiency may be obtained by less excess air being used or by returning to the furnace heat recovered from the flue gases. Either results in higher furnace temperature.

Furnace temperature then limits both capacity and efficiency. The effect of water tubes in furnace walls is to absorb heat by radiation, leaving less heat in the gases, and to produce a lower temperature in the furnace than would be the case with refractory walls entirely exposed, assuming all other conditions, particularly as to rate of fuel-burning ratio of coal to air, and furnace volume, the same in each case.

Since the action of slag is the cause of most of the furnace difficulties, and since the other difficulties become quite minimized if furnace temperatures are such that slag does not occur, it may be said that the temperature at which softening of ash occurs is the desired limit of furnace temperature, and that the combination of fuel-burning rate, rate of air supply, and water-tube surface exposed should be such that this temperature should not be reached.

At the beginning a number of reasons for the use of water tubes in a boiler furnace were stated. In reality there is only one reason, and that is decreased cost of steam production Decreased cost of steam production may be realized through greater thermal efficiency, increased capacity, or use of cheaper coal, but certain things that can produce greater efficiency, such as reduced excess air, will result in higher furnace temperature. Greater capacity produced by greater fuel-burning rate can also result in higher furnace temperatures. Cheaper coal may mean lower grade coal, having ash which fuses at a lower temperature. Spending money for water tubes in furnace walls may then result in reduced steam cost by preventing such effects of high furnace temperature as have been discussed and by permitting operation either at increased efficiency or at higher capacity or with cheaper coal. The decision in a particular case as to whether water tubes should be installed in the walls of a furnace, and the area of water tube surface to be installed, depends on the load it is desired to develop, the economical limit of excess air, and the fusion temperature of the ash in the coal. The increase in cost of such tube area must be set up against reduction in cost of boiler and furnace, against the reduction in cost of coal consumed, and against reduced price of coal per ton.

The presence of water tubes in a furnace reduces furnace temperature, but does not directly affect overall boiler efficiency to any considerable extent through this reduction in temperature alone. Water tubes in furnace walls absorb heat radiated from the flame and furnace gases, which heat is transmitted to the water contained in the tubes. This heat finally appears in the steam leaving the boiler. The amount of heat that the flame and gases give up to the furnace walls is greater when water tubes are present than when the walls are entirely refractory. As a result, gases will then enter the first bank of boiler tubes at a lower temperature. This is on the assumption that other conditions are

---

[1] Consulting Engineer, Riley Stoker Corporation. Mem. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Fuels Division, Philadelphia, Pa., October 7 to 10, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the same; that is, that the same weight of coal is burned per hour and that the coal is burned with the same amount of air, or that the CO_2 in the gases is the same. The gases enter the boiler tubes at a lower temperature as a result of this heat absorption in the furnace, but leave the boiler tubes at only a slightly lower temperature. Under these assumed conditions the only gain in thermal efficiency that can be realized is in lower exit-gas temperatures. If, then, the difference in exit-gas temperatures is negligible, the gain in thermal efficiency is negligible. If, instead of placing tubes in the furnace walls, an amount of boiler-tube surface was added to the last bank or last pass, approximately equivalent in area to the area exposed to radiation, the final gas temperature would be about the same as if this area were placed in the furnace.

This is illustrated in Fig. 1 by means of a curve of gas-temperature drop. A curve is plotted with per cent of boiler surface

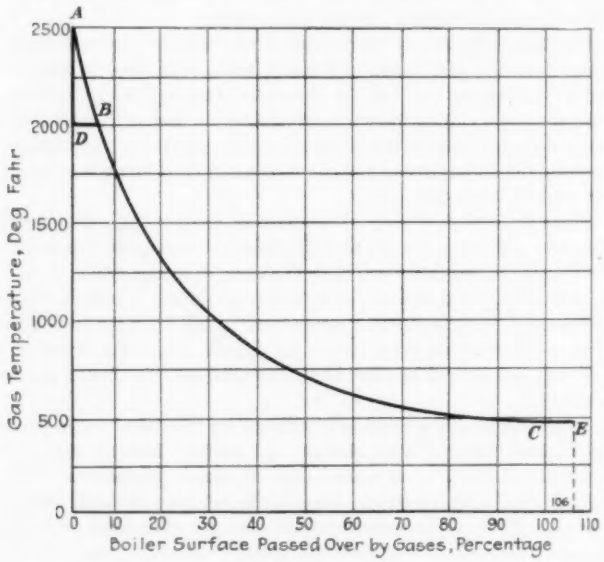

FIG. 1

passed over by gases as abscissas and temperature of gases as ordinates. The curve indicates how the gases drop in temperature as they pass through the boiler setting from the furnace to the outlet. For a boiler unit without water tubes on the furnace walls, the gases enter the first tubes at an assumed temperature of 2500 deg. fahr., and this point is indicated as the point *A* on the curve. On arrival at the boiler outlet 100 per cent of the boiler surface has been passed over by the gases and the temperature of the gases has dropped to an assumed temperature of 460 deg. fahr. This point is represented as *C* on the curve. If water-tube surface is placed on the furnace walls and coal is then burned in the furnace at the same rate as previously, and burned with the same weight of air, the gases will enter the tubes at a lower temperature than in the first case.

Assume that sufficient tube area has been placed in the furnace to reduce the temperature of the gases entering the boiler tubes to 2000 deg. fahr. With respect to the coordinates used on the curve in Fig. 1, this condition of the gas would be represented by the point *D*. A curve could then be drawn from *D* representing the change in gas temperature as boiler surface was passed over. Assume a horizontal line drawn from *D* to intersect the curve *A-C* at *B*. Gases would then be entering the first row of boiler tubes at the same temperature as if they had passed over (*D-B*) percentage of the tube area in the case where no tubes were in the furnace. A curve drawn from *D* would then be the same as the curve *B-C* but transposed a horizontal distance *D-B*, and instead of drawing the curve from *D* the curve *B-C* would be extended to *E*, so that the horizontal distance from *C* to *E* would be equal to *D-B* and the temperature at *E* would represent the final temperature of the gases leaving the boiler. The reduction in gas temperature is equivalent to the addition of tube area in the last pass represented by the horizontal distance from *C* to *E* or from *D* to *B*.

On this assumed curve the increase in area is indicated as about 6 per cent of the boiler-tube area. With a given boiler and with a given operation in which the assumed curve may be realized, the addition of surface in the furnace exposed to radiation, equivalent to 6 per cent of the boiler-tube area, will result in reduction of gas temperature about as indicated by the curves (from 2500 deg. fahr. to 2000 deg. fahr.), but the final gas temperature has only been reduced about 13 deg. fahr. With 14 per cent CO_2 in the gases, this 13 deg. fahr. represents about one-third of 1 per cent of the heat in the coal.

We may say then that water-cooling a furnace does not result in any appreciable increase in thermal efficiency if the same amount of coal is burned with the same amount of air. The same idea may be expressed by saying that the absorption of heat by radiation from the flame and gases in the furnace does not of itself result in a material increase in boiler efficiency. Thermal gain through the use of water tubes in the furnace is obtained through burning coal with a smaller quantity of air or with a higher percentage of CO_2 than would be permissible with refractory walls.

That the amount of boiler tubes exposed is a factor in furnace temperature is well illustrated by certain types of horizontal water-tube boilers which have had tile covering the lower row of tubes in such a way as to present the effect of a flat refractory arch over the fire. If in such cases the tile covering was removed and flat tile laid above the tubes, allowing the tubes to be exposed to radiation, the furnace temperature was reduced. In making calculations in connection with water-cooled furnace walls the exposed boiler tubes should then be included.

When coal is burned, a gas is produced which in weight is equivalent to the weight of air used for combustion plus that portion of the coal combined. The weight of gas produced per pound of coal burned is indicated by the percentage of CO_2 in the gas. The more air per pound of coal the less the percentage of the CO_2; and the less weight of air per pound of coal the greater the percentage of CO_2. Burning a pound of a particular coal results in a particular amount of heat. This heat would all be absorbed by the products of combustion if no heat was lost by radiation. The difference between the heat generated and the heat radiated is that which is absorbed by the products of combustion, and the amount of this absorbed heat determines the temperature of the gas entering the boiler-tube space. If burning a pound of coal results in the release of 14,000 B.t.u. and the production of 15 lb. of gas, and if 5000 B.t.u. are radiated to surrounding surfaces, the absorption of the remaining 9000 B.t.u. will result in a temperature rise of about 2230 deg. fahr., or a total temperature of 2300 deg. fahr. of the gases entering the boiler tubes if air is supplied at 70 deg. fahr. If the ash in the coal softens or fuses below this temperature, trouble will be encountered due to slag in the furnace. The above condition represents about 14 per cent CO_2. If slag results, it will then be desirable either to arrange for more heat to be absorbed by radiation or to operate at a lower percentage of CO_2. It will be seen then that the addition of water tubes in the furnace in such a case will result in high thermal efficiency through permitting higher CO_2 to be maintained. This is practically the only way in which water-cooled walls can result in higher boiler efficiency.

As stated before, the decision as to the use of water-cooled walls and as to the amount to be used must be made for each indi-

vidual case. It is necessary to consider the size of the boiler, the amount of steam to be made, the variation of load, the kind of coal to be burned, and the efficiency expected or economically possible.

For example, assume a boiler of 500 rated horsepower burning coal, the ash of which fuses at 2300 deg. fahr. Assume the projected area of boiler tubes exposed to the furnace to be 200 sq. ft. Assume that it is desired to burn the coal with 14 per cent CO_2. If the boiler operated at 200-lb. pressure, the exit-gas temperature would be about 610 deg. fahr. and the thermal efficiency would be about 79 per cent, developing 1250 boiler horsepower. Under those conditions the temperature in the furnace would be about 2550 deg. fahr. and would result in slagged ash. It would then be necessary to reduce the CO_2 to about 12 per cent or to place water tubes in the furnace walls having an exposed area of about 150 sq. ft. projected area. Prices for such walls vary up to $35 per square foot. At $20 the cost of the water cooling would be $3000. If, instead of spending the money for water cooling, the furnace was operated at 12 per cent, the resulting efficiency would be about 75 per cent. If the coal burned contained 14,000 B.t.u. per lb. and cost $5 per ton delivered, the difference in cost of coal for one year would be about $4000, providing the boiler operated at this load for 24 hr. a day and 300 days a year. Obviously in such a case it would be decided to install the water tubes in the furnace wall.

Assume, however, that 1250 horsepower was a peak which occurred only occasionally and that the total time during which this load was carried amounted to only the equivalent of 30 days continuous operation. If water cooling should be installed, the cost would still be $3000, while the saving in coal cost would only be $400. If off-peak loads did not exceed about 800 to 1000 horsepower, then water tubes would not be installed and the furnace would be operated with 12 per cent CO_2 during peak loads.

In this example if it is assumed that fixed charges on water-wall costs be taken at 15 per cent, the annual charge against the water-wall installation would be $450 per year. If, then, the peak-load period exceeded a total of about 35 days per year, there would be a net gain by spending money for the water walls.

The point that it is desired to bring out in this example is that the furnace temperature may be modified either by using water walls for absorption of heat by radiation or by supplying a greater quantity of air with a given quantity of coal and having a greater weight of gas for absorbing a given quantity of heat. The example is used to illustrate the fact that a charge may exist in either case and that in actual design these charges should be computed and compared.

Frequently a plant is faced with the necessity for greater steam production, with its steam-producing units already operating at the limit of their capacity. The limit may be because of coal-burning capacity, draft, or furnace temperature. Coal-burning capacity may be limited due to furnace temperature, as in the case of clinker formation in the fuel bed with stoker firing. To obtain more capacity by installing additional steam units may cost more than the units alone. In some cases a new boiler house needs to be constructed and in some cases no space is available for any additional units. If furnace temperature is the condition limiting steam production, as it most frequently is, additional capacity may be obtained at the least expense by the addition of water tubes in the furnace. This procedure will undoubtedly become more and more common in the future.

There have been cases in which water tubes have been placed in a furnace for capacity effect and a less number of tubes used in the convection portion of the boiler. It is true that a square foot of tube area exposed to radiation in a furnace will absorb far more heat than the average square foot of surface in the convection portion of the boiler. To take an example again, assume a 500 rated horsepower boiler to deliver 1500 developed horsepower. Assume half the convection-tube surface removed and replaced with tubes in the furnace walls, leaving 2500 sq. ft. of convection surface. In such a case there would not be 2500 sq. ft. put in the furnace, but more probably 600 or 700 sq. ft. in projected area, or about 1000 sq. ft. in total tube area. Gases would enter the tubes at a lower temperature as a result of the water-cooled walls, but would leave the convection surface at a higher temperature as a result of having only half the normal convection surface. The temperature of the gases leaving the convection surface would be about 750 deg., assuming other conditions as in the previous example. This would represent about $3^1/_2$ per cent loss in thermal efficiency. In such a case it is common to express the load in terms of percentage of normal rating of the convection surface; that is, in this example the boiler would be said to operate at 600 per cent of rating.

By means of this arrangement greater capacity is obtained at less cost, as the saving in cost of convection surface will be greater than the cost of the water tubes in the furnace. However, there will be a charge against this saving due to increased coal cost resulting from higher exit-gas temperature. Generally it will pay to add heat-recovery means in the form of an economizer or air preheater. There is a decided tendency toward using less convection surface, absorbing more heat by radiation in the furnace, and recovering more heat from the gases leaving the convection surface.

To sum up, each case must be considered on its own merits, and a few fundamentals should be kept in mind. Water-cooled furnace walls do not appreciably increase overall efficiency through heat absorption and reduction in temperature of furnace gases, but rather through making it possible to carry higher percentages of CO_2 than would otherwise be possible. The expense of water-cooled furnace walls is justified only through savings in coal and cost of equipment. Load factor should be studied in a given case and calculations made to determine whether it is more economical to burn more coal for a short period or to pay for water-cooled surface in the furnace. Increased capacity may be obtained through the use of water-cooled furnace walls, but at the expense of coal cost, unless heat-recovery means are also provided. It may be found possible to get more capacity in a given space and at a lower cost together with greater overall efficiency by using water-cooled furnace walls with less convection surface and the addition of heat-recovery equipment.

Discussion

J. A. Drogue.[2] The author very elaborately goes into economics of water-wall furnaces. The writer would relate some of the operating characteristics and experiences with the water-wall furnace at our plant.

For fifteen months we operated this boiler for six days a week, twenty-four hours per day, at about 300 per cent rating. Our mill goes into production promptly at 6 a.m. on Monday and continues through the week until the following Sunday morning. During this time we had no other boiler to go to in case of emergency, and it was absolutely necessary to carry the mill load at all times on this one boiler. A few words of explanation will counteract any thought you may have on the poor management of the plant in getting caught with only one boiler. Our new layout was such that we had to remove four old boilers (which incidentally would not carry the mill load in event of losing the boiler in question) to make room for new units.

On two occasions in the past several months, due to some work we did or did not do over the previous week end, we were brought

[2] Ball Brothers Company, Noblesville, Ind.

face to face with the necessity of a shutdown or an attempt to run through the week with possible disastrous results. The mill operators were informed of the impending shutdown, and all process work was tapered off to a minimum load. At this point the fire was quenched to a stage when the surface of the fire bed ceased to be incandescent and at the same time the induced-draft fan continued to run. Without the use of a stream of water or a man-cooler two men working in shifts entered the furnace and made necessary adjustments, and the mill was back into production in one hour and thirty minutes. During the past winter we experienced six weeks of close to zero weather, and a lengthy shutdown over the week-end no doubt would have proved costly, since buildings with their various machines and water lines must be kept from freezing, not to mention the necessity of maintaining temperatures in some of our buildings at a point that will insure correct process on starting the mill on Monday morning.

During this cold spell and at various times during the winter it was necessary for us to do our periodical cleaning in and around our one boiler, and this was accomplished in the twenty-four hours shutdown period from Sunday morning until Monday at the same time. A conservative estimate of our money lost per hour in the event of a shutdown is placed at $900.

I feel sure you will agree that it would have been impossible for us to have entered a refractory furnace of similar size, even though it were air cooled, without requiring a much longer time to cool to the point where a man could enter and work.

In the paper mention is made of an item of $4000 as the added cost of water walls on a given job, and my impression is that the author endeavors to show in dollars and cents the justification of a water wall. After the experience of fifteen months as outlined, the thought has come as to what might have been our loss in dollars if we did not have water walls.

A. G. Christie.[3] The subject of water-cooling of furnace walls is one in which the writer has had an intensive interest for many years. The author has clearly stated the ultimate effect of water cooling on furnace performance, and he has shown that if the same amount of coal is burned with the same amount of air, water cooling of the furnace does not result in any appreciable increase in thermal efficiency. While this conclusion is a logical deduction, there are some features of water cooling in a furnace which the author does not discuss.

For instance, in large powdered-coal furnaces it is held that the cooling effect of the water walls does not extend more than a few feet into the furnace and that the temperature of the central mass of the turbulent combustible flame is unaffected by the presence of water-cooled walls. If this is granted, then the effect of the walls is to produce a relatively cold envelope of gases on the outside of the furnace and an intensely hot core. If the gases passed into the boiler tubes in uniform layers, the tube surfaces in the sides and ends of the boilers would receive relatively cool gases while the central tube sections would receive as hot gases as if no water cooling were present. In such a case the tubes would slag over in this portion as fully as if no water-cooled furnace walls had been used.

These conditions are to some extent offset by the turbulence in the furnace which tends to whirl the colder side layers of gases into the interior mass and thus tends to equalize furnace temperature. In spite of this mixing, experience has shown that severe slagging can occur in the central part of the lower boiler tubes even with water-cooled walls when powdered coal is used. Boiler tubes in the form of slag screens have been found desirable in many cases to prevent such slag formation under these conditions.

[3] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

The author indicates that any gains in boiler thermal efficiency with water-cooled walls are due to the use of a smaller quantity of air together with a higher percentage of CO_2 than would be permissible with refractory walls. These considerations of decreased air and higher CO_2 must therefore have been assumed in the paper of Messrs. Bennett and Oberholtzer in estimating the increased efficiencies resulting from the use of water-cooled walls.

Melvin D. Engle.[4] The author has very clearly pointed out that the use of water walls in themselves does not result in an appreciable increase in boiler and furnace efficiency. There has been a tendency to make extravagant claims for water-cooled furnace walls, and it is helpful to the industry to have some one point out wherein the use of water walls is actually justified.

There are two factors that the author has failed to mention that are important in considering the advisability of installing water-cooled furnace walls. These are, first, the fact that water walls should increase steam-generating unit availability and, second, that water walls permit more rapid increase in steaming rate.

Greater availability will reduce the unit cost of boiler plants; and the ability to pick up and drop load rapidly without shortening the life of furnace walls is becoming more and more important in the operation of large electric systems. Steam stations that act as standby for systems supplied by hydroelectric plants at considerable distance from the load will find this feature of particular importance.

The author states that the use of water-cooled furnace walls prevents the formation of clinker in the fuel bed on stokers. Operating experience has not fully borne out this contention for stokers of great length and width. This is probably due to the fact that the gases of combustion in a furnace act as a shield to prevent the water-cooled walls from cooling zones at any great distance from the walls.

The author also stresses the point that the use of water-cooled furnace walls materially lowers the temperature of the gases entering the boiler. Is it not a fact that the water wall only lowers the temperature of the gases entering the boiler a few feet from the water-cooled wall? Is it not a fact that the gases from the center of the furnace enter the boiler at practically the same temperature whether the walls are water-cooled or of refractory material? If the gases of combustion act as a shield for the transmission of heat by radiation, the answer to both of these questions must be "yes."

Another statement worthy of further discussion is the statement in the paper that we should limit the furnace temperature to the softening temperature of the slag carried along by the furnace gases. There is reason to believe that this cannot be done in many cases without a serious loss in furnace and boiler efficiency. Would it not be better to design the entrance to our boilers so that they can chill the molten slag below its freezing temperature without "bird nesting?" Such a design will result in more efficient utilization of the heat in the fuel.

The author is to be complimented on his frank discussion of the subject of water-cooled furnace walls. The extravagant claims made by some exponents of the use of such apparatus have been a hindrance rather than a help in the promotion of the use of this very useful boiler-plant equipment.

S. M. Finn.[5] The La Mont wall using small bare tubes approximates European practice, while the covered wall is strictly American. Both are dependent for their proper functioning upon

[4] Station Engineering Department, Edison Electric Illuminating Company of Boston, Boston, Mass. Jun. A.S.M.E.

[5] Vice-President and General Manager, Drake Non-Clinkering Furnace Block Company, New York, N. Y.

circulation—the former, forced circulation; the latter, natural circulation. It is upon this little-understood subject of circulation that these remarks are offered. They are conclusions based on academic investigations of our consulting engineer, Mr. J. Gould Coutant, of New York, and the practical experience of the writer and his colleagues.

The function of circulation in boilers is radically different from the function of circulation in water walls. Circulation in boilers is for the purpose of boiling water and liberating steam, but in water walls circulation within the water-wall tubes is the means of maintaining proper metal temperatures which enable tubes to withstand pressure, by carrying away heat from the zone of high heat concentration to the remote cooler portions of the boiler.

There are two fundamentals that affect circulation, as follows:

(1) Heat absorption by the fluid in the tubes
(2) Hydraulic head.

Heat absorption by water in water-wall tubes is subject to the usual unknown quantities encountered in heat-exchange calculations. It is further complicated by the absorption of radiant heat passing through the walls of the tubes to be absorbed by a very uncertain medium—water, water and steam, saturated steam, or superheated steam. The possibility of error in calculations is great.

Hydraulic head conduces the flow of water; the water is the vehicle for carrying away heat from the hot spots. The rate of flow depends on the difference in head between the heated and unheated columns of water. The flow is restricted by surface friction, eddies, and bends. It varies due to highly localized circumstances, outstanding among which are: variations in local rates of combustion; variations in the transparency of the gases, which affect the transmission of radiant energy; variation in firing.

The science of each of these two fundamentals is well known; combined, together with feedwater conditions which form scale, they present an intangible problem which can be solved only from practice.

In Europe it is typical to avoid evaporating water in walls in contact with radiant heat from fire, thus eliminating possibility of incrustation; also it is typical to use small bare tubes requiring forced circulation or its equivalent, for the purpose of maintaining the allowed safety metal temperature or safety creep stress. Such installations permit absorption of radiant energy up to 80,000 B.t.u. per sq. ft. per hour. Boilers in which this construction is illustrated are the Schmidt, Benson, Loeffler, and Brown-Boveri.

In America it is typical to evaporate water in water walls in contact with direct radiant heat from fire, avoiding the possibility of incrustation by lower rates of heat absorption; also it is typical to use large tubes that permit natural circulation. Large tubes, having thick walls, necessitate lower absorption.

Under standard furnace conditions, as defined by the writer in an earlier paper,[6] fire sends out radiant heat at a rate of intensity of 70,000 to 80,000 B.t.u. per hour per square foot of furnace enclosure. The absorption of this intensity must be reduced by protective tube coverings in zones of intense heat concentration. Bare tubes are used at distant points where radiant heat is diffused as though it were light. The reduction in heat absorption is for the express purpose of avoiding incrustation and maintaining the allowed safety metal temperature or creep stress. Constructions of this kind include the Drake armorclade tube, the Drake thermo fit water-wall block; Bailey & Foster.

Bare tubes (in American practice) are used for ordinary pressures which require relatively thin tubes. It is improbable that they will be used for high pressures, at least in zones of high heat concentration, due to the possibility of overheating the metal and exceeding the safety creep-limit stress.

The reason is obvious. The thicker the metal wall of the tubes the higher the temperature of the metal because of its resistance to the flow of heat through it.

Recent research shows that the tensile strength of metals is subject to another limitation than elastic limit and yield point, known as creep limit. Incidentally, a tube in which the creep-limit stress is exceeded may rupture a long time after the furnace has been in service.

Although the knowledge of "creep limit strength" of materials is insufficient to apply for all practical purposes, it will nevertheless be found to support the following contention, viz.: It is necessary to reduce the radiant-heat intensity to bare tubes as the wall thickness is increased. We submit the following practical demonstration:

Two decades ago 300 lb. was high boiler pressure. Tubes 4 in. in diameter, No. 8 gage, with a wall thickness of 0.165 in., were found satisfactory for exposure to a diffused radiant heat of an intensity of 85,000 B.t.u. per sq. ft. per hour.

Then stokers were installed with bridge walls located midway between the two headers of the boiler. As ratings increased, the radiant-heat intensity increased and tubes began to fail. Thicker tubes, to reduce the metal stresses, were used with some success, but satisfactory conditions were not obtained until the bridge wall was moved toward the rear header, which distributed the radiant heat and reduced the radiant-heat intensity back to 85,000 B.t.u. per sq. ft. per hour.

It is apparent that there is a relation between the safety creep-limit stress, incrustation, and radiant-heat intensity which is nearly proportional to the thickness of the wall of the tube.

For example, boilers built for 450 lb. working pressure having 4-in. tubes, No. 6 gage, 0.205 in. wall thickness, are now usually installed to absorb as a maximum 70,000 B.t.u. per sq. ft. of projected area of boiler-tube surface exposed to radiant heat of the fire per hour.

From the suggested axiom that permissible radiant-heat intensity is directly proportional to the tube thickness we deduce an empirical formula based on the known successful 300-lb. practice as a basis of comparison, as follows:

Tube thickness times intensity of the 300-lb. practice divided by proposed tube-wall thickness equals permissible radiant heat intensity. Set up as an equation applying to the 450-lb. boiler we have:

$$\frac{0.165 \times 85{,}000}{0.203} = 69{,}000 \text{ B.t.u. per sq. ft. per hour.}$$

This checks closely with manufacturers' practice.

A Schmidt boiler (European) with a closed-circuit water wall built for 1360 lb. pressure, has 2-in. diameter bare tubes, 0.188-in. walls and is absorbing between 70,000 and 80,000 B.t.u. per sq. ft. per hour.

From the foregoing formula, $\frac{0.165 \times 85{,}000}{0.188} = 74{,}600$ B.t.u. per sq. ft. per hour is the permissible limit, but no evaporation and the equivalent of forced circulation make higher absorptions possible.

A three-drum bent-tube boiler at Lakeside Station, built for 1390 lb. working pressure, with 3-in. tubes 0.3125 in. thick, was set high above the furnace, in which position 50,000 to 60,000 B.t.u. per sq. ft. of projected tube area could be absorbed. Computing, on the suggested basis, the allowable distributed B.t.u.

[6] "Water and Air Cooled Walls for High-Temperature Furnaces," delivered at the Iowa Engineers Society meeting, January, 1929.

per square foot per hour radiant-heat intensity for tube thickness, we have:

$$\frac{0.165}{0.3125} \times 85{,}000 = 45{,}500 \text{ B.t.u.}$$

It has been pointed out that water circulation in water walls is a combined problem of heat absorption and hydraulics. The water acts as a medium to convey heat away from a hot zone to a remote cool zone and is dependent for flow on the difference in hydraulic head between the heated and cool column of water.

At this point Coutant's Relations become important—that, if steam pressure increases four times, the velocity head is reduced to one-quarter due to smaller steam bubbles caused by the higher pressure and the velocity of the water is reduced one-half.

The bubbles weight increases approximately four times.

The slower velocity of the water in circulation will carry a greater amount of heat to remote cool sections per unit weight, but as boiler pressures increase, the internal diameters of the tubes decrease with increased resistance; therefore no advantage is obtained due to the relatively higher heat-carrying capacity of the high-pressure steam bubbles.

A unit of net tube cross-sectional area has a constant heat-carrying capacity for pressures from 150 to 1600 lb. per sq. in. It has been found that 4-in. tubes on 7-in. centers having approximately 10.5 sq. in. net cross-sectional area are satisfactory for carrying away approximately 50,000 B.t.u. per sq. ft. of water-wall surface per hour; equal to 1 sq. in. net cross-sectional area of tube per 2780 B.t.u. per sq. ft. of water wall per hour. This 1 sq. in. of net cross-sectional area will carry away 2780 B.t.u. per hour for every square foot of water wall, irrespective of the length of the tubes (within practical tube lengths) because of increased velocity caused by the greater hydraulic head due to the longer tubes.

On this basis, 3-in. tubes should be placed on 4-in. centers. If placed on 6-in. centers, the tubes should be recessed in the wall or covered to reduce absorption.

It also indicates that $2^1/_2$-in. tubes on $2^9/_{16}$-in. centers is the minimum limit of natural circulation. Smaller tubes or $2^1/_2$-in. tubes on wider centers require forced circulation.

It is believed that, if the foregoing rules are adhered to, no difficulties will be experienced with water walls due to circulation.

FSP-52-28

A Calorimetric Determination of Thermal Properties of Saturated Water and Steam From 0 Deg. Cent. to 270 Deg. Cent.[1]

By N. S. OSBORNE,[2] H. F. STIMSON,[2] and E. F. FIOCK,[3] WASHINGTON, D. C.

In this paper a description is given of the method, apparatus, measurements, results, and formulations involved in the work on steam which has been completed to date at the Bureau of Standards.

The method has been developed in accordance with the principles set forth in a rigorous analysis of the thermodynamic processes involved in a change in state of a saturated fluid.

The apparatus has been designed and built to provide a means for accurately controlling, observing, and accounting for the amount, the change in state, and the change in energy of a sample of water.

The observations have been carried out as a systematic series of experiments in the range from 0 deg. cent. to 270 deg. cent. (to 55 atmospheres pressure) yielding as a result the values of three characteristic thermal properties of the saturated fluid.

The formulation of the results establishes the values of heat content, latent heat, and entropy, and constitutes an exhibit of the thermal behavior of saturated steam in the region covered by the experiments.

The results are assembled in a coherent, consistent table of the properties of steam, available as a foundation for a more complete steam table.

It is found that, when reduced to a uniform basis, after critical study and analysis, most of the source data on saturated steam are in satisfactory accord.

I—INTRODUCTION

THE measurements here described were undertaken to meet a need for more data to be used as the basis for a steam table suited to present and prospective demands of steam-power engineering. The work was initiated as a result of the conference of engineers and physicists which was held in Cambridge, Mass., on June 23, 1921.[4] The program of experimental work undertaken by the Bureau of Standards was a part of a greater project which has been sponsored and largely supported by The American Society of Mechanical Engineers. Harvard University and Massachusetts Institute of Technology have cooperated in this project by undertaking definite programs of investigation.

The importance of international accord as to the basis of steam-power calculations has been recognized here and abroad. This has resulted in the international cooperation of engineers and investigators in the correlation of their work, with the object of ultimately developing a universally acceptable steam table.

In the program of securing new data for the revision and extension of the steam table, the part which was undertaken by the Bureau of Standards is concerned with the energy changes which occur in the fluid, water, when a mixture of the liquid and vapor phases is subjected to changes of state. The thermal properties which characterize these changes may be determined by calorimetric measurements made upon samples of the fluid under its own vapor pressure, or, in other words, at the saturation limit. In the present work a systematic series of such calorimetric measurements has been carried out. A group of thermal properties has been determined which constitutes a calorimetric survey of the behavior of steam in the saturation region extending from 0 deg. cent. to 270 deg. cent. The theory of the experimental method employed and the analysis of the physical processes are given in two publications,[5] of which the latter gives the more general and complete theoretical treatment. Brief descriptions showing the development of the design and construction of the equipment, the progress of the experimental work, and the tentative results obtained have appeared from time to time as progress reports.[6] Because of the tentative nature of the results previously published, the work has been described only briefly. In this report of the measurements completed to date, a more complete account will be given of the design, construction and use of the apparatus, and of the reduction and formulation of the results.

Recently a study[7] has been made of published source data from previous calorimetric work on water and steam in the saturation state. It is therefore unnecessary to include in this paper any of the details of that study, but the revised values and the appraisals there made serve as the basis for their comparison with the results of this present group of measurements. These results have been formulated into an exhibit of the calorimetric behavior of water as saturated liquid and vapor, with which other groups of source data may be correlated. This formulation, starting with liquid water under its own vapor pressure at 0 deg. cent., extends up to 270 deg. cent., and for this range constitutes a consistent, coherent table of observed thermal properties of saturated steam, and may be regarded as an available foundation for a more extensive formulation of the properties of steam.

II—GENERAL DESCRIPTION OF METHOD AND APPARATUS

Before attempting to describe any of the details of design, construction, and operation of the apparatus, which, it must be admitted, is somewhat complicated, the general scheme will be

outlined. A general photographic view of the equipment as assembled in the laboratory for operation is shown in Fig. 1.

1—Method

The method makes use of a single calorimetric equipment by means of which measurements are made to determine several of the important thermal properties of the fluid. A sample of the fluid in a closed container at some chosen saturation state is heated electrically to some other chosen saturation state, or else is withdrawn either as saturated liquid or as saturated vapor. The energy required for each of these three processes is added and measured electrically. The amount of energy added per unit mass is characteristic of the particular experimental process observed. The group of measurements yields essentially the heat content or enthalpy, together with several other important properties, and establishes the thermal behavior of the fluid in the region covered by the survey.

Electrical Measuring Instruments Still for Purifying Water Assembled Calorimeter

Fig. 1 General View of Assembled Equipment

2—Apparatus

The apparatus consists essentially of a calorimeter which provides a place where a sample of water may be so isolated from other bodies as to enable its amount, state, and energy to be accounted for. The sample may be made to pass through a chosen, accurately determined change of state while the accompanying gain or loss of energy is likewise accurately determined. The design of the apparatus provides for several such experimental processes selected for their physical simplicity and for their fitness to exhibit the thermal behavior of the fluid. The arrangement of the apparatus is shown in the diagram, Fig. 2.

A quantity of water, part liquid and part vapor, is enclosed in a metal calorimeter shell. The water is circulated rapidly about the interior in such a manner as to distribute heat and promote close approximation to thermal equilibrium. An electric heater continually bathed with flowing water provides a means of adding measured energy which is speedily distributed throughout the calorimeter system. Outlets with valves provide for the introduction or withdrawal either of liquid or of vapor. Detachable receivers suitable for weighing are connected to the outlets to hold the samples of water transferred.

For confining the energy, the calorimeter is well insulated from the influence of external sources of heat and cold. In operation the temperature of an enveloping shell is kept very close to that of the calorimeter shell itself. The heat which passes by leakage to or from the calorimeter system is accounted for as a small correction which is determined. The energy consumed in circulation and added to the system as heat is another small correction which is determined.

Means are provided for observing the following quantities:

- *a* Temperature of the calorimeter and contents
- *b* Vapor pressure in the calorimeter
- *c* Mass of fluid contents of the calorimeter
- *d* Energy added to the system, including electric energy converted to heat and the small corrections for thermal leakage and circulation.

The apparatus is designed to permit three special types of measurements to be made. In the ideal case of perfect manipulation and control of experimental conditions these would consist essentially of observations of the following processes:

1. Heating with fixed amount of contents (Heat-capacity determinations)
2. Isothermal expansion by adding heat, evaporating liquid, and removing *saturated vapor* (Latent-heat experiments)
3. Isothermal expansion by adding heat, evaporating liquid, and removing *saturated liquid*.

3—RÉSUMÉ OF THEORY OF METHOD

By using the results of the published theory,[8] the measured quantities may be expressed algebraically in terms of familiar thermal properties. The experimental determinations of heat capacity of a sample of water give as a result the increase in the quantity

$$H - L\frac{u}{u' - u}$$

over the observed range of temperature, in which H and L denote, respectively, in energy units, the heat content of saturated liquid and heat of vaporization per unit mass, and u and u' denote specific volume of saturated liquid and vapor, respectively.

In the latent-heat experiments we measure the energy which is added when water is evaporated and withdrawn as saturated vapor at constant temperature. This amount of energy per unit mass is equal to

$$L + L\frac{u}{u' - u}$$

The ratio $u/(u' - u)$ is the fraction of a unit mass evaporated, but remaining within the calorimeter when unit mass is withdrawn.

The quantity $L \times u/(u' - u)$ is complementary both to the determinations of heat capacity and to the determinations involving vapor withdrawal when the values of H and L are desired. This quantity is measured conveniently at any desired temperature by observing in supplementary calorimetric experiments of the third type the energy required to produce the necessary evaporation when a certain quantity of saturated liquid is withdrawn.

Thus the three different types of experiment yield values of three quantities referred to certain temperatures. These quantities,

$$H - L\frac{u}{u' - u}, \quad L + L\frac{u}{u' - u}, \quad \text{and } L\frac{u}{u' - u}$$

are denoted by the symbols, α, γ, and β. From these are derived finally the values of heat content of saturated liquid, H, heat content of saturated vapor, H', and heat of vaporization, L. In addition to these three energy quantities, characteristic of the fluid, there also may be derived from the calorimetric data the entropies of the saturated liquid and vapor; and by use of vapor-pressure data, obtained from other sources, specific volume and internal energy may be calculated.

The properties of water at the saturation limit which may be derived from the calorimetric data, and the formulas by which these derivations are made are as follows:

$$H = \alpha + \beta$$
$$H' = \alpha + \gamma$$
$$L = \gamma - \beta$$
$$\Phi = \int \frac{\alpha d\Theta}{\Theta^2} + \frac{H}{\Theta} = \int \frac{d\alpha}{\Theta} + \frac{\beta}{\Theta}$$
$$\Phi' = \Phi + \frac{L}{\Theta}$$

in which the following notation is used:

H = heat content per unit mass of saturated liquid ($\epsilon + \pi u$), referred to an arbitrary zero
H' = heat content per unit mass of saturated vapor, referred to the same zero as H
L = heat of vaporization per unit mass ($H' - H$)
u = specific volume of saturated liquid
u' = specific volume of saturated vapor

$$\left.\begin{aligned} \alpha &= H - L\frac{u}{u' - u} \\ \beta &= L\frac{u}{u' - u} \\ \gamma &= L\frac{u'}{u' - u} \end{aligned}\right\} \text{measured quantities}$$

Θ = temperature in centigrade absolute
ϵ = internal energy per unit mass
π = vapor pressure at saturation limit
Φ = entropy per unit mass of saturated liquid, referred to an arbitrary zero
Φ' = entropy per unit mass of saturated vapor, referred to the same zero as Φ.

III—DESCRIPTION OF CALORIMETER

The term "calorimeter" will be used here to denote that portion of the apparatus where the observed thermal process occurs. It is the part from which external influences are so isolated that the experimental processes may be accurately controlled and observed. The calorimeter is thus the relatively small part of the apparatus within which we may account accurately for energy added, amount and state of matter, and work done. It forms the nucleus around which the whole experimental equipment is developed.

The calorimeter was designed so that each of the three thermal processes previously mentioned could be separately observed. From these observations the corresponding group of thermal properties of water can be derived. Several general principles have aided in developing the design. These precepts may be enumerated as follows:

[8] Trans. A.S.M.E., vol. 52 (1930), paper FSP-52-20.

a A preliminary analytical study throws important light upon the applications of the thermal processes leading most directly to the desired results.

b Simplification of the experimental processes by refinement in the details of equipment and manipulation makes departures from the ideal experiment small or negligible, and thus promotes reliability.

c Advance consideration of the relative importance of individual refinements is more to be desired than makeshifts to account for and eliminate inconsistency of results.

d The apparatus should be moderately proportioned so as to promote accuracy, and facilitate construction, assembly, and operation.

e The best available materials and workmanship are most economical in the end.

f Proof tests of materials, particular features of design, and of partly assembled portions of the whole, reduce hazards to the completion of the work.

These principles may appear so obvious as to need no mention, but they suggest ideals to be sought and are recalled at this point to indicate a background against which closer details may be viewed in proper perspective.

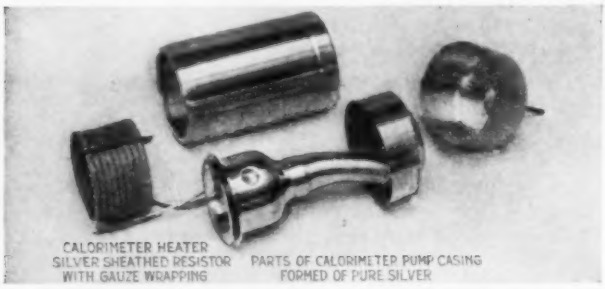

FIG. 3 PARTS OF PUMP CASING AND CALORIMETER HEATER

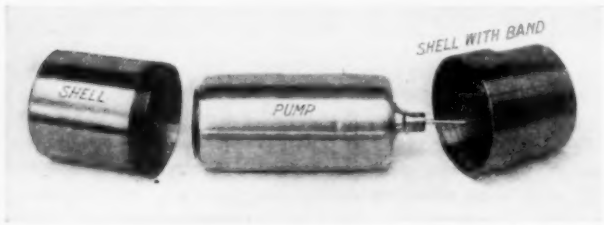

FIG. 4 CALORIMETER PUMP AND SHELL

1—CALORIMETER SHELL

The purpose of the calorimeter shell shown at *C* in Fig. 11 is to provide a receptacle or reservoir for the sample of water under observation. This shell is cylindrical in shape, having spherical ends, and is made of an alloy of 80 per cent copper and 20 per cent nickel. It contains, in addition to the water, the parts which serve as operating organs. These consist of a circulating pump, electric heater, etc., and will be described presently. To provide for installation of these parts the shell is made with a joint normal to its axis. The two main portions of the shell were shaped by cold drawing. Each is accurately machined, one with a right-hand and the other with a left-hand thread at the joint. The parts are brought together by a monel-metal band threaded correspondingly. The joint is made tight by the pressure which a tongue on one portion exerts on a gold-wire gasket lying in a groove in the other portion. To assemble this joint three special powerful wrenches shown in Fig. 5 were provided. Two of these are clamped about the smooth cylindrical surfaces, while the third wrench engages a series of rectangular notches in the monel band. The two clamps are yoked together at the outer end and a threaded drawbar provides the driving force in the final closure of the joint. In this operation sufficient initial stress must be developed in the band to insure a perfect seal against the vapor pressure of the water at any subsequent operating temperature. The amount of force with which the shell is drawn together was determined by making actual proof tests with saturated steam at a higher temperature than the experiments are intended to reach. As expected, these proof tests showed that the joint acted as a safety valve which would open at a rather definite steam pressure, and close again after the pressure was moderately relieved.

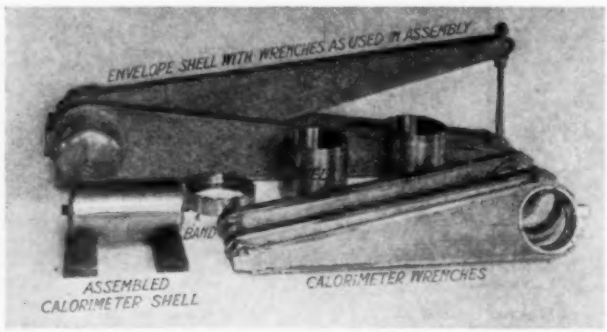

FIG. 5 WRENCHES AND MANNER OF ASSEMBLING SHELLS

The interior of the shell is heavily plated with silver, burnished after each successive plating. This is for the purpose of avoiding contact of the water with the base metal of the shell, silver being more resistant to hot water than the copper-nickel alloy. The exterior is likewise silver plated to give it a bright surface.

The various plugs and fittings which serve as ducts for tubular connections with the outside and for electric power connections are made of alloys of silver, and sealed with gold gaskets in tongue-and-groove joints.

2—CIRCULATING PUMP

The purpose of the circulating pump is twofold. It maintains a rapid circulation of the liquid about the walls of the calorimeter shell for distributing heat and thus promotes thermal equilibrium. It provides at the same time a source of liquid at the top of the calorimeter for keeping the heater surface bathed with water spread out in a thin, flowing stream.

Vigorous circulation lessens the time required to equalize the temperature of calorimeter and contents, and permits observations of steady initial and final temperatures to be made promptly.

Another advantage of the rapid distribution of heat is that, during the time when heat is being added electrically, temperature gradients on the calorimeter surface are kept small. The mean temperature of the surface may be obtained with reference to the opposed envelope surface by means of distributed thermo-elements for accurate evaluation of the thermal leakage.

The method of bathing the heater by a continuous thin flowing layer of liquid brings the evaporating surface close to the energy source and thereby accomplishes quiet evaporation, producing dry saturated vapor with very little disturbance of temperature in the entire system. This feature will be discussed later.

The construction of the pump is indicated in Figs. 3 and 11. It is of the centrifugal type, specially designed for the requirements of this particular case. The pump circulates about six

liters of water per minute, the equivalent of the entire contents passing around every five seconds. The flow circuit divides at the top, the larger part following the wall of the shell and the rest flowing through a port, down over the heater, and thence down to the inside storage space. To circulate the two streams, one of large flow and low head, and the other of small flow and greater head, the pump wheel or impeller is made in two parts rotating together and delivering into the same casing. As a result of tests of the characteristics and efficiencies of a series of model pumps, this final design combining two stages in parallel, each of different characteristics, was developed, and was found to give satisfactory heat-distributing capacity with a tolerably small power input.

The energy consumed in the pump is dissipated as heat added to the calorimeter system, and is objectionable if its amount is indeterminate or too great. Too large a pump energy input would interfere with the accurate observation of the initial and final temperatures. Too much fortuitous variation in the pump energy would impair the accuracy of accounting for energy from this source.

The normal speed of the pump wheel is 900 r.p.m. This speed was changed in certain experiments as found desirable. The method of speed control will be indicated later. The power input is determined calorimetrically and varies from 0.05 to 0.10 watt, depending on controlled conditions. The flow in the inner circuit over the evaporator and through the stage which maintains the head for keeping the main flow channel full is about one liter per minute. The flow in the main channel is about five liters per minute. The efficiency in pumping the water from intake to discharge at the top of the calorimeter was found to be about 28 per cent. The construction of a pump of this size and character designed to operate continuously in water up to 300 deg. cent. with no other lubrication of the running parts than that furnished by the water, built of materials which would be unaffected by the action of the water, involved some interesting problems.

The impeller runs on ball bearings of iridium alloy. The balls are about 1.2 mm. in diameter, ten balls in the lower and seven in the upper bearing. The main part of the runner is built up of silver-palladium alloy. The shroud and clearance ring of the upper stage are made of one piece of silver-gold alloy riveted to the runner. The vanes are machined to streamline curves. The lower stage has neither shroud nor clearance ring.

The five parts of the pump casing and flow channels are formed of pure silver. These parts go together with well-fitting slip joints fastened, where necessary, with pins. The entire pump, discharge tube, and flow-channel casing form a unit which, when assembled, is borne rigidly within the calorimeter shell on three supports of streamline form, machined from a solid piece of silver-gold alloy which fits the central opening at the bottom of the shell.

The pump runner is driven by a square on the lower end of the main runner shaft which engages the square in the upper end of the tubular propeller shaft of silver-palladium alloy. This propeller shaft extends down through the lower tubular support of the shell and on down to the stuffing box, where it engages the stuffing-box shaft of hardened tool steel with another square joint.

3—Stuffing Box

The stuffing box, built to provide for the rotation of the drive shaft for the calorimeter pump without permitting leak of water by it, is shown at *WSB* in Fig. 11. A cylindrical recess 5 mm. in diameter and 12 mm. deep in the monel body was fitted closely with two small ring-shaped packing retainers. The one which goes above the packing is of silver-palladium alloy, and the one below of phosphor-bronze. These retainers fit the 1.0-mm. hardened steel drive shaft within 0.01 or 0.02 mm. on the diameter, so that very little space is left through which the packing can flow. The packing consists of soft kid-leather washers impregnated with paraffin. Pressure is transmitted to the packing in the recess by means of an appropriate number of cupped washers of spring steel. These are compressed to the desired degree by means of a gland threaded into the body of the stuffing box. In order that there shall be no leak, it is necessary that the hydrostatic pressure in the packing be greater than the vapor pressure in the calorimeter. To prevent undue wear on the pump shaft the number of spring washers, the method of combining them, and the amount of deformation imparted to them are adjusted to meet the needs of the experimental conditions. To avoid the difficulties of finding a packing which would be satisfactory at high temperatures, the stuffing box is placed outside the lagging and water cooled. The size of the pump shaft where it engages the packing was reduced to 1 mm. to cut down the wear. Below the packing the shaft is larger and is provided with a ball bearing to take the downward thrust. The race for this bearing is attached to the outside of the body of the stuffing box by a threaded joint and can be removed readily for examination of the packing. A brass collar prevents undue upward motion of the shaft. Power for driving the pump is supplied from below, as will be more fully described later, and transmitted to the pump shaft by a hollow drive shaft having squared slip joints to provide easy assembly yet positive drive.

4—Electric Heater

The electric heater furnishes the means by which the major portion of the measured energy is added to the calorimeter system. As far as the heat-capacity experiments of the first type are concerned, no extraordinary restrictions as to characteristics of this part are necessary, as the exact path by which the change from an initial to a final temperature occurs is of no importance if the energy account is faithfully kept. In the case of evaporation experiments, and particularly those of the second type, much may depend on the way in which the energy is supplied and utilized in the evaporation process. The question as to the actual state of steam used in latent-heat measurements is the moot point which has frequently been raised as affecting the dependability of published values. If the energy could be supplied exactly at the surface where it is required for evaporation, none of it would go to superheating either the liquid or the vapor. Evaporation would then proceed quietly, and dry saturated vapor would be produced. In this calorimeter the electric heater, which is in fact an evaporator, has been developed to effect quiet evaporation and the formation of dry saturated steam with very little disturbance of thermal equilibrium in the calorimeter and contents.

The evaporator-heater as installed is shown in section at *H* in Fig. 11, and photographically in Fig. 3. In this electric heater a resistance wire of constantan 0.4 mm. in diameter, with gold leads of the same size, forms the resistor. This resistor is insulated by embedding it tightly in dry clay which completely fills the pure silver tubular sheath. The portion of the sheath containing the resistor is flattened to a thickness of about 2 mm. The end portions containing the gold leads are drawn to a diameter of about 2 mm. The flattened portion is wrapped spirally with a strip of pure silver fine-wire gauze, fastened by spot welding at a number of points. The flat resistor portion is then bent into the final helical form as shown, and the leads bent so as to pass downward and out of the shell through the fitting.

The purpose of the gauze wrapping is to insure even distribution of the stream of water which flows through the annular

port, and thence down as a thin sheet enveloping the evaporator.

The resistance of the completed heater is about 10 ohms. The insulation resistance between the resistor element and the silver sheath was found to be about 90 megohms when cold.

The evaporator when installed is held in its central position just below the water port by a three-armed silver support carried on the central portion of the discharge tube of the pump. The water is led from this port by guides of silver gauze and brought to the very top of the evaporator. The excess of liquid which flows off the evaporator is led quietly down into the central reservoir by a similar guide or apron of gauze.

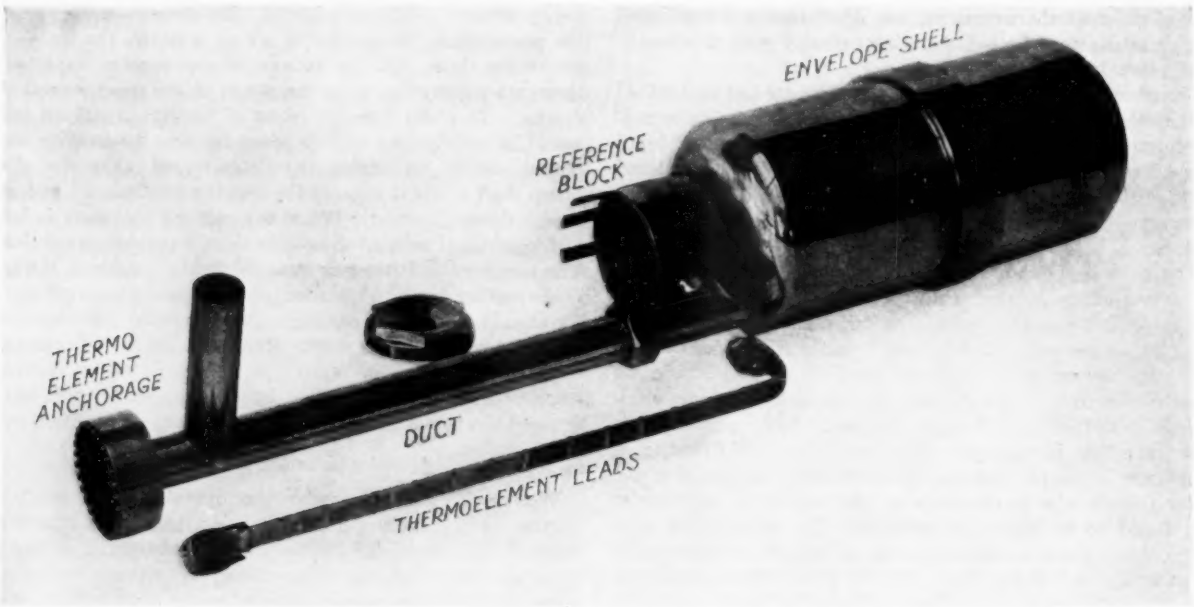

FIG. 6 ENVELOPE SHELL WITH REFERENCE BLOCK, DUCT, AND THERMOELEMENT LEADS

5—ENVELOPE

The chief purpose of the envelope which surrounds the calorimeter shell is to provide a receptacle in which the shell may be installed to isolate it from adventitious or fortuitous sources of energy.

We may regard the space between the calorimeter shell and the envelope as a barrier to heat flow, pervious to only a slight extent. The necessary metal connections between the calorimeter and its surroundings furnish other restricted channels for heat flow. The thermal-leakage rate may be made small by refinement of construction, but can only be annulled completely by avoiding temperature difference. This may not be actually possible, but by first making the thermal insulation very good and then in operation keeping the temperatures under control, it is possible to keep the heat leak extremely small in all cases and to account accurately for the unavoidable small heat leak which does occur. Provision has been made for both these measures in the present calorimeter, as will presently be shown.

The envelope is shown at *E* in Fig. 11. This outer shell is very similar in construction to the shell of the calorimeter. It is of the same material, made in two parts, assembled in the same manner. This shell is made strong as a precautionary measure in case the inner shell should fail to hold the water sample under pressure.

The calorimeter shell is supported axially within the envelope by means of two tubes of silver-palladium alloy, one at the top and one at the bottom. Besides furnishing strong, stiff supports, these tubes serve also as channels for transfer of fluid to or from the calorimeter, either as liquid or vapor. The lower tube also encloses the propeller shaft of the circulating pump. The upper tube serves as an opening through which a tool may be introduced for adjusting parts. The metal of these tubular supports was chosen because it possessed the desired characteristics of resistance to action of hot water, strength, thermal resistivity, and satisfactory workability.

To avoid the danger of injury to the delicate supporting tubes by accidental shock to the system when in place, six metal pegs are fixed in the wall of the outer shell, extending radially inward nearly to the surface of the inner shell but not touching it. These are placed in two planes near the top and bottom of the cylindrical part of the inner shell, and are so adjusted in length as to prevent any eccentric displacement which would endanger the supporting tubes.

Thermal leakage may take place by either of four types of heat flow, namely, radiation, solid conduction, gaseous conduction, and convection. The first of these, radiation, is made small by silver plating and polishing the outer surface of the calorimeter shell. This finish has a tolerably low emissivity in the temperature range of these experiments.

Conduction through the metal parts extending across the insulating space is kept within bounds by choice of materials and proportions of the necessary supporting tubes and electrical leads. The supports have already been described above. The electrical leads which contribute to thermal leakage comprise 21 chromel and 14 copel thermoelement wires each 0.1 mm. in diameter. Each of these materials has low thermal conductivity, and these leads contribute little to the total heat leak. The electric current and potential leads are a larger factor. These are of gold wire. The current leads are about 0.6 mm. in diameter and about 4 cm. long. The potential leads are about 0.2 mm. in diameter and 8 cm. long. They are disposed in the envelope space about as shown in Fig. 11.

Heat leak by gaseous conduction and convection was dealt with at first by providing means for evacuating the envelope

space to a low residual-gas pressure of about 0.0003 mm. of mercury. At this pressure the heat leak by this path is insignificant. The calorimeter was operated this way during much of the earlier work at moderate temperatures. At temperatures of 200 deg. cent. and over, trouble developed due to leaks appearing in the envelope system surrounded by oil. Presence of the small amount of oil which penetrated into this evacuated space, produced thermal effects which were baffling until finally

traced to their cause. After contending with this difficulty for some time, it was decided to discontinue the evacuation of the envelope. Instead, it was filled with nitrogen at about atmospheric pressure. This practice gave a slightly greater thermal-leakage coefficient, but inasmuch as this coefficient was determined as a part of the systematic routine and the actual heat-leak correction made in every experiment, a small percentage change in an already extremely small correction term was of no consequence.

Supplementing the above-mentioned features of thermal insulation of the calorimeter, there is a thermometric device for indicating the relative temperatures of calorimeter and envelope surfaces, and also a means for controlling these temperatures. The thermoelements which serve for the first of these form a part of the whole thermometric system which will be described in detail presently. The thermal control bath which surrounds the envelope and is the medium for effecting temperature control will next be described.

6—CONTROL BATH

The control bath as shown in Fig. 11 is contained in a brass casing, which, when assembled, supports the calorimeter in its envelope through the axial connecting tube at the bottom. The bottom of the bath casing is a circular brass plate which is supported by three flattened tubular columns. These columns rest on a lower deck, which is a part of the outer casing which holds the lagging. This lower deck is borne on a main support of three columns, which thus carry the main calorimetric unit.

The somewhat involved construction of these enclosures was made necessary in order to provide in advance for an assembly or dismantling without unnecessary disarrangement of delicate or remote parts. This precaution has proved a great advantage, when, in operation, either failure of a part or need for change or readjustment have necessitated access to more or less remote points inside.

A mineral oil of suitable viscosity and flash point is circulated in the bath by the path indicated in Fig. 11. A centrifugal pump drives the oil about this circuit. Each of four electric-heater units supplies energy for some specific purpose. The one for principal heat supply furnishes most of the heat which escapes to the outside, and part of that which is used to raise the temperature of the bath. This so-called "main heater" is located on the outer wall of the bath casing. It is made of nichrome wire, 0.8 mm. in diameter, wound first in helical form, then flattened to a ribbon-like coil. After the outer wall of the bath casing had been covered with a thin layer of alundum cement baked hard, this heating element was wound on, and another coat of alundum cement applied to hold it in place. The two windings have a resistance of 10 ohms each and can be used either singly, in series, or in parallel. This heater will of course not produce a quick response in the bath to a change in current. To provide for quick response an "auxiliary heater" is installed in the upper portion of the oil space above the envelope shell. This auxiliary heater is a copper-sheathed, clay-insulated unit similar in principle to the calorimeter heater but proportioned and shaped for this place. Its resistance is about 10 ohms.

To provide for automatic regulation of the bath temperature a third or "regulating heater" of 10 ohms, similar in construction to the one just described, was installed in the oil return flow just ahead of the pump intake. The current in this heater is automatically varied to maintain constant temperature in the bath by the thermoregulator, which will soon be more fully described.

A fourth heater, called the "central heater," is an auxiliary heater attached to the fitting on the central tube at *CH*, Fig. 11. This enables the operator to keep the upper end of the central supporting tube of the calorimeter at a higher temperature than the calorimeter so as to avoid condensation. The central heater is of the clay-insulated, copper-sheathed type wound spirally on a core of copper to which it is hard-soldered. This core is clamped to the fitting which it is desired to heat.

A refrigerating coil is installed in the bath to permit operation at temperatures down to 0 deg. cent. This consists of a tube as shown at *RC*, Fig. 11, and may be used to carry carbon dioxide, cooled by throttling from high pressure. By connecting the refrigerating coil to the water supply it can be used to cool the system after experiments at high temperature.

The thermoregulator is actuated by an oil dilatometer in which the variation of temperature causes motion of a mercury column in a small tube, thus making or breaking an electric circuit. This impulse operates a relay which effects the change in heating current. The thermoregulator is of the selective-setting type long used in this laboratory. When heating up, a

valve is left open, permitting the escape of expanded fluid. When the desired temperature is reached the valve is closed, heating currents are readjusted, mercury contact finally set, and the temperature is then automatically held.

The dilatometer of the regulator is a long, thin-walled tube wound in helical form and installed in the oil stream where it meets the envelope shell as shown at *TD* in Fig. 11.

The insulating material used for lagging is calorox. No attempt was made to make the heat leak from the bath very small by using great bulk of lagging. It was thought more expedient to conserve space and weight by wasting a little more electric power. The outer casing is water cooled to keep it from getting too hot to the touch.

The various connections extending up more or less rigidly from the calorimeter unit emerge through easily fitting tubular

wells in the top of the control-bath casing. This permits near closure of the oil space, at the same time allowing for differential expansion of the parts. Flexible connections are brought out through tight fittings. Special wells are provided through which the resistance thermometers are inserted into their receptacles, yet to be described.

The control bath is designed to conserve space and heat capacity by utilizing the circulating oil as a medium for rapid transfer of heat rather than as a heat reservoir. It is necessary to provide for the change in volume of the oil over the temperature range used. An outlet at the top leads through a water-cooled tube to a trap with two oil reservoirs, each of three liters capacity. The supply flask is above, inverted, with spout below the overflow. The other is below to receive oil which overflows. This arrangement keeps the oil level at a definite height in the wells whether temperature is rising or falling.

7—THERMOMETRIC INSTALLATION

Temperatures at various chosen points on the calorimeter and envelope are observed by the combined use of platinum resistance thermometers and thermoelements. A heavy copper reference block located in the bath at *R*, Fig. 11, serves as the thermal union between the resistance thermometers and the reference junctions of the thermoelements. The thermometers thus measure the temperature of the reference junctions, and the thermoelements indicate the small temperature differences which exist between the reference block and the principal junctions located at the chosen points.

The three thermometers fit into copper receptacles which are hard-soldered to the reference block. Thirteen thermoelements, each having reference junctions on this same block, have principal junctions at points on the calorimeter shell and its envelope as shown in Fig. 11. Each element is made of 0.1-mm.-diameter chromel and copel wire, stranded so that two copel and three chromel wires lead to the junctions. Each element has three junctions, a principal one at the place where indication of the temperature is desired, and two reference junctions on the reference block. From these, gold wires lead to the outside. A diagram of a single thermoelement is shown in Fig. 8.

Copel-chromel elements were chosen because of their comparatively high thermoelectric power and relatively low thermal conductivity.

The reference block is especially designed to avoid temperature gradients and keep all the reference junctions and resistance thermometers at the same temperature. It is attached to the calorimeter envelope through a short tube of heavy copper-nickel. From this block a similar tube extends laterally and thence by a right turn vertically upward and out of the bath where it terminates in an airtight insulating seal, *S*, Fig. 11, for the wires, which are led out through this duct. A side connection near the top is used in the evacuation of the envelope or the filling with gas. The reference block itself is a heavy cylindrical mass of copper with circular steps inside like an amphitheater. These steps afford space for attaching the reference junctions of thermoelements. Three flat-tubular copper receptacles are attached to the block to receive the spatula-

(Five times actual size.)

like ends of the resistance thermometers which are inserted from above. This well-conducting copper mass forms a thermal union between the thermometers and the thermoelements in which only extremely small temperature gradients can persist.

However, if left entirely unprotected from the direct influence of the oil stream whose temperature is controlled by the automatic thermoregulator, this block would experience sensible fluctuations of temperature from the controlled mean, which would interfere with precise observations. In order to damp out these fluctuations there is provided a mantle in the form of a figure of revolution fitting the cylinder and the envelope shell at *M*, Fig. 11. It moves vertically in guides so that it can be placed as shown, or raised to a higher level. When in the upper position the oil passes within the mantle and bathes the reference block directly. This is the proper position when the mean temperature of the bath is being changed. When steady temperatures are to be observed the mantle is lowered, thus keeping the reference block more remote thermally from the circulating oil and obliterating the periodic fluctuations, at the same time allowing the block to follow the mean temperature of the oil.

For insulating and supporting the thermoelements within the

envelope, where this cannot be accomplished merely by spacing the bare wires, mica is used. All the junctions are insulated with mica except for the principal junctions of Nos. 9 and 10, which are soldered directly to the central tube, and No. 12 which is assembled without insulation for test purposes. By making suitable connections outside, the thermoelements can be used either as individuals for survey of temperature distribution, or in groups to indicate average surface-temperature difference for heat-leak control. The group of five on the calorimeter can be used in series to refer the calorimeter temperature to the resistance thermometers.

The 28 gold wires leading out from the reference junctions in the reference block are carried through a multicellular duct built up of mica strips in which each wire has its own passageway. The wires which lead downward from the reference block to the principal junctions are guided and supported by threading through appropriate thin strips of mica. The method of attaching junctions to the metal parts so as to insure electric insulation and provide at the same time good thermal union is shown in Fig. 9. The gold terminal to which are hard-soldered the two wires forming the junction is clamped firmly between mica washers to the metal surface under a nut threaded to a stud. By the same device connections are made between the gold wires and the reference junctions, simply leaving out any mica washer from between the gold terminals. Thermal "tie-downs" of the gold wires are made in the reference block to intercept lead conduction which otherwise might reach the reference junctions and vitiate their indications. Each wire is twice tied down before connecting with its reference junction, thus reducing the effect of lead conduction from a possible error of nearly a degree, in an extreme case, to about one ten-thousandth of this amount. A total of 80 tie-downs find place within the reference block, and a total length of about 6 meters of bare wires, coiled in helical spirals, is accommodated in the 32 cu. cm. of space within this block, requiring considerable care in stowage to keep them all clear of each other. After assembly the whole system of insulated thermoelements showed an insulation resistance of several megohms to the calorimeter unit at 500 volts.

The thermoelements are made up of fine stranded wires so that they will have appropriate resistance and still be sufficiently flexible to be manipulated into suitable shapes for stowage. The total series resistance of the group consisting of elements Nos. 1 to 5, inclusive, is about 100 ohms. This resistance gives critical damping with the potentiometer and galvanometer used for observing. The resistances of the other combinations used are made up to similar total values by series resistance coils on the instrument board.

The copper ring *TA*, Fig. 11, furnishes an isothermal anchorage for the junctions between the gold lead-out wires and the copper wires which lead over to the instrument board. These circuits are entirely of copper to avoid parasitic thermal e.m.f.'s. Two special switches each of copper were built to permit the individual thermoelements to be quickly connected to the potentiometer in the desired combinations. One of these is a double-pole twelve-throw dial switch, and the other a quick double-throw six-pole knife switch. Where soldered joints were made, special care was taken to insure against thermal gradients in the joints. Every precaution was taken to reduce parasitic thermal e.m.f.'s in the measuring circuits to a negligible amount.

Four platinum resistance thermometers, specially constructed for this purpose, were used as working standards for the temperature measurements. These are of the four-lead potential-terminal type. They are made small and compact to fit the receptacles described above. The platinum windings are of 0.05 mm. diameter, wound seven turns to the millimeter on a flat plate of mica, notched at the edges to receive the wire. The windings occupy a length of about 10 mm. The thermometers are encased in platinum sheaths 0.5 mm. in outside thickness, 5 mm. wide, and 60 mm. long. These sheaths are hard-soldered to tubes of copper-nickel 3.2 mm. in diameter, through which the gold lead wires threaded through mica strips are led out to the seals at the top where copper wires are joined on.

The platinum windings were annealed by flashing, using an electric current of short duration sufficient to heat the wires to redness momentarily.

The thermometric reference block is closed at the top by a flexible annular diaphragm of silver to allow freedom for differential expansion between the outer envelope and the suspended calorimeter shell with its supporting tubes. The top of the block is terminated by a monel ring hard-soldered to the copper, having a blunt-edged flange upon which the silver diaphragm is clamped by the threaded nut bearing against a washer. At the inner edge the diaphragm is similarly clamped to the fitting which joins the supporting tube below and connects with the distributing tube above, through a union.

8—Throttle and Reheat Tube

This device has not been used up to the present time, but as it was installed in the calorimeter from the first assembly and had some influence on the design, although left inoperative, it will be briefly described. The extension of the silver-palladium outflow tube within the calorimeter is threaded in the lower portion of its length with a pitch of 80 threads to the inch. A plug of silver-gold alloy is fitted to this thread so that it can be placed anywhere in the threaded part. A coil consisting of 170 cm. of silver tube is connected at two points of the outflow tube. By placing the plug between these points, vapor flowing out of the calorimeter is first reduced in pressure and temperature as it leaks by the plug threads, and then flows through the coil where it is reheated by absorbing heat from the saturated vapor which surrounds the tube. This is the arrangement provided for a fourth type of experiment in which the heat content of superheated vapor would be determined.

As the calorimeter was used in the first three types of experiments the throttling plug was left out entirely, leaving free passage for vapor up the outflow tube.

IV—ACCESSORY APPARATUS

1—Flow Lines and Control Valves

The flow lines provide connections between the calorimeter and the outside receivers, and are used to conduct the flow in the transfer of fluid to or from the calorimeter. The lines at the bottom provide for the introduction and withdrawal of liquid, while those at the top are used in the withdrawal of vapor. Fig. 2 shows diagrammatically the various paths along which liquid and vapor can be conducted, and the relative positions of the control valves.

The valves used in the flow lines are all of the diaphragm type, which permits motion for operation without the use of packing, and will be described later. Part of these can be operated as shut-off valves, and two as throttles for reducing pressure and controlling rate of flow.

All flow lines are of silver or silver-palladium tubing. Those which are at the pressure existing inside the calorimeter are of silver-palladium, except one small silver tube at the bottom. This bottom tube emerges from the side of the lower supporting tube, in the lagging space, and leads downward near the stuffing box to the outside as shown at *WL* in Fig. 11. It serves for introduction or removal of liquid, and is the only connection to

the calorimeter which has to be broken for dismantling the control bath. The silver-palladium exit tube at the top of the calorimeter has two horizontal branches, one leading to a throttle valve and one to a pressure-transmitting device or pressure capsule, which will be described later. From the throttle valve a silver-palladium manifold tube leads to three shut-off valves located in the control bath. From each of these a comparatively large silver tube leads out through the top of the control bath and the lagging to a silver tempering coil which is provided with means for evacuation, through a diaphragm valve. The liquid line at the bottom leads through a diaphragm valve which serves either as a liquid throttle or shut-off, to a similar tempering coil. All four tempering coils terminate in unions which fit the threaded portions of the valves on the containers for the water. All four vacuum valves lead to a common vacuum line, which is provided with a metal trap in which water remaining in the connecting lines can be caught and weighed.

The diaphragm valves already spoken of were designed to eliminate the use of packing. One of these will be described to illustrate this feature. In the section shown at *VV* in Fig. 11 it may be seen that the action which opens and closes the valve is the vertical motion of a stem relative to a seat. The face of the stem is a soft silver disk, and the seat in this type is a rather blunt but finely machined edge of silver-palladium alloy. Longitudinal motion of the stem is permitted by an annular silver diaphragm of 0.2 mm. thickness, clamped to seal tightly near the outer and inner edges. Rotation of the stem is thus prevented. The portion of the stem outside the diaphragm is a cylinder fitting freely in a recess in the valve bonnet, so that the stem moves perpendicularly to the plane of the seat. Excessive flexure of the diaphragm is prevented by the metal support behind it, and by limiting the travel of the stem. In this type of valve used on the containers and in the vacuum lines the motion is imparted to the stem by a differential thread arrangement. The differential screw has a square end which can be turned by a detachable key.

Each of the three shut-off valves in the bath, one of which is shown at *V*, is of this same diaphragm type, but the motion is imparted to the stem in a different manner. These valves have to be opened and closed as nearly instantaneously as possible, and no intermediate positions in the motion are required. Therefore, instead of the differentially threaded stem, an entirely different mechanism was designed to accomplish this purpose. Their stems are attached to vertical struts, leading outside the control bath to a spring and lever system shown at *VM*. By means of the adjusting screws illustrated, the mechanism can be set so that any desired force of the stem on the seat will be furnished by deformation of the spring lever *SL*.

It is evident from the diagram that by a single motion of the operating lever *OL* the valve can be completely opened or closed. The provision by which these operations are automatically carried out at a signal from the standard clock will presently be described.

The shut-off valve in the liquid line was changed during the liquid-withdrawal experiments from the type shown at *WV* to a type similar to the vapor shut-off valves in the control bath. Provision was made for the remote control of a slow-motion screw which actuated the handle of the mechanism. The opening of the valve could thus be controlled to regulate the rate of withdrawal of liquid.

The vapor throttle valve is similar to the shut-off valves, but because of the fineness of operation demanded of it, certain changes were necessary. The seat is made flat with a 0.5-mm. aperture, and the silver disk on the stem is made slightly conical where it engages the seat. The operating mechanism outside the oil bath was changed to the form shown in Fig. 11 and was provided with a slow-motion screw to operate the valve handle. This slow-motion screw is operated from the instrument table by a positive mechanical control. The spring lever was replaced by a heavier brass one which acts as a rigid member. All joints are made as free from backlash as possible, and the spring *K* is provided to take up the residual slack. For some of the latent-heat experiments at high pressures, a set of 8 silver-palladium disks, each 0.1 mm. in thickness and with 0.5-mm. holes in the centers, was introduced between the valve stem and the seat to provide more paths for vapor and thus cut down the sensitivity of the valve to motions imparted to it by the observer.

Considerable difficulty was experienced in the evolution of the throttle valves. The two described proved to be the most satisfactory of several which were tried.

2—Containers for Water

The containers for the water, as shown at *WR* in Fig. 11, are made of 1.6-mm. silver in cylindrical form with hemispherical ends. Their capacity is about 425 cu. cm. Those for use in transferring liquid are provided with reentrant silver tubes reaching nearly to the bottom. Each container is provided with an outlet tube of silver bent as indicated in the figure and leading to a diaphragm valve. The body of this diaphragm valve terminates in the male half of a union, threaded to fit any of the unions on the tempering coils. The weight of each container and its valve is about 1000 grams.

3—Pump-Speed Control

The speed of the circulating pump in the calorimeter is accurately controlled to make the rate at which it supplies energy to the water definite and reproducible.

The long external drive shaft for this pump has squared ends which couple the pump positively to a liquid tachometer rotating at the same speed as the pump. The tachometer, of the well-known Veeder type, is driven by a motor which draws its power from a 50-volt storage battery. The impeller maintains a column of kerosene at a height which is determined by the speed. A column of mercury, in a side tube off the kerosene column, is maintained at a level which also varies with the speed. In a manner similar to that of the thermostat, this mercury column, by its motion, serves to make and break an electric circuit. As a result, more or less resistance is placed in the armature circuit of the driving motor, in the direction required to maintain a constant head of mercury. The kerosene column furnishes a sensitive means for the direct observation of the pump speed, which latter is maintained practically constant by the automatic control.

To check the constancy of the pump rate, a revolution counter was geared directly to the pump shaft. Observations with this counter at infrequent intervals showed that the pump rate is maintained constant at any desired value to about 0.1 per cent.

4—Timing Devices

In the α and β experiments the time of electric heating, and in the γ experiments the time of withdrawal of vapor, must be observed. For the first of these there was constructed a double-pole double-throw switch operated by a spring and a release which is actuated by an electric impulse from the standard clock. This automatic switch not only opens or closes within less than a tenth of a second, but also requires the same time interval for action in either direction. In operation it was used to switch the connection from a 30-volt storage battery to either the calorimeter heater or to a spill coil having nearly the same resistance.

To provide for timing the flow in the γ experiments, the

actuating mechanisms of the three previously described shut-off valves are equipped with pulley wheels rigidly attached to the operating levers and rotating about the same axes as these levers. Cords firmly attached to the wheels can be led in either direction around the wheels and thence up to a spring. The spring is permitted to operate by the release of a catch at a signal from the standard clock. The spring thus furnishes the power for opening or closing the valves at a chosen time, either individually or in any desired combination. The time required for complete opening or closing of a valve is less than 0.1 sec.

Signals from the standard clock are received only on the exact seconds, the 59th being omitted. The key in the clock circuit is closed by the operator during the 59th second so that the zero signal is used either for starting and stopping the power or for diverting the vapor flow. The integral number of minutes involved in an observed process is observed on a watch.

5—Pressure-Measuring Instruments

Provision was made for observing pressure, and although no measurements are included in this report, the installation will be described. A side tube from the outflow tube just after it emerges from the vacuum space leads to a pressure capsule *PC*, Fig. 11, which is also in the oil bath to avoid condensation. The pressure capsule is made of monel metal with a 4-cm.-diameter sheet-monel diaphragm, *D*, 0.08 mm. thick, stretched across the capsule. This diaphragm transmits the pressure from the vapor on one side to oil on the other. The diaphragm is allowed a displacement at the center of only 0.25 mm. from the mean position before coming against the solid supporting walls of the capsule. When the highest working pressure is applied, no permanent deformation of the diaphragm will result. The diaphragm, however, is sufficiently flexible for a very small pressure change to deflect it across the chamber. A measurement of the opposing pressure when the diaphragm is balanced midway in the capsule will then give the pressure of the vapor. All the monel surfaces on the vapor side are silver plated to prevent chemical action of the hot vapor with the metal. A 0.2-mm. gold-wire ring was used to make the diaphragm gas-tight in the capsule. Monel screws were used in addition to the monel case and diaphragm so that there would be no differential expansion of the parts, which would cause leaks or change in tension of the diaphragm. Oil is used to transmit the pressure from the diaphragm in the capsule to a gage of the deadweight type with piston rotating in oil.

6—Electrical Measuring Instruments

The electrical measurements comprise observations of thermometer resistance, thermoelectromotive force, and electric power input.

The resistances of the thermometers are measured with a Mueller[9] bridge built by O. Wolff. The bridge coils are immersed in a thermostatted oil bath. A separate commutator switch permits the observation of any chosen one of four thermometers. The bridge coils were recalibrated whenever it was found desirable by the method outlined by Mueller. A measuring current of 4.5 milliamperes was used both in the calibration and in the measurements of temperature. A galvanometer-scale deflection of 1 mm. corresponds to approximately 0.0001 ohm, or about 0.001 deg. cent. for the thermometers used.

The electromotive forces of the thermoelements, amounting in nearly all cases to less than 20 microvolts, are measured on a Wolff potentiometer designed by F. Wenner. By comparison with another instrument which had been calibrated at the Bureau of Standards, the corrections to the indications of this instrument were found to be negligible in the range in which it is used. When the temperature of the calorimeter is being observed, a scale deflection of 1 mm. corresponds to 0.002 deg. cent. or less.

The power input is measured on a Diesselhorst potentiometer built by O. Wolff. It was calibrated at the Bureau of Standards before, during, and after the experimental work, and showed no changes of more than 1 part in 30,000. The scale deflection was greater than 2 mm. per division on the last dial in the measurements on current and potential drop.

The standard cells to which the potentiometric measurements are referred are Eppley unsaturated cadmium cells. They are kept in a cork-lined box and calibrated frequently against the standards maintained at this Bureau. Two of these cells are used with the potentiometer for power measurement to guard against fortuitous changes in voltage between calibrations. Their electromotive forces, as measured and used in this work, are expressed in international volts. This international volt is defined at $^1/_{1.0183}$ of the voltage of the normal Weston cell at 20 deg. cent.

The volt-box ratio and the resistance of the 0.01-ohm manganin standard used in the measurements were verified at this Bureau before, during, and after the experiments, and showed no changes of more than 1 part in 30,000.

7—Weighing Instrument

The balance used in the weighings is a two-kilogram Troemner balance with a sensitivity of one scale division per milligram. Provision was made for suspending the counterpoise and the containers for water in a closed cabinet below the balance pans. All weighings are made by the method of substitution. The weights are of brass, platinum plated, and calibrated at this Bureau. Correction is made for buoyancy of the air on the weights. In this method of weighing, no correction for the air buoyancy on the water sample is necessary. Changes in buoyancy are compensated for by making the volume of the counterpoise approximately the same as the volume of a container. The weighings are made to the nearest milligram.

8—Thermometric Standards

All temperatures used in this work are measured on the international Centigrade scale of 1927,[10] which is defined, in the interval 0 to 660 deg. cent., by assigning the temperatures 0, 100, and 444.60 deg. cent. to the ice point, steam point, and sulphur boiling point, respectively, all at the pressure of one standard atmosphere (760 mm. of mercury); and establishes other points by means of a standard resistance thermometer of pure platinum, making use of a formula of the form:

$$R_\theta = R_0(1 + A\theta + B\theta^2)$$

in which θ is temperature, R_0 the resistance at the ice point, and A and B are constants found by calibration at the steam point and the sulphur boiling point.

Before starting the calorimetric measurements the resistance thermometers were calibrated directly at the ice, steam, and sulphur points as outlined above. Later on in the work it was found expedient to calibrate the thermometers by comparison with a laboratory standard. A standard resistance thermometer of the strain-free type was inserted into a special copper receptacle which is in good thermal contact with the copper reference block in the control bath. This strain-free thermometer is calibrated at the ice, steam, and sulphur points directly, and the constants of the calorimetric spade-type thermometers are determined by direct comparison in position in the control bath. In this way it was possible by holding the bath at a constant temperature to

[9] Mueller, Bureau of Standards Scientific Paper No. 288.

[10] Burgess, *B. S. Jl. of Research*, Research Paper No. 22, p. 635, Oct., 1928.

make very accurate comparisons between the strain-free thermometer and the calorimetric thermometers. However, the strain-free thermometer was not so well adapted for indicating the temperature of the upper reference block during the calorimetric experiments, and for this reason the calorimetric thermometers were used in the actual experiments.

The thermoelements used in measuring the calorimeter temperature were calibrated in place against the resistance thermometers. The accuracy of this calibration is of little importance because of the extremely small values of the observed thermoelectromotive forces.

9—Purification of Water

Dissolved gases are removed from the water samples used in the experiments. In a specially designed still, ordinary distilled water is subjected to another distillation under a pressure of about 0.1 atmosphere. During this redistillation, a pump is continually removing the permanent gases, together with some water vapor from the condenser, at such a rate that there is little opportunity for the permanent gases to redissolve in the condensate. In special test experiments the amount of residual gas remaining in the condensate was found to be less than $^1/_{1000}$ of the amount usually contained in distilled water. After a water sample is thus freed from dissolved gases it is not allowed to come into contact with air again either before or during its use in the experiments, but is always kept and transferred under its own vapor pressure.

V—DESCRIPTION OF MEASUREMENTS

The keynote in the description of the experiments is that an accurate account must be kept of each of three primary observed quantities, namely, the amount of fluid subjected to the process, the change in state, and the amount of energy exchanged. The energy account consists primarily of that which is added and measured electrically, but includes also the energy added by the pump and the energy exchanged by thermal leakage. In the following discussion the method employed for the evaluation of all these factors will be described.

1—Accounting for Mass of Water

The mass of water which is subjected to a change in state enters as a direct factor in the reduction of the data. The results, therefore, can be no more reliable than the determinations of the masses. In addition, a quantitative account of the aggregate mass of the water involved in any set of experiments throws important light upon the reliability of the data derived from the experiments. Equality of the amount put in to the total removed indicates that there has been no gain or loss of fluid through leaks, and that there have been no accidental errors in the determination or recording of weights. In this work such a mass accounting has been carefully kept, and important revelations have resulted from it. From time to time water leaks from the calorimeter and air or oil leaks into the calorimeter have been indicated, located, and eliminated. When the mass accounts balance properly, the results assume an added degree of certainty.

The procedure employed in filling the calorimeter and in removing that water which remained after the completion of a series of experiments is the same for the α, β, and γ experiments. It will therefore be described here once for all.

A container having a reentrant tube is evacuated and filled with a charge of water from the still. The valve on the container is heated to a little above 100 deg. cent. to drive off external moisture, and the whole is cooled in a current of air, from a fan, to the temperature of the room. This treatment was found to bring the containers to a reproducible condition for weighing, and will be spoken of hereafter as "conditioning."

The container and its charge of water are first weighed and then attached to the tempering coil at the bottom of the calorimeter. The calorimeter and coil are then evacuated through the vacuum valve, until a McLeod gage in the system indicates a pressure of less than 0.001 mm. The system is then considered tight and sufficiently gas free.

The vacuum valve is then closed and the container valve opened. The water in the container is forced into the calorimeter by its own vapor pressure when heat is applied with a gas torch. Usually the entire charge is introduced, but the flow can be stopped after any chosen part has gone in if the container is suspended during the filling from one arm of a crude balance.

When the desired mass of liquid has flowed into the calorimeter, the lower calorimeter shut-off valve is closed, the tempering coil is surrounded with boiling water, and the container is immersed in cold running water. Virtually all the water remaining in the lines is thus distilled back into the container. After a few minutes the container valve is closed and the coil is again evacuated, this time through the liquid air trap which has previously been evacuated and weighed. The vacuum valves and the valves on the trap are closed and the container and trap are detached, conditioned, and weighed. The change in weight of the container minus the weight of the water caught in the trap (always less than 1 milligram, and therefore negligible when the operations are properly carried out) gives the mass of the water in the calorimeter system.

After a set of experiments in which part of the water sample may or may not have been removed, the water remaining in the calorimeter is withdrawn into the container. This process is hastened by having the calorimeter and tempering coil hot and the container cool. When as much liquid as will flow out has been collected in the container, its valve is closed and that which remains in the calorimeter is collected in the liquid air trap. The masses thus removed are weighed as described above.

In the constant-mass or α experiments the mass weighed in is equal to the mass removed if the operations have been properly performed. In the withdrawal or β and γ experiments the masses of water removed as saturated liquid or vapor must be included in the mass accounting.

2—Heat-Capacity Determinations

The measurements of the first type which determine the change in value of the quantity $H - L\frac{u}{u' - u_,}$ denoted by the symbol α, were, with a few exceptions, taken in ten-degree intervals. The whole range from 0 deg. cent. to 270 deg. cent. was divided into three sections, 0 to 100, 100 to 200, and 200 to 270, each of which could generally be covered in a single day's work. Starting at the lowest temperature of one of the sections, 0 deg. cent., for instance, the initial temperature is observed. Then electric energy is added to heat the calorimeter and water approximately 10 degrees. The temperature is again observed and energy added for another period. There is thus obtained a series of observed temperatures, between which the added energy is measured. By keeping a continuous account of the energy, including heat leak and pump energy, the change in α from the initial starting point of the series to any stopping point can be determined independently of the intermediate intervals. A single series of measurements of this kind gives as a result the amount of energy, Q, added to change the temperature of the calorimeter and contents from any one to any other of the observed temperatures. A second series carried out in a similar manner over the same intervals of temperature

but with a different mass of water in the system gives as a result a second series of values of Q corresponding to these same temperature intervals. Two such series of measurements suffice to determine a series of values for the changes in α and for the changes in another quantity which is designated as Z, over the temperature intervals covered. This quantity Z, as described more fully in the paper on the analysis,[11] is a characteristic property of the calorimeter as used, and its value depends on the temperature but is independent of the total amount of water in the system. Actually, in each range of temperature several series were made in which the masses of water contained were chosen so as to give large differences in total heat capacity.

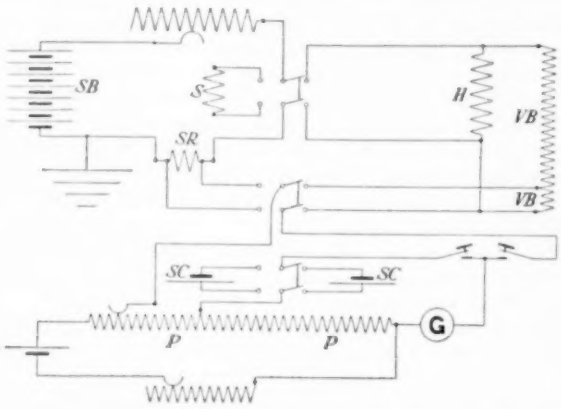

FIG. 10 WIRING DIAGRAM FOR CALORIMETER HEATING POWER AND ITS MEASUREMENT

SR, standard resistance	G, galvanometer

Reduction of the results of such a group as a whole by the method of least squares yields a series of values of α, which is a property of saturated liquid water, and a series of values of Z, which is a property of the calorimeter as it was used. The individual values of α, corresponding to each experiment, can then be calculated for purposes of comparison to show the degree of reproducibility of the measurements of α.

In all the measurements of this type a tight-fitting cap seals the calorimeter at A, Fig. 11. The water samples are introduced and removed as liquid through the connection at the bottom of the calorimeter as previously described.

The shut-off valve in the water line is outside the boundary of the calorimeter, and so a small part of the water introduced into the system is outside the calorimeter and does not enter into the thermal process observed. This fact in no way affects the result because the method of reducing the observations eliminates it as a quantity independent of the amount of filling. Only minor differences, such for instance as fortuitous changes in the temperature of the small emergent portion of the water sample, can affect the results. These effects would appear as accidental errors in a large group of measurements.

The energy imparted by the pump during an experiment is taken into account in computing the results. The pump power is determined by supplementary experiments in which no electric power is supplied and heat leak is determined, as will be described presently.

In the heat-capacity experiments it is not important that the pump power be known accurately. The method of reduction by combining results of experiments differing only in amount of water sample used eliminates the pump energy from the final result except for its variation from one experiment to another Changes in this factor would enter as accidental errors in a series. Experiment showed that no systematic difference in pump power resulted from the use of different amounts of water.

The group of measurements in the range 0 to 100 deg. cent. differed from those in the other higher ranges in several respects. In the first place, it was necessary to cool the calorimeter from the laboratory temperature down to the starting point of the series as a preliminary to the experiments. At best this preliminary cooling was a slow process. On the other hand, the pressures in this range were low and the work was freer from leakage troubles incident to pressure. The measurements from 100 deg. to 200 deg. could be made more expeditiously, but difficulties incident to the higher temperatures and pressures were greater. Above 200 deg. these difficulties increased and other obstacles to operation were encountered. These resulted in a greater percentage of failures, and necessitated occasional suspension of the observations for changes and repairs.

A determination of heat capacity in the range 0 deg. to 100 deg. will be described to illustrate the principal features of the determinations over any temperature range. The procedure is in general as follows:

A weighed sample of water is introduced into the calorimeter. To provide a medium for extracting heat from the calorimeter and expedite the cooling down to the initial temperature of the series, helium is introduced into the space between the calorimeter and its envelope to a pressure of about 10 cm. of mercury. This gas was used because of its relatively high thermal conductivity.

Carbon dioxide is used as the refrigerating medium both for cooling the bath down and for holding it at the low temperature while the calorimeter is being cooled. During this period of cooling the calorimeter the bath is held very near but not below 0 deg. cent., because freezing of the water in the lower tube must be avoided.

The automatic thermoregulator is used during this time to maintain a practically steady temperature of the bath. It operates by compensating the excess refrigeration with electric heating, automatically regulated in the manner previously described.

When the calorimeter has cooled to the desired temperature, the bath temperature is raised to the same value. The helium is then pumped out of the envelope space, leaving the residual pressure less than 0.001 mm. of mercury. The automatic thermoregulation, the pump speed, and the power supply which is to furnish heat to the calorimeter are all finally adjusted. The mantle around the reference block is lowered, and after a short wait for a steady state to be reached the preliminaries are complete and the observations are begun.

The initial temperature of the calorimeter is measured by taking simultaneous readings on the resistance thermometers and the e.m.f.'s of the five thermoelements on the calorimeter in series. Two observations on each of the three thermometers are taken for a determination of a single temperature. Readings are begun two minutes previous to the time chosen for switching on the power to the calorimeter heater, and are continued at twenty-second intervals until the six temperature observations have been made. The order used in reading the thermometers is not important, but was kept the same at the beginning and end of each experiment.

The operator increases the energy supply to the bath a little before switching on the power to the calorimeter heater, so that the envelope temperature and the calorimeter temperature will start to rise at nearly the same time and the same rate. On the chosen instant the automatic switch is thrown and the current started in the calorimeter heater. The operator, guided by indications of the differential thermoelements, keeps the power

[11] See reference in footnote 8.

supply to the bath so adjusted that the rising temperatures of the calorimeter and envelope are kept very nearly together.

At one-minute intervals the small temperature differences as indicated by the differential thermoelements are observed. The recorder observes the current and potential drop in the heater on the alternate minutes.

The heating is continued for an integral number of minutes and stopped on the zero of that minute when the temperature is nearest to 10 deg. By proper preliminary adjustment of the power supply the final temperature is brought in nearly all cases to within less than 0.1 deg. of the chosen even temperature.

Just before the end of the heating period the operator decreases the power supply to the bath so that the bath temperature will not exceed the final temperature of the calorimeter. On the chosen instant the automatic switch is thrown, and the current stopped in the calorimeter heater. As quickly as possible the bath temperature control is shifted to the thermoregulator and a few minutes are allowed for the establishment of a steady state. During this interim, readings of the differential thermoelements are continued. Within 10 seconds after the power is turned off, the calorimeter temperature has become uniform.

When the bath temperature has become steady, the temperature of the calorimeter is observed as previously described. During the interim the power now on the spill is readjusted to take care of the change in the heat capacity of the calorimeter and its contents over the next 10-deg. interval. This makes it possible to stop at very nearly 20 deg. with an integral number of minutes of heating.

The final temperature of the first interval is the initial temperature of the second interval. The experiments are continued in steps of 10 deg. as far as desired.

For temperatures of 60 deg. and above, no refrigeration is required for the satisfactory regulation of the bath temperature.

3—Latent-Heat Determinations

The measurements of the second type which determine the value of the quantity $L + Lu/(u' - u)$, denoted by the symbol γ, were carried out at certain chosen temperatures at which the values of L, the heat of vaporization, were desired.

The process of evaporating and removing saturated vapor is a flow process, and in these experiments the instrument is used as a flow calorimeter with storage for the fluid sample. The experiments are carried out strictly as flow experiments proceeding at a steady state. It was possible to perform them as successive determinations, immediately following one another without disturbance of the steady condition. Sometimes as many as eight separate measurements were made in one series during a day's work.

The procedure for the measurement of latent heat is in general as follows:

A weighed charge of water is introduced into the calorimeter. Three containers are evacuated, conditioned, weighed, and attached to the three vapor lines. The lines up to the shut-off valves are then evacuated and the vacuum valves closed.

In the following discussion the three flow lines for vapor and the corresponding shut-off valves will be designated as Nos. 1, 2, and 3. This numbering is convenient for the description of the manipulation, but has no further significance. In the preliminary operations to establish the steady state the receiver in position 1 is used, and it will be spoken of as the "spill." When in use, each of the tempering coils at the top is immersed in boiling water, and each of the receivers in cold running water.

During the preliminary heating of the calorimeter and bath, the shut-off valve and the receiver valve in the spill line are open. This prevents any leak past the throttle from causing pressure to build up on the diaphragms of the valves in the vapor lines. The calorimeter pump is running during the heating up, and its speed is adjusted to the desired value.

When the temperature chosen for operation is reached by both the calorimeter and the bath, and when the bath temperature is properly held there by the thermoregulator, the withdrawal of vapor can be begun.

The current for the calorimeter heater, previously adjusted to the value to give the desired rate of evaporation, is then turned on. The throttle is opened and gradually adjusted to the rate of flow which will maintain the calorimeter temperature constant and equal to the practically constant temperature of the envelope. The flow into the spill in line No. 1 is continued for about a half-hour while the operator completes the adjustment of the throttle to bring the calorimeter to a steady temperature. This much time at least was allowed to insure that any liquid which had lodged in the tubes could be swept out and a steady state of flow of dry saturated vapor established.

Meanwhile the automatic throw mechanism for the shut-off valves is adjusted so that No. 1 will close and No. 2 open at a chosen signal from the standard clock. The valve on the receiver in line No. 2 is opened to allow passage of vapor when shut off valve No. 2 opens.

Before starting the measurements, a survey of the temperature existing at various points in the system is made to verify the existence of the steady state.

Six temperature observations are taken at times ten, twenty, and thirty seconds before and after the transfer of the flow from line 1 to line 2. For these observations, simultaneous readings are taken of the resistance of a single thermometer and the e.m.f. of the five thermoelements on the calorimeter in series.

On the chosen minute the flow is shifted from line 1 to line 2. Observations of the temperatures of the calorimeter and reference block are made on each succeeding minute, the operator maintaining the calorimeter temperature as nearly constant as possible by adjustment of the throttle valve. Observations are made of current and potential drop in the calorimeter heater on the alternate minutes. Meanwhile determinations are made of the mass of water which has been removed, by weighing the spill and the residual water in the lines which has been caught in the liquid air trap. A weighed receiver is put in position 1 and the tempering coil evacuated. The valve mechanism is reset to be ready for the transfer of the flow from line 2 to line 3.

Water samples removed are usually about 30 grams. The time of an experiment is therefore determined by the rate at which the energy is supplied to the calorimeter. After the desired amount of water has been collected in position 2, temperatures are again measured as before.

The above-described procedure is repeated as long as time or the quantity of water in the calorimeter permits, each experiment constituting an independent determination.

4—Evaporation Factor

The α experiments yield values of the quantity $H - L\,\frac{u}{u' - u}$ and the γ experiments yield values of $L + L\,\frac{u}{u' - u}$. To determine the values of H and L from these quantities it is necessary to know the value of the quantity $L\,\frac{u}{u' - u}$, which has been designated as β.

In the analysis[12] it is shown that this correction term β may be determined calorimetrically as the amount of energy which is supplied per gram of saturated liquid withdrawn at a constant temperature.

[12] See reference to footnote 8.

MH, main heater
AH, auxiliary heater
RH, regulating heater
CH, central heater
RC, refrigerating coil
CW, cooling water

(One-quarter actual size.)

The procedure for a determination of β at a given temperature is as follows:

A weighed charge of water is introduced into the calorimeter. The temperatures of the calorimeter and the bath are brought to the value chosen for operation. The electric power on the spill is adjusted so that the proper rate of withdrawal of water will approximate a chosen value. The pump speed is adjusted and controlled as in the α and γ experiments.

A weighed container is attached to the lower tempering coil and the coil evacuated. The shut-off valve in the liquid line is now of the throttling type previously described, with arrangement for control by the operator at the instrument table.

The temperature of the calorimeter is measured as in the α experiments, and the power is similarly thrown on. As quickly as possible the operator opens the throttle for the liquid and adjusts it until the temperature of the calorimeter is constant and practically equal to the bath temperature. As in the α experiments, readings of the differential thermoelements and the power to the heater are recorded at the successive one-minute intervals. At the chosen instant for stopping the experiment the power is cut off. The throttle is closed at such a time that the final temperature of the calorimeter is nearly the same as that of the bath. If the calorimeter is a little too hot, more liquid can be withdrawn until the desired state is reached. The final temperature is then measured as before. The water withdrawn is collected and weighed in the manner already described.

No provision was made for making more than a single β experiment at a time, and therefore it was necessary to measure only the time of electric heating and not the time of flow.

5—Thermal Leakage

When a difference of temperature exists between the calorimeter and its envelope, there is an accompanying transfer of heat by radiation, conduction, and convection. For small temperature differences the amount of energy transferred per unit time is proportional to this temperature difference.

In operation it is impossible to keep the temperatures of the calorimeter and its envelope identical at all times. The existing temperature difference can, however, be kept very small, and over a period of time can be so controlled that the integrated value is almost zero. In the measurements this ideal was approached as the operator gained experience.

To properly correct for the thermal leakage in those experiments where the temperature difference did not integrate to zero, a set of experiments was performed to determine the thermal-leakage coefficient. These experiments are performed under temperature conditions which are identical, as far as is possible, with those prevailing during the α, β, and γ experiments, except that the temperature difference between the calorimeter and its envelope is purposely much greater. The total amount of energy transferred under this exaggerated temperature difference, the value of the difference, and the time over which the difference exists, are observed. No electrical energy is added to the calorimeter, and during most of the time of an experiment the pump is stopped. Thus practically all of the observed energy change is due to thermal leakage. Because the calorimeter was used both with the envelope space evacuated and filled with nitrogen, a set of heat-leak experiments under each of these conditions was necessary. These heat-leak experiments are carried out as follows:

The calorimeter is charged with about 250 grams of water and its temperature and that of the bath are brought to the temperature chosen for operation. The initial temperature is observed with the pump running, and on the next minute the pump is stopped. The temperature of the bath is then raised or lowered until the envelope is either hotter or colder than the calorimeter by an amount corresponding to about 100 microvolts ($^2/_3$ deg.) on the differential or regulating thermoelements. At one-minute intervals readings of this indication are recorded in microvolts over a period of from 30 minutes to one hour. At the end of this time the bath temperature is brought back to that of the calorimeter, and on an integral minute the pump is started to insure uniformity of temperature throughout the calorimeter. The final temperature is then observed as before.

The pump is stopped during most of the time of the experiment, so that the uncertainty in the determination of the energy supplied by the pump does not enter into the determination of the thermal-leakage rate. Small corrections are made for the energy supplied by the pump during the short intervals at the beginning and end of the experiment.

The data obtained in such an experiment, when combined with the previously determined heat capacity of the calorimeter and its contents, yield the amount of heat transferred per microvolt-minute at the temperature of the experiment. In accordance with Newton's law of cooling, this coefficient or thermal-leakage rate can be used as a factor which, when multiplied by the resultant number of microvolt-minutes for any experiment at that temperature, gives directly the net heat exchange due to heat leak. At the higher temperatures where a small difference in temperature corresponds to a much larger difference in vapor pressure, the bath was kept colder than the calorimeter in the heat-leak experiments. This insured against the direct transfer of heat from the bath to the calorimeter by active boiling in the lower support tube.

The heat-leak experiments, on account of the method in which they are performed, furnish an opportunity for the direct calibration of the thermoelements against the resistance thermometers. If the bath temperature is measured both before and after it is changed, simultaneous indications of the five thermoelements on the calorimeter in series can be interpreted directly in terms of the thermometers, since the change in the calorimeter temperature in the short interval of time involved is small. Only the five series thermoelements were so calibrated, because the indications of the others need not be expressed in degrees.

6—Pump Energy

The energy supplied to the calorimeter by the pump appears as a correction which must be applied to obtain the total energy added in the α, β, and γ experiments. As previously shown, the knowledge of the true value of this pump energy is not of vital importance in the determinations of α, but it appears directly in the evaluation of β and γ, and must therefore be carefully determined.

The pump-energy determinations are carried out as follows:

The calorimeter, containing a known mass of water, is brought, along with the bath, to the temperature chosen for the observation. The pump speed is regulated to the desired value. The initial temperature of the calorimeter is measured at a chosen time. At one-minute intervals the indications of the differential thermoelements are recorded. The bath temperature is raised from time to time to reduce the integrated value of the temperature difference between calorimeter and envelope to virtually zero. After a period varying from 30 minutes to one hour the final temperature of the calorimeter is observed.

The data obtained from such an experiment, together with the previously determined heat capacity of the calorimeter and its contents, yield directly the rate at which energy is supplied to the calorimeter by the pump.

Similar experiments carried out with different quantities of water in the calorimeter showed no systematic variation in the pump-energy rate with the mass of the water.

Experiments were performed with the pump running at various speeds, but throughout most of the work the speed employed was about 900 r.p.m.

VI—RESULTS OF MEASUREMENTS

1—Alpha Experiments

In the following record of results of measurements, the experimental data have been assembled in the form of tables. An example of the record of a single determination of heat capacity of the calorimeter and its charge of water, over a ten-degree interval, is given in Table 1. The total time of experiment,

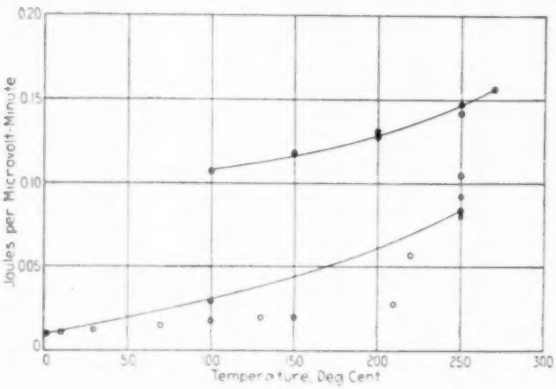

Fig. 12 Heat-Leak Coefficient

(Lower curve with space evacuated; upper curve with nitrogen in space.)

over which the heat-leak correction and the pump energy correction are applied, is the interval between the middle instants of the initial and final periods of temperature readings. The total heat-leak factor for this interval is the sum of the heat-leak indications at one-minute periods during this time. This factor in microvolt-minutes multiplied by the heat-leak coefficient in joules per microvolt-minute gives the heat-leak correction in joules. Numerous determinations of the heat-leak coefficient were made and the values observed have been assembled in the form of a chart, Fig. 12.

The correction for pump energy is computed as the product of the total time of the experiment by the pump power. The values of the pump power taken were those determined from time to time in the special blank experiments for obtaining this quantity. Nearly 200 pump-energy determinations were made throughout the experimental work, and the values observed have been assembled in the form of a chart, Fig. 13. In computing the results of the work on heat capacity the values for pump power have been modified at various times in the light of additional determinations. It has not been necessary to revise the earlier calculations on the basis of a uniform value for pump power, because this factor has so little effect on the final result.

A partial reduction of the observations is given in Table 2. This includes the computation of the initial and final tempera-

[a] Time determined with a sidereal chromometer and must be multiplied by 0.99735 to obtain mean solar seconds.

tures of the calorimeter, and the computation of the electric energy added. The indication of each of the three platinum resistance thermometers is computed separately. The mean of the three is then taken as the temperature of the reference block. The mean of the six readings of the five series thermo-elements on the calorimeter, reduced to degrees, gives the difference in temperature between the reference block and the calorimeter. The observed temperature of the reference block minus this difference, equals the calorimeter temperature at the middle instant of the series of temperature observations.

The computation of temperature from the observed resistance of the platinum thermometers is made by use of the Callendar formula:

$$\theta = 100(R_\theta - R_0)/(R_{100} - R_0) + 0.01\,\theta\,(0.01\,\theta - 1)\delta$$

The constants, R_0, $R_{100} - R_0$, and δ are determined, as previously described, by calibration either directly or indirectly, using ice, steam, and boiling sulphur as fixed points.

In computing the electric energy, corrections are applied for potentiometer calibration, standard 0.01-ohm resistance, volt-box ratio, and for the fraction of the total measured current which is carried by the volt box as a shunt across the heater. These corrections are added to the mean values of the potentiometer readings for current and voltage. The product of the corrected mean values of current and voltage, multiplied by the number of seconds of electric heating, gives the total energy added electrically. An approximation is involved in taking the means of the readings before taking the products, but in all these experiments the power was so nearly constant that even in the extreme case this is less than 1 part in 100,000, and therefore negligible.

The principal data from the entire group of experiments of this type are given in Table 3. These experiments are arranged in groups, each of which includes all those covering a certain temperature interval. The masses given are corrected to the nearest milligram for error in the weights. These masses are the amounts of water introduced into the system, including the portion filling the water line out to the shut-off valve. The initial and final temperatures and total electric energy are computed as described above.

The entire energy added, Q, is the sum of the total electric energy, pump energy, and heat leak. This entire energy actually added is adjusted to the value it would have had for the even temperature interval which was approximated, giving the values of $Q]_1^2$. The calculation of α_m, the mean value of α for an entire group of experiments, follows next. This is a least-square calculation using the formula:

$$Q]_1^2 = [M\alpha + Z]_1^2$$

This reduction, using the entire group of values of M and $Q]_1^2$ for a single temperature interval, yields the mean value α_m, and $Z]_1^2$. Using this value of $Z]_1^2$, which is a constant for the calorimeter as used, the individual values of $\alpha]_1^2$ for each experiment are next computed, and compared with the mean for the group.

In the last section of Table 3 the principal data are assembled from those α experiments which were carried out in intervals of more than 10 deg. cent. A considerable number of these, particularly between 0 deg. and 100 deg., were made in 100-deg. non-stop experiments which serve as control experiments, adding greater certainty to the values at 100 deg. and 200 deg. cent. than the experiments in shorter instalments alone give.

In order best to utilize the whole aggregate of α experiments, the results are assembled in Table 4 for the purpose of computing the values of the change in α from 0 to 100, from 100 to 200, and from 200 to 270 from the entire series of energy measurements. With very few exceptions the energy account for each of these three large intervals was kept continuously, the stops at the intermediate 10-deg. points for observing temperatures being made for the purpose of independently establishing these intermediate values of α, but without interruption of the heat-leak and pump-energy control.

The independent determinations of $\alpha]_0^{100}$, $\alpha]_{100}^{200}$, and $\alpha]_{200}^{270}$ are computed in Table 4 after summing up the total energy added in each entire experiment. The calculations for α_m and Z are made for these groups of data by least-square reduc-

Even temperature interval 200–270°. $Z]_{200}^{270}$ = 85,122.5 int. joules. Mean value of $\alpha]_{200}^{270} = \alpha_m$ = 289.077 int. joules per gram

[a] Calculated from experiment 192.

tion, in the same manner as for the 10-deg. groups in Table 3. The value for each individual experiment is then calculated and the deviations from the mean found.

The next step in Table 5 in the reduction is the adjustment of the 10-deg. values of α, taking into account the results of the last calculation of the change in α between the temperatures of 0, 100, 200, and 270 deg. cent. This adjustment consists in distributing the discrepancy between the 10-deg. steps and the 100- or 70-deg. steps proportionately so as to make the adjusted values of the 10-deg. steps add up to the same value as the overall. Having so adjusted the intermediate values, they are next summed up, giving as the result of this entire group of α experiments the table of values of $H - L\frac{u}{u' - u}$ at each multiple of ten degrees reckoned from 0 deg. cent.

No adjustment for smoothing the trend of values has, up to this point, been introduced into the reduction. This will be undertaken under the head of "Formulation," to be described later.

2—Gamma Experiments

An example of the record of a single determination of γ, equal to $L\frac{u'}{u' - u}$, is given in Table 6. The total time of the experiment in this case is the time between the automatic shifting of the flow of vapor from the spill to the receiver and the shifting to the next receiver, and applies to the electric heating, the pump energy, and the heat leak. The temperature readings are so distributed as to give the initial and final temperatures at these instants of starting and stopping the experiment. The readings of the thermometer with leads in the n position and of the thermoelements 1–5 were taken at one-minute intervals during the experiment. These readings serve to determine the variation of temperature of the calorimeter during the experiment.

A reduction, showing the calculation of γ, is given in Table 7. This reduction makes use of the formula:

$$\gamma_1 = \frac{1}{\Delta M}(Q_E + Q_P + Q_L - [Z + M_2\alpha]_1^2) + \frac{\Delta H'}{\Delta\theta}(\theta_1 - \theta_m)$$

in which Q_E, Q_P, and Q_L denote the amounts of energy added electrically by the pump and by heat leak, respectively. The term $[Z + M_2\alpha]_1^2$ expresses the energy correction for the difference of the final temperature of the calorimeter and its contents from the initial. The last term expresses the energy correction

TABLE 5 ADJUSTMENT OF VALUES OF $\left[H - L\frac{u}{u' - u}\right]$ AND ASSEMBLY OF FINAL VALUES RECKONED FROM 0 DEG. CENT.

Even temperature 270°. Z_{270} = 1328 int. joules per deg. cent. α_{270} = 4.100 int. joules per gram deg. cent. Mean value of $\gamma_{270} = \gamma_m$ = 1665.21 int. joules per gram

for variation in the temperature of steam withdrawn. This correction was found to be in every case less than 0.00001 of the whole, and has been omitted from the final calculation of γ.

The principal data from the gamma experiments are assembled in Table 8 and the computation of γ completed for the entire series.

3—Beta Experiments

An example of the record of a single determination of β, equal to $L\frac{u}{u'-u}$, is given in Table 9. This is similar to the record for a gamma experiment, but differs from it in that the total time of the experiment over which the energy account is kept is longer than the time of electric heating and removal of liquid.

Table 10 shows the calculation of β. This calculation makes use of the following formula:

$$\beta_1 = \frac{1}{\Delta M}(Q_R + Q_P + Q_L - [Z + M_2\alpha]_1^2) + \frac{\Delta H}{\Delta\theta}(\theta_1 - \theta_m)$$

The principal data from the β experiments are assembled in Table 11 and the computation of β completed for the entire series.

VII—FORMULATION

1—Formulation of Calorimetric Data

In what has gone before we have the record of the experiments and reduction of the data yielding the values of the three characteristic properties of the fluid, namely:

$$H - L\frac{u}{u'-u}, \qquad L\frac{u'}{u'-u}, \qquad \text{and } L\frac{u}{u'-u}$$

denoted by the symbols α, γ, and β, respectively. As a first step in the formulation of the more familiar and more useful thermal properties of steam for engineering purposes, the experimental results are assembled, the values smoothed by means of empirical equations, and the blank spaces filled in by interpolation or by extension, using other experimental data where necessary. This assembly and formulation is given in Table 12. The empirical equations used are also given there. It has not yet been found possible to obtain empirical equations of a simpler form to represent the experimental results to an accuracy warranted by the experimental precision. There is a possibility that a simple formula for expressing the thermal behavior of steam may eventually be discovered. Such a formula would be extremely useful, particularly so if of a form well adapted to thermodynamic calculations and if in agreement with physical facts. In the meanwhile, equations lacking this ideal simplicity of form may be tolerated in the operations of obtaining numerical tabulations of thermal properties which result from experiment. In the present instance fidelity to observation has not been sacrificed to superficial simplicity.

Two formulas have been used for α, one of which fits the results in the range from 0 deg. to 170 deg. cent., and the other in the range from 170 deg. to 270 deg. cent. The formula for β fits the results in the range from 100 deg. to 270 deg. cent. The values of β in the range from 0 deg. to 100 deg. cent. have been computed from previously published vapor-pressure and liquid-density data.

The experimental values of L have been obtained from the observed values of γ and the smoothed or calculated values of β, using the relation $L = \gamma - \beta$. The empirical formula for L fits the experimental results to better than one part in 2300. The form of this equation has been chosen in accordance with the usually accepted belief that at the critical temperature (374 deg. cent.) the heat of vaporization becomes 0 and approaches this value at a negative infinite rate, and that no real values exist at higher temperatures. Below 100 deg. cent. the values given by the equation are in accord with results of other observers.

Total energy supplied = 2332.6 joules
Mass withdrawn = 62.722 grams
Energy per gram = 37.190 joules per gram
Mean bridge reading during experiments = 48.08421
Mean ref. block temp. during experiment = 240.0169 deg.
Mean t.e. 1–5 during experiment = 5.78 microvolts = 0.0192 deg.
Mean calorimeter temperature during experiment = 239.9977 deg.
Heat content at initial minus heat content at mean $(H_1 - H_m)$ = 0.016 joules per gram

$L\frac{u}{u'-u}$ at 240.0010 deg. = 37.206 joules per gram

TABLE 11 PRINCIPAL DATA FROM β EXPERIMENTS

[a] Values in parentheses are calculated from previously published vapor-pressure and specific-volume data.

$$\alpha = 1.240777 \log_{10}\frac{\theta+7}{7} + 415.2412\left(\frac{\theta}{100}\right) + 0.6912\left(\frac{\theta}{100}\right)^2 - 0.044874\left(\frac{\theta}{100}\right)^4. \qquad \text{(Range 0–170°)}$$

$$\alpha = 412.91945\left(\frac{\theta}{100}\right) + 3.844\left(\frac{\theta}{100}\right)^2 - 0.5238\left(\frac{\theta}{100}\right)^4 + 0.0213\left(\frac{\theta}{100}\right)^6. \qquad \text{(Range 170–270°)}$$

$$\frac{100\,\theta}{\theta+273.1} = \left(\frac{\theta}{100}\right)^{10/2}\left[0.304065 + 0.0193\left(\frac{\theta}{100}\right) + 0.00662\left(\frac{\theta}{100}\right)^2\right] + 0.04830. \qquad \text{(Range 100–270°)}$$

$$L = 0.002562(374-\theta)^3 - 5.883(374-\theta) + 249.9(374-\theta)^{\frac{1}{2}} - 113(374-\theta)^{\frac{1}{4}}. \qquad \text{(Range 0–270°)}$$

The calculated values of γ are now obtained from the calculated values of L and β, completing the formulation of the properties measured calorimetrically.

2—Derivation of Heat Content and Entropy From Calorimetric Data

It is now possible to complete the formulation of heat content and entropy, using the smoothed and extended values of the calorimetric data. The results of these derivations are given in Table 13. The values of heat content of saturated liquid water, H, given in column 2 are obtained as the sums of the values of $\alpha]_0^\theta$ and of $\beta]_0^\theta$, calculated, in Table 12. The values of heat content of saturated vapor H' are equal to $H + L$. The calculation of entropy of the saturated liquid has been made using each of the two formulas:

$$\Phi = \int \frac{\alpha d\Theta}{\Theta^2} + \frac{H}{\Theta} = \int \frac{d\alpha}{\Theta} + \frac{\beta}{\Theta}$$

together with the two empirical equations for α, suited to the two ranges of temperature. Thus a check was obtained on the accuracy of the computations. These are rather laborious owing to the complicated form of the α equations. The values of entropy, heat content, α, and β are mutually consistent. The values of entropy of the saturated vapor are obtained by adding L/Θ to Φ, which makes these values consistent with the values of L.

3—Discussion of Accuracy

To the user of experimental data consisting of numerical values of physical quantities, it is important to know how trustworthy the figures are. In compiling a table of the properties of steam, over a large range of conditions, from various experimental sources, the choice of the most truthful figures to take as the basis for formulation must be based on a consideration of accuracy of the experimental results.

It is not a simple problem to make an estimate of the accuracy

of steam data based on calorimetric measurements because so many factors enter, each of which contains an element of uncertainty. The experimenter is probably best acquainted with the facts which should be considered in arriving at such an appraisal. Taken together with the evidence included in a description of the work, and making due allowance for possible bias, an experimenter's own judgment as to accuracy may prove useful to the critical reader.

By careful study of all the factors which enter into the measurements, a figure can be assigned to each which represents an estimate of the magnitude of the outstanding systematic error which remains in each factor after all known corrections for standards and calibrations have been applied. Since the signs of these various outstanding sources of systematic error are unknown, they may be considered as combining fortuitously in the final result.

In addition to these a figure can be deduced, for each of the quantities measured calorimetrically, from the differences actually exhibited by individual results, which denotes an estimate of the magnitude of the error of each final result arising from accidental errors in making the measurements.

Having made these preliminary estimates it is possible, with the aid of the theory of probability, to combine them and finally obtain a figure which represents an estimate of the limit of variability within which it can be expected the true value lies with any certain degree of likelihood.

Such an analysis has been made of the results of the present investigation, by consideration of every source of error both systematic and accidental, which seems to have a significant effect. A final estimate has thus been obtained for each of the three thermal properties, H, L, and H'. In each case limits have been estimated such that there is only one chance in a hundred that the true value lies outside these limits. This is a purely arbitrary way of expressing an index of the accuracy of the results. Such an estimate admits the one chance in a hundred of the error being greater than the index, and also admits a chance that some important source of systematic error has been overlooked or underestimated.

On this basis it is estimated that there is only one chance in a hundred that the values given for H differ from the truth by as much as 1 part in 2000. It is estimated to be equally unlikely that the values given for L and H' are as much as 1.5 joules per gram from the truth in the range of the experiments from 100 to 270 deg. cent.

ACKNOWLEDGMENTS

It is impossible to acknowledge adequately all the aid which has contributed to the success of this endeavor. The initiative can be attributed to Mr. Geo. A. Orrok. His vision and forethought focused attention on the pace at which steam-power development was outstripping physical knowledge of properties of steam, and his active interest enlisted the generous support of the steam industries through The American Society of Mechanical Engineers for the research project of which the present work is a part.

Manufacturers have been glad to undertake special tasks to further the work. The Hider Steel Ball Works showed an especially generous scientific interest in accepting, at a nominal cost, the problem of grinding tiny iridium-alloy balls needed in the construction of the apparatus.

Nearly every division of the Bureau of Standards has cooperated in the work, and individuals of the staff have given valuable assistance. To the skill and handicraft of Mr. William Hausstein, instrument maker, is due much of the excellence of mechanical construction of parts of the apparatus.

Without attempting to do justice individually to all who have cheerfully helped this research along, it can be said that whatever success has been attained should be credited to the hearty cooperation of many contributors.

FSP-52-29

Calorimetry of a Fluid[1]

By NATHAN S. OSBORNE,[2] WASHINGTON, D. C.

A rigorous analysis of the thermal processes involved in the change of state of a saturated fluid shows that four types of calorimetric processes each yield values of a characteristic thermal property of the fluid. This group of calorimetric properties may be used to formulate the thermal behavior of the fluid in terms of familiar and convenient properties within the range of the experimental possibilities.

The principles of a calorimetric method of determining the thermodynamic characteristics of a fluid are outlined. The method has been developed at the Bureau of Standards and used in the determinations of the properties of saturated water and steam, published simultaneously with this paper. This paper supplements that report and furnishes the theoretical groundwork for the experimental work.

The results of the analysis have been used as a guide in developing a systematic experimental project which has resulted in the determination of an important group of properties of saturated steam.

I—INTRODUCTION

THIS paper presents the principles of a systematic method of observing the thermal behavior of fluids. The method is intended primarily for the purpose of obtaining data useful in heat engineering.

Certain characteristic thermodynamic properties of a fluid exhibit its behavior with respect to changes of temperature, pressure, volume, and energy. Knowledge of these properties is indispensable to engineers in analyzing problems which arise from the use of fluids in heat engines. It is customary to collect and arrange in the convenient form of numerical tables and graphical charts the values of these properties for fluids used as media in thermodynamic processes.

The most formidable problem in the preparation of a thermodynamic table or chart for a given substance is to obtain data adequate as to kind, range, and accuracy. With very few exceptions existing thermodynamic tables have been prepared from scanty and incongruous data collected from various sources, and on that account require great dependence on the compiler's appraisal.

The discrepancies between steam tables bear witness to the difficulties of measuring thermodynamic properties and emphasize the need of further development of methods of measurement.

II—CALORIMETRY AS A METHOD OF SURVEYING THERMAL BEHAVIOR OF A FLUID

Measurement of the amount of heat which enters or leaves a mass of fluid when its state changes affords a means of studying thermal behavior appropriate for formulating those thermodynamic properties of a fluid which are important in engineering calculations.

Although calorimetry has been used for obtaining certain indispensable data, the full possibilities and advantages of this mode of experimental study as a systematic basis for a complete thermodynamic formulation have not been utilized. Formerly when measurements of heat were made only in terms of the heat capacity of a chosen standard substance, such as water, when the technique of temperature control and measurement was only beginning to be developed, and when methods for controlling thermal leakage in calorimeters were yet crude, it was expedient to avoid where possible the inherent difficulties of calorimetric methods and use simpler and more easily manipulated means, such as the simultaneous observation of pressure, volume, and temperature, for establishing the thermal behavior of a fluid.

Development of trustworthy standards and methods for electrical measurements brought new possibilities to calorimetry both as to increased accuracy and enlarged scope. The adopting and perfecting of electric heaters, resistance thermometers, and thermocouples, have made it possible to develop calorimetry into a reliable agency for thermal research. Ways to confine heat within a definite region, in opposition to the inherent tendency of heat to dissipate, have been developed, and it is now possible to refine the various elements of a calorimetric apparatus to such a degree that the measurements will be consistently accurate.

Conservation of energy is the keynote of calorimetry. One conception of a calorimeter is a place where we confine measured energy while observing the change in state which it produces in a measured sample of fluid.

If the sample is part liquid and part vapor the definite relation between saturation pressure and temperature makes it possible to keep a definite control on the state of the sample and to make it pass through definite processes which effectively exhibit its thermal characteristics.

The proposed method makes use of a single calorimetric equipment by means of which a system of measurements may be made which will determine some of the most essential thermodynamic properties of a fluid. In this method a sample of the fluid in a closed shell at some chosen temperature is heated electrically from the initial temperature and pressure to some other chosen state, or is withdrawn at any chosen temperature and pressure either as liquid or vapor. The energy input required for each of these processes is measured electrically. The amount of heat added per unit mass in any of these processes is characteristic of the fluid and of the particular experimental process observed.

As the aggregate result of the group of measurements it turns out that the property of a fluid which is of utmost importance as a measure of available energy in a thermal process—that is, the "heat content" or "total heat"—is the one most directly determined by the several calorimetric processes, but that specific heat, entropy, and specific volume also may be determined from this group of measurements. The method has been developed at the Bureau of Standards for determining the properties of steam, and has previously been described in part.[3] The analysis previously given, which was restricted to a saturated fluid, has been revised so as to make it more general, and now includes application of the method to determinations of properties of the superheated vapor.

In order better to visualize the physical aspect of the method, reference will be made to the actual apparatus which has been developed in collaboration with H. F. Stimson and E. F. Fiock. This apparatus has been completed and has been used for a series of measurements extending over several years. Brief illustrated descriptions of the general form of the apparatus, of some of the important details of construction, and of tentative experimental results obtained have appeared from time to time as progress reports.[4]

A comprehensive account[5] of the construction, method of use, and results already obtained is now in preparation for publication. This account will contain the evidence as to the soundness of the method and the reliability of the results obtained. Only a very concise description of those vital features of the apparatus and procedure which pertain to the analysis of the method will be given here.

III—DESCRIPTION OF EQUIPMENT AND EXPERIMENTS

1—Equipment

The apparatus consists essentially of a calorimeter where a sample of water may be sufficiently isolated from other bodies to enable its amount, state, and energy to be accounted for. The sample may be made to pass through a chosen, accurately determined change of state while the accompanying gain or loss of heat is likewise accurately determined. The design of the apparatus provides for several such experimental processes selected for their physical simplicity and for their fitness and sufficiency to exhibit the thermal behavior of the fluid.

A quantity of water, part liquid and part vapor, is inclosed in a metal shell. The water is circulated rapidly about the interior in such a manner as to distribute heat and promote close approximation to thermal equilibrium. An electric heater continually bathed with flowing water provides a means of adding measured heat, which is speedily distributed throughout the calorimeter system. Outlets with valves provide for the introduction or withdrawal of either liquid or vapor. Detachable receivers suitable for weighing are connected to the outlets to hold the samples of water transferred.

For confining the heat the calorimeter is well insulated from the influence of external sources of heat and cold. In operation, the temperature of an enveloping shell is kept very close to that of the calorimeter shell itself. The heat which passes by leakage to or from the calorimeter system is accounted for as a small correction which is determined. The power consumed in circulating the fluid and added to the system as heat is another small correction which is determined.

Means are provided for observing the following quantities:

a Temperature of the calorimeter and contents.

b Vapor pressure in the calorimeter.

c Mass of fluid contents of the calorimeter.

d Heat added to the system as electric power converted to heat and also the small corrections for thermal leakage and circulation.

The apparatus is designed to permit four special types of experiments to be made. In the ideal case of perfect manipulation and control of experimental conditions these would consist essentially of the following processes:

1 Heating with fixed amount of contents.

2 Isothermal expansion by adding heat, evaporating liquid, and removing *saturated vapor.*

3 Isothermal expansion by adding heat, evaporating liquid, throttling, reheating, and removing *superheated vapor* at the saturation temperature and reduced pressure.

4 Isothermal expansion by adding heat, evaporating liquid, and removing *saturated liquid.*

2—Heat-Capacity Determination

The experiment of the first type is a heat-capacity determination. In this experiment the temperature is raised from an initial to a final equilibrium value by adding heat, keeping the amount of fluid in the calorimeter constant. The pressure, the densities, and the relative proportions of vapor and liquid will change in the manner characteristic of the fluid. The volume of the container will change slightly with temperature and pressure. A single experiment of this type will determine the thermal capacity of the calorimeter and contents over the interval through which the state of the system is changed. This interval may be expressed in terms of either the temperature or the pressure, according to convenience. Two experiments of this kind, each extending over the same interval, but with different amounts of fluid in the calorimeter, will differ in observed thermal capacity by the thermal capacity of the difference in contents. Thus, the thermal capacity of the instrument may be eliminated and a value found for the thermal capacity of unit quantity of a definite combination of saturated liquid and vapor.

This result expresses a definite thermal property of the fluid, for its value is dependent only on the nature of the fluid and on the initial and final states. It bears a definite and simple relation to other more familiar thermal properties, particularly the change in heat content of the saturated liquid which it approximates in value and which is determined by this type of experiment supplemented only by experiments of type 4. An experiment of the first type is thus substantially a determination of the change in heat content of the saturated liquid. The resultant heat quantity differs from the change in heat content by a correction term which is determined by the fourth type of experiment, and is small in amount at low temperatures, increasing with temperature and pressure.

3—Latent-Heat Determination

An experiment of the second type is virtually a latent-heat determination. In this experiment a definite portion of the contents of the calorimeter is withdrawn as saturated vapor at the calorimeter temperature, which is maintained approximately constant during the experiments by adding heat to compensate for the energy absorbed in evaporating the fluid. Such changes in the experimental conditions as do occur will be accidental deviations from the ideal constancy aimed at. These deviations can never be absolutely annulled, but their amount may be controlled by proper refinement of equipment and operation so that the effect is either negligible or else may be evaluated as a small correction.

The result of a single experiment of this type is a determination of the amount of heat which must be supplied when unit quantity of saturated vapor is removed from the calorimeter. This includes not only the quantity of heat required to evaporate the unit mass removed, but also the heat to produce an additional amount of vapor sufficient to fill the space which is vacated by the fluid withdrawn. The observed heat quantity differs from the latent heat of vaporization by this extra amount, and this correction turns out to be the same as that required to evaluate the heat content of the liquid from the result of the first type of experiment.

4—Superheat Determination

The third type of experiment is a measurement of the heat content of superheated vapor referred to that of saturated liquid at the same temperature. This experiment differs from the second by throttling the sample of vapor from the state of saturation to a lower pressure, leaving the temperature at which it is withdrawn the same as before. The second type of experiment is the limiting case where the throttling is zero and the change in heat content becomes equal to the latent heat of vaporization. A still more general type of experiment would be the case where fluid is withdrawn at any temperature and pressure which can actually be produced and observed. The special cases are simpler to deal with in actual experiments, although the more general case is useful in developing the theory.

The throttling device consists of a closely fitting threaded metal plug at the entrance to the vapor outflow tube. Throttling occurs as leakage past this thread, and the degree of throttling or drop in pressure may be adjusted by advancing or withdrawing this plug. After passing the throttle the vapor enters a tube which is coiled within the vapor space of the calorimeter and leads to the outlet where the vapor is finally withdrawn from the calorimeter. The coiled tube between the throttle and the outlet is for reheating the vapor after reduction of pressure. The throttle and reheat tube are both situated in the vapor space, where they are always bathed with saturated vapor. Condensation of saturated vapor on the tube supplies the heat necessary to bring the flowing vapor back to the saturation temperature at which the calorimeter is being operated. The heat thus absorbed is a part of the total supplied to the calorimeter.

The whole process is equivalent to isothermal throttling of initially saturated vapor, effected in a place where any cooling which occurs in the process is automatically compensated without disturbing that uniform distribution of temperature which permits control and annulment of thermal leakage.

In this experiment the amount of heat is measured which must be supplied when unit quantity of vapor is produced by evaporation, reduced in pressure, and removed from the calorimeter at the saturation temperature which prevails within, where the evaporation takes place. This quantity of heat includes the latent heat of vaporization of unit mass, the correction for an extra amount evaporated to fill the vacated space, and the heat absorbed by the vapor in the process of isothermal throttling from saturation to the reduced pressure.

5—Determination of Correction

The fourth type of experiment determines the correction which is needed to reduce the results of the other three experiments to simpler terms. This correction is observed directly as the heat added to keep the system in equilibrium when a sample of saturated liquid is withdrawn, and is simply the heat required to vaporize enough liquid to fill the space vacated.

Further discussion of the physical interpretation of the results of the several types of calorimetric experiments will be reserved until after the quantitative relations have been analyzed. It will then become evident that the group of experimental processes each observed quantitatively over a range of experimental conditions, determines a group of thermal properties which, together with general thermodynamic relations and the two additional observed quantities, temperature and pressure, establish the thermal behavior of the fluid in a manner thoroughly consistent and suitable for practical formulation.

In actual experiments, slight departures from the ideal conditions of constant temperature, constant outflow, and constant energy input will be bound to occur even with the most refined technique attainable. In order to take into account these fortuitous variations from the ideal processes, the analysis will be developed first for the general case and then by proper specializations applied to the four particular experimental processes which are expected to be useful in practice.

IV—Analysis of Calorimetric Processes

1—Notation

M = mass of fluid contents of calorimeter
θ = temperature on the thermodynamic scale
π = saturation vapor pressure
V = internal volume or capacity of calorimeter
u = specific volume of saturated liquid
u' = specific volume of saturated vapor
x = fraction of fluid contents of calorimeter which is vapor. Quality factor
Q = net heat added to calorimeter and contents in any experiment including electric power input, thermal leakage, and heat dissipated in work of circulating fluid
W = external work done by the system in any experiment
$-dM$ = any infinitesimal element of mass of fluid transferred from calorimeter
y = fraction which is vapor of any infinitesimal element ($-dM$) transferred
p = pressure at which any infinitesimal element ($-dM$) is transferred
v = specific volume of fluid transferred
E_A = internal energy of calorimeter
E_x = internal energy of contents
ϵ = internal energy of unit mass of saturated liquid
ϵ' = internal energy of unit mass of saturated vapor
e = internal energy per unit mass of fluid transferred
H = heat content per unit mass of saturated liquid referred to the value at some arbitrary temperature as zero. $H = \epsilon + \pi u$
H' = heat content per unit mass of saturated vapor referred to same zero as H. $H' = \epsilon' + \pi u'$
L = heat of vaporization of unit mass of fluid. $L = H' - H$
h = heat content per unit mass of fluid transferred, referred to same zero as H. $h = e + pv$
q = heat added to unit mass of saturated liquid in a reversible process
q' = heat added to unit mass of saturated vapor in a reversible process
Φ = entropy per unit mass of saturated liquid
Φ' = entropy per unit mass of saturated vapor
ϕ = entropy per unit mass of superheated vapor
σ = specific heat of saturated liquid $\frac{dq}{d\theta}$
σ' = specific heat of saturated vapor $\frac{dq'}{d\theta}$

Subscripts 1 and 2 denote initial and final equilibrium values, respectively, of the quantities to which they are attached.

2—Derivation of General Equation

The purpose of the analysis which follows is to formulate the relations between the quantities observed in the experiments and the properties of the fluid which are to be determined, with the ultimate object in mind of making a systematic formulation of the thermal behavior of the fluid in a convenient form. We shall briefly recall, of the things which happen in the experiment of the more comprehensive or general type, those changes or operations which directly concern the analysis.

A measured quantity of heat is added and distributed to the calorimeter and its fluid contents, part liquid and part vapor, and at the same time fluid is gradually withdrawn. These two actions are under the control of the operator. As a result a change occurs in the state of the calorimeter and the fluid within it. Accompanying this change of state, work is done on or by the system against external forces. The change in state is determined by suitable observation of the temperature and pressure, and these data, together with the observed data on the transfer of the fluid, gives a basis of accounting in terms of external work and internal energy for all the measured energy added in the form of heat. This accounting follows the principle of conservation of energy and is the first step in the analysis. The usual direction of the operations in an actual experiment is determined by convenience of electrically measuring heat into the system and of measuring outflow of fluid, and by the direction of pressure change in throttling. Except for these practical limitations these operations are not limited in sense, and the analysis is not restricted to either direction.

We shall define the system to which the principle is to be applied as that space wherein by observation we may account for heat added, amount and state of matter, and work done. This definition is essentially a description of the calorimeter and its contents, a system which, it is true, changes in mass, but for which, nevertheless, the energy account may be kept. In the present analysis we shall disregard as insignificant all changes of energy within the system other than measured heat added, external work done or change of internal energy, thus excluding changes in potential or kinetic energy of the aggregate mass. It then follows from the principle of conservation that whatever net energy is added to the system as heat must appear either as net increase of internal energy of the system in its final state of equilibrium over that in its initial state, as net internal energy of fluid withdrawn, or as net work done against external forces, all these quantities being expressed in the same energy units. We may write this in our chosen notation

$$Q = [E_A]_1^2 + [E_x]_1^2 - \int_1^2 e dM + W \quad \ldots\ldots [1]$$

Since the various elements of internal energy appear in the present analysis only in intermediate steps where numerical evaluation is not required, it is not necessary yet to introduce a reference value, but it is sufficient to specify that all these elements of internal energy are referred to the same state as a datum.

This rudimentary equation will next be transformed into a form adapted to our purpose by introducing specifications as to the mass, volume, quality, and specific properties of the fluid.

In the first place, the total volume V of contained fluid may be expressed in terms of its total mass M, the quality factor or vapor fraction x, and the specific volumes of the saturated vapor and liquid, u' and u, in the equation

$$V = Mxu' + M(1 - x)u \quad \ldots\ldots [2]$$

Likewise the total internal energy, E_x, of the contained fluid may be expressed in terms of M, x, and the internal energies of the saturated vapor and liquid, ϵ' and ϵ, in the equation

$$E_x = Mx\epsilon' + M(1 - x)\epsilon \quad \ldots\ldots [3]$$

Eliminating Mx from [3] by use of [2],

$$E_x = M\epsilon + (V - Mu)\frac{\epsilon' - \epsilon}{u' - u} \quad \ldots\ldots [4]$$

and since by definition $H' = \epsilon' + \pi u'$ and $H = \epsilon + \pi u$, and also since $H' - H = L$, we have

$$L = \epsilon' - \epsilon + \pi(u' - u) \quad \ldots\ldots [5]$$

whence we may eliminate ϵ and ϵ' in Equation [4] and obtain

$$E_x = V\left(\frac{L}{u' - u} - \pi\right) + M\left(H - \frac{u}{u' - u}L\right) \quad \ldots\ldots [6]$$

Before substituting this value for E_x into Equation [1] we will find a similar equivalent for W, the external work done by the system. This consists of two possible parts, one the work done against the external pressure by reason of an increase in volume of the calorimeter shell, and the other the work done by the fluid as it issues from the calorimeter. The first part is the product of the constant and uniform external pressure by the increase of the external volume, and in all practical cases would be insignificant, particularly if the envelope space were evacuated for thermal insulation. The second part is the total work done by all the elements $(-dm)$ removed, each of which in emerging does a bit of work equal to the product of the instantaneous pressure p by the volume $v(-dm)$ transferred. Neglecting the insignificant part, the whole work done by the system during an experiment is therefore

$$W = -\int_1^2 pvdm \quad \ldots\ldots [7]$$

Returning to Equation [1] and substituting for E_x from [6], for W from [7], and h for $e + pv$, we have as the general equation applying to all the processes to be considered—

$$[Q]_1^2 = \left[E_A - V\pi + \frac{V}{u' - u}L\right]_1^2 + \left[M\left(H - \frac{u}{u' - u}L\right)\right]_1^2 - \int_1^2 hdM \quad \ldots\ldots [8]$$

3—Remarks on the Physical Interpretation of the General Equation

Equation [8] is an expression for the heat added in a complete experimental process of the general type which has been considered. It is now in convenient form for physical interpretation and for application to the special cases of the four types of experiment of the simpler kind, for the second member shows how the whole amount of heat added is disposed of, taking into account the quantity, distribution, state, and properties of the fluid, and the characteristics of the container. This equation properly applies to any process where heat is exchanged with a quantity of fluid consisting of part liquid and part vapor, as, for example, the operation of a boiler or a condenser, provided, of course, that we are able to keep the account of energy and material correctly. The main difference between our ideal calorimeter and a boiler consists in the refinements provided for accurate bookkeeping. The scale upon which a calorimeter is constructed, of course, need be only large enough for convenient construction and operation and accurate observation.

If we examine the individual terms of the second member of Equation [8] we shall see that each of the three terms denotes a particular portion of the heat added, or its equivalent, very definitely identified with a particular part of the entire process.

The first term involves the internal volume and internal energy of the container itself but is independent of the amount of fluid contents, excepting that enough fluid must always be present to maintain the saturation condition. This term includes those characteristics of the calorimeter which affect the heat-absorbing capacity of the system. Neither of the other two terms refers to the calorimeter itself.

The second term expresses the heat added by virtue of the combined change in amount and state of the portion of fluid within the calorimeter between the beginning and the end of the experiment. This term is entirely independent of the inter-

mediate process by which this change takes place, being completely determined by the initial and final values of mass and temperature.

The third term completes the account by expressing the heat taken away from the system by the portion of fluid withdrawn. This term depends for its value not only on the initial and final states of the system, but upon the state of the issuing stream at every instant during the course of the experiment.

Inasmuch as the physical operations upon which Equation [8] is based are indifferent as to direction, the equation is not limited in its application to changes in a particular sense. If, instead of an electric heating current, we should employ a current of cooling fluid in a coiled tube so that it could absorb and take out heat, the equation would still apply for a decrease instead of a rise in temperature, although the measurement of the heat would then have to be provided for in a different way. Also, except for the case of the throttling process, the transfer of fluid may occur either to or from the calorimeter without affecting the validity of the equation. Indeed it is possible even to apply it to a case where both directions of flow occur simultaneously, as, for instance, if we should introduce liquid and remove vapor at the same time, thus simulating the action of an ordinary steam boiler, or by reversing this process make the system operate as a condenser.

As far as theory is concerned, Equation [8] is general in its application to the types of thermal processes which may take place in a saturated fluid, considered as an isolated system. We shall consider in detail the four specific types of experiments which are adapted to the determination of the thermal properties of the fluid.

4—Constant-Mass Experiments

In the first type of experiment the amount of fluid in the calorimeter is to be kept constant during a single experiment. For this condition, the last term in Equation [8] vanishes. We shall use the symbol Z to denote the quantity $E_A - V\pi + \frac{V}{u' - u} L$. Let M_a and M_b denote the masses of the contents in two separate experiments in each of which the temperature of the calorimeter and contents is changed from θ_1 to θ_2. Let Q_a and Q_b denote the measured quantities of heat added in the two experiments, thus obtaining the following two equations:

$$Q_a = [Z]_1^2 + M_a \left[H - \frac{u}{u' - u} L \right]_1^2 \quad \ldots\ldots [9]$$

$$Q_b = [Z]_1^2 + M_b \left[H - \frac{u}{u' - u} L \right]_1^2 \quad \ldots\ldots [10]$$

Solving these two simultaneous equations for $\left[H - \frac{u}{u' - u} L \right]_1^2$ and $[Z]_1^2$, we have

$$\left[H - \frac{u}{u' - u} L \right]_1^2 = \frac{Q_b - Q_a}{M_b - M_a} \quad \ldots\ldots [11]$$

$$[Z]_1^2 = \frac{Q_b M_a - Q_a M_b}{M_a - M_b} \quad \ldots\ldots [12]$$

5—Evaporation Experiments

In an experiment of type 2, saturated vapor is withdrawn from the calorimeter and consequently the h in Equation [8] becomes H'. In order to take into account the effect of variations in the state of the vapor, H' may be separated into two parts, one a constant value, H_1', and the other the deviation, $H' - H_1'$, from this constant value. If we substitute for h these two values into Equation [8], the last term, which expresses the energy transferred in the outflowing stream, may be divided, one portion corresponding to the value for outflow at the steady state corresponding to H_1', and the other the effect of the variation of the state of the vapor from this ideal steady state. Making this substitution, also substituting Z for $E_A - V\pi + \frac{V}{u' - u} L$ and expanding the expression $\left[M \left(H - \frac{u}{u' - u} L \right) \right]_1^2$ into the form

$$(M_2 - M_1) \left(H - \frac{u}{u' - u} L \right)_1 + M_2 \left[H - \frac{u}{u' - u} L \right]_1^2$$

we have

$$Q = [Z]_1^2 + M_2 \left[H - \frac{u}{u' - u} L \right]_1^2 - (M_2 - M_1) \left(H - \frac{u}{u' - u} L \right)_1 - (M_2 - M_1) H_1' - \int_1^2 (H' - H_1')\, dM \quad \ldots\ldots [13]$$

Combining terms,

$$Q = [Z]_1^2 + M_2 \left[H - \frac{u}{u' - u} L \right]_1^2 - (M_2 - M_1) \left(L + \frac{u}{u' - u} L \right)_1 - \int_1^2 (H' - H_1')\, dM \quad \ldots\ldots [14]$$

and solving for $\left(L + \frac{u}{u' - u} L \right)_1$,

$$\left(L + \frac{u}{u' - u} L \right)_1 = \frac{1}{M_2 - M_1} \left\{ -Q + [Z]_1^2 + M_2 \left[H - \frac{u}{u' - u} L \right]_1^2 - \int_1^2 (H' - H_1')\, dM \right\} \quad \ldots [15]$$

In Equation [15] the quantities $[Z]_1^2$ and $\left[H - \frac{u}{u' - u} L \right]_1^2$ would be determined from the results of experiments of type 1. As a matter of fact, an experimenter would aim to keep conditions so steady that these two quantities would be negligible.

The quantity $\int_1^2 (H' - H_1')\, dM$ if large enough to be significant would be determined by periodic observations of the state of the outflowing vapor during the experiment. By refinement of equipment and manipulation this correction as well as the two just previously mentioned would all be kept very small. The requirement to make them all zero would be to maintain constant temperature and pressure, and for this ideal experimental condition we should have the simpler form of equation

$$\left(L + \frac{u}{u' - u} L \right)_1 = - \frac{1}{M_2 - M_1} Q \quad \ldots\ldots [16]$$

in which M_2, M_1, and Q are determined by observation, thus allowing the quantity $L + \frac{u}{u' - u} L$ to be determined at a certain chosen temperature in each experiment. This quantity is the property of the fluid, characteristic of this experiment, which was previously mentioned as being approximately the

heat of vaporization at low temperatures and pressures where the ratio $\frac{u}{u'-u}$ is small.

6—Throttling Experiments

In an experiment of type 3 superheated vapor is withdrawn at the temperature θ, and the reduced pressure, p, and for this case the h in Equation [8] may be denoted as $(h)_{\theta p}$. In a manner similar to that followed in the case of evaporation experiments $(h)_{\theta p}$ may be separated into a constant and a variable part; that is,

$$(h)_{\theta_1 p_1}, \text{ and } (h)_{\theta p} - (h)_{\theta_1 p_1}$$

but $(h)_{\theta_1 p_1}$ is equal to $H_1' + [(h)_{\theta 1}]_{\pi_1}^{p_1}$. Substituting $H_1' + [(h)_{\theta 1}]_{\pi_1}^{p_1} + (h)_{\theta p} - (h)_{\theta_1 p_1}$ for h in Equation [8], substituting Z for $E_A - V\pi + \frac{V}{u'-u} L$, and $(M_2 - M_1)\left(H - \frac{u}{u'-u} L\right)_1 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2$ for $\left[M\left(H - \frac{u}{u'-u} L\right)\right]_1^2$ as in the previous derivation of the special equation for evaporation experiments, we have

$$Q = [Z]_1^2 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2 + (M_2 - M_1)\left(H - \frac{u}{u'-u} L\right)_1 - (M_2 - M_1)H_1' - (M_2 - M_1)[(h)_{\theta 1}]_{\pi_1}^{p_1} - \int^2 \{(h)_{\theta p} - (h)_{\theta_1 p_1}\} dM \quad \ldots\ldots [17]$$

Combining terms,

$$Q = [Z]_1^2 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2 - (M_2 - M_1)\left[(h)_{\theta p} - H + \frac{u}{u'-u} L\right]_1 - \int_1^2 \{(h)_{\theta p} - (h)_{\theta_1 p_1}\} dM \quad \ldots\ldots [18]$$

and solving for $\left[(h)_{\theta p} - H + \frac{u}{u'-u} L\right]_1$,

$$\left[(h)_{\theta p} - H + \frac{u}{u'-u} L\right]_1 = \frac{1}{M_2 - M_1}\left\{-Q + [Z]_1^2 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2 - \int^2 [(h)_{\theta p} - (h)_{\theta_1 p_1}] dM\right\} \ldots [19]$$

The previous remarks about determining the values of the correction terms which account for the variability of experimental conditions apply to Equation [19] as well as to Equation [15], the only difference being that the last term in [19] accounts for whatever variation may occur in the state of the superheated vapor during the course of the experiment, and both temperature and pressure need to be specified, while in Equation [15] the relation between temperature and pressure is definitely fixed for the saturated vapor. The simpler form of equation for the ideal experimental condition of constant temperature and pressure in the latter case would be

$$\left[(h)_{\theta p} - H + \frac{u}{u'-u} L\right]_1 = -\frac{1}{M_2 - M_1} Q \quad \ldots\ldots [20]$$

in which M_2, M_1, and Q are determined by observation, allowing the quantity $(h)_{\theta p} - H + \frac{u}{u'-u} L$ to be determined at a certain chosen state. This quantity differs from the characteristic property determined in the preceding experiment merely by the addition of the increase of heat content, $(h)_{\theta p} - H_1'$, which corresponds to the change in state produced by the throttling from the saturation state $\theta_1 \pi_1$ to the state $\theta_1 p_1$ at which the vapor leaves the calorimeter. The latent heat of vaporization, which is the change of heat content, $H_1' - H_1$, for the constant-pressure change of state from saturated liquid to saturated vapor, is included in the result, and also the same factor or correction, $\frac{u}{u'-u} L$, for fluid evaporated which remains in the calorimeter. Except for this correction term the quantity measured with this calorimeter in a flow experiment is the increase in heat content for the entire change in state from the saturated liquid within the calorimeter to the state at which the fluid is withdrawn.

7—Experiments in Which Saturated Liquid Is Withdrawn

In an experiment of type 4, saturated liquid is removed from the calorimeter so that h in Equation [8] becomes H.

In a similar manner as before we substitute $H_1 + H - H_1$ for H,

$$Z \text{ for } E_A - V\pi + \frac{V}{u'-u} L$$

and

$$(M_2 - M_1)\left(H - \frac{u}{u'-u} L\right)_1 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2$$

for

$$\left[M\left(H - \frac{u}{u'-u} L\right)\right]_1^2$$

and have

$$Q = [Z]_1^2 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2 + (M_2 - M_1)\left(H - \frac{u}{u'-u} L\right)_1 - (M_2 - M_1) H_1 - \int_1^2 (H - H_1) dM \quad \ldots\ldots [21]$$

Combining terms,

$$Q = [Z]_1^2 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2 - (M_2 - M_1)\left(\frac{u}{u'-u} L\right)_1 - \int_1^2 (H - H_1)\, dM \quad \ldots\ldots [22]$$

and solving for $\left(\frac{u}{u'-u} L\right)_1$,

$$\left(\frac{u}{u'-u} L\right)_1 = \frac{1}{M_2 - M_1}\left\{-Q + [Z]_1^2 + M_2\left[H - \frac{u}{u'-u} L\right]_1^2 - \int_1^2 (H - H_1) dM\right\} \quad \ldots\ldots [23]$$

Again, as in the two previous cases, we have the three correction terms for variability of experimental conditions, two of which are determined from the results of separate experiments of type 1, and the last by periodic observations of the state of the issuing fluid.

The form of equation for ideally perfect operation of this type of experiment would be

$$\left(\frac{u}{u'-u} L\right)_1 = -\frac{1}{M_2 - M_1} Q \quad \ldots\ldots [24]$$

8—Résumé of Theory of Experiments

As the result of a complete group of the four distinct types of experiments, each carried out as a series extending over the range of temperature and pressure within which the properties of the fluid are desired, we have four calorimetric quantities, each of which is characteristic of the process and of the particular fluid used, and each of which is completely determined with respect to the state of the fluid. We shall find it convenient to designate each of these four properties of the fluid by a symbol for use in formulating the intermediate steps by which other thermal properties are derived from these directly measured quantities. In addition to the four quantities which are calorimetric—that is, measured heat quantities—we may include the observed vapor pressure π, thus making five experimental quantities, four of which are functions of temperature, while the other (λ) is a function of temperature and pressure, as the basis from which to formulate the thermal behavior of the fluid. The definitions of these quantities are

$$\alpha = H - \frac{u}{u' - u} L \quad [25]$$

$$\gamma = L + \frac{u}{u' - u} L \quad [26]$$

$$\lambda = (h)_{\theta p} - H + \frac{u}{u' - u} L \quad [27]$$

$$\beta = \frac{u}{u' - u} L \quad [28]$$

It may be noted that $u/(u' - u)$ is a pure ratio and that L denotes the magnitude of a physical quantity which may be determined by experiment independently of any arbitrary choice of a zero datum. Hence the quantities γ and β may be evaluated at any chosen temperature without regard to any arbitrary datum. The quantity α on the contrary contains the quantity H involving the internal energy of unit mass of the fluid which we are able to evaluate only with respect to some arbitrarily chosen reference value. Consequently the quantity denoted by the symbol α can be determined experimentally only as a difference in value between two states of the liquid. The symbol α is used with reference to the same arbitrary zero which is chosen for the quantity H, so hat the same arbitrary constant is tacitly understood for both.

In the series of experiments the quantity α referred to this zero may be determined either by measurement extending from the zero state to the various chosen temperatures throughout the range; or else by measurements of convenient intermediate increments of α, which must cover the entire range.

The quantity λ, like γ and β, is determined experimentally at a definite state, the arbitrary constant being canceled when the difference between $(h)_{\theta p}$ and H is taken.

These five independently observed quantities, when taken together with the thermodynamic relations which hold, in general, for all fluids, are sufficient to establish completely the thermodynamic properties of a fluid over the range of conditions and to the accuracy determined by the experiments.

It will shortly be shown possible to deduce from these five directly measured thermal properties the other more familiar thermal properties which are generally employed in dealing quantitatively with the thermodynamic processes of the fluid.

The completeness with which the whole system of thermal properties may be formulated from a group of data of this type is in practice limited by the experimental possibilities. The method cannot be expected to be ideal in every particular, and the shortcomings must be watched for, not only in the preparations for experiments but in the formulation of results.

The employment of this group of independent experimental data, together with the necessary thermodynamic general relations, results in a formulation which is self-consistent.

The question of reliability of results is extremely important, and in providing data for engineering purposes no opportunity should be overlooked to check the accuracy of results. This may be done, in the first place, by scrupulous attention to details of apparatus, manipulation, observation, and calculation. In the second place, if possible, experimental results from different methods should be subjected to the test of mutual agreement with the general laws of thermodynamics.

The first four of the group of data—that is, the four calorimetric quantities—are characteristic thermal properties of a fluid, which have been employed here solely for the reason that they are useful in the experimental study of the fluid by the calorimetric method. We shall next outline a method by which the thermal behavior as thus determined may be expressed in terms of the more fundamental properties as usually formulated for engineering calculations.

V—Outline of Method of Formulation of Data

The precise manner of evaluating and expressing as functions of temperature or pressure, or both, the various thermal properties which we may desire to formulate is a detail which may be handled in several ways.

There are three ways of exhibiting physical quantities in terms of independent variables, viz., empirical equations, graphs, and tables. Each of these has some virtue, but none is indispensable. It would probably be advantageous to express the properties of steam finally by all three methods as far as possible, but the process by which the data are thus formulated may depend to a considerable extent on the character of the data themselves and on the possibility of obtaining satisfactory empirical equations to represent the experimental facts. The process of formulation should also provide for the comparison of independent experimental data from different sources, and for the appraisal and adjustment of the numerical values to represent the best estimate of the truth.

We shall present here merely an outline of such a process which may be applied to the group of experimental data which we have recapitulated just above, resulting from the observations which may be made in the calorimeter specified.

By simple algebraic combination of Equations [25], [26], [27], and [28], and without utilizing any further thermodynamic relations whatever, we may deduce the following group of equations

$$H = \alpha + \beta \quad [29]$$

$$H' = \alpha + \gamma \quad [30]$$

$$h = \alpha + \lambda \quad [31]$$

These three equations show how the four directly measured heat quantities, α, β, γ, and λ, determine the heat content of the fluid either as saturated liquid, saturated vapor, or as superheated vapor at any pressure below saturation, in each case referred to the value at a chosen reference state.

It should be noted that these equations do not, in general, yield values of H, etc., as functions of temperature or temperature and pressure. They yield a value of H, for example, for every saturation temperature at which α and β have been determined. Only in case α and β are expressed as functions of temperature will these equations lead to an equation for H as a function of temperature. Each of the quantities H, H', h,

derived in this manner from the experimental data should be considered as denoting a series of values of that particular thermal property corresponding to the various chosen states of the fluid at which the observations have been made. If, therefore, the experiments have been suitably distributed as to temperature and pressure, we have thus the skeleton of a steam table, complete as far as heat content is concerned, which may be elaborated by interpolation, by graphical representation, or by formulation into an equation.

Thus heat content, perhaps the most vital of the thermal properties required in engineering calculations, is directly determined calorimetrically.

Owing to the fact that the type of calorimeter chosen for this method operates at the saturation limit, the range of the determination is continuous along the saturation limit and into the superheat region, thus bridging a gap which would otherwise need to be crossed by extrapolation.

The latent heat of vaporization, equal to $H' - H$, is directly determined by the equation

$$L = \gamma - \beta \quad [32]$$

The ratio u'/u of the specific volumes of the saturated vapor and saturated liquid is determined by the equation

$$\frac{u'}{u} = \frac{\gamma}{\beta} \quad [33]$$

which results directly from Equations [26] and [28].

To proceed further with the derivation of thermal properties from the group of experimental data, it is necessary to use relations which depend on the second law of thermodynamics. We shall use the general relation

$$dh = \theta d\phi + vdp \quad [I]$$

which is a statement combining the substance of the first and second laws for a fluid subjected to a reversible change of state. We shall also use Clapeyron's equation

$$\frac{L}{u' - u} = \theta \frac{d\pi}{d\theta} \quad [II]$$

which is deducible from [I] for the special case of evaporation at a constant temperature.

It is, of course, necessary to have a knowledge of the zero of temperature on the thermodynamic scale relative to the working scale used in the measurements. Wherever temperature θ appears as a factor it is to be referred to this absolute zero of temperature. As a consequence of this last relation, [II], it follows that

$$\frac{u}{u' - u} L = \theta u \frac{d\pi}{d\theta} \quad [III]$$

and therefore from Equations [25], [28], and [26] that

$$\alpha = H - \theta u \frac{d\pi}{d\theta} \quad [34]$$

$$\beta = \theta u \frac{d\pi}{d\theta} \quad [35]$$

$$\gamma = \theta u' \frac{d\pi}{d\theta} \quad [36]$$

It will next be shown that the entropies of the saturated liquid and of the saturated vapor are determined by the calorimetric data α, β, and γ directly through these additional relations.

If we solve Equation [I] for $d\phi$ we have

$$d\phi = \frac{dh}{\theta} - \frac{v}{\theta} dp \quad [IV]$$

and since $\frac{dh}{\theta} = d\left(\frac{h}{\theta}\right) + \frac{h}{\theta^2} d\theta$, we have, by substituting in Equation [IV],

$$d\phi = d\left(\frac{h}{\theta}\right) + \frac{h}{\theta^2} d\theta - \frac{v}{\theta} dp \quad [V]$$

and now applying this equation to saturated liquid, noting that $h = H = \alpha + \beta$, and $vdp = ud\pi$,

$$d\Phi = d\left(\frac{H}{\theta}\right) + \frac{\alpha}{\theta^2} d\theta + \frac{\beta}{\theta^2} d\theta - \frac{u}{\theta} d\pi \quad [37]$$

But by Equation [35] the last two terms cancel, so

$$d\Phi = d\left(\frac{H}{\theta}\right) + \frac{\alpha}{\theta^2} d\theta \quad [38]$$

and by integration of this equation,

$$\Phi = \frac{H}{\theta} + \int \frac{\alpha}{\theta^2} d\theta \quad [39]$$

Applying Equation [V] to the saturated vapor, noting that

$$h = H' = \alpha + \gamma \text{ and } vdp = u'd\pi,$$

$$d\Phi' = d\left(\frac{H'}{\theta}\right) + \frac{\alpha}{\theta^2} d\theta + \frac{\gamma}{\theta^2} d\theta - \frac{u'}{\theta} d\pi \quad [40]$$

But by Equation [36] the last two terms cancel, so

$$d\Phi' = d\left(\frac{H'}{\theta}\right) + \frac{\alpha}{\theta^2} d\theta \quad [41]$$

and by integration,

$$\Phi' = \frac{H'}{\theta} + \int \frac{\alpha}{\theta^2} d\theta \quad [42]$$

Equations [39] and [42] are suitable for calculation of the entropies of the saturated fluid from the calorimetric data. The first step—that is, calculation of H and H'—has already been indicated. The values of $\frac{H}{\theta}$ and $\frac{H'}{\theta}$ may be calculated directly. The term $\int \frac{\alpha}{\theta^2} d\theta$ must be evaluated by taking account of how α varies with temperature. An empirical equation for $\frac{\alpha}{\theta^2}$ as a function of temperature would be a convenient means of evaluating this term, and for this purpose need only conform to the data in the range used and be integrable. The constants of integration depend upon the arbitrary zeros chosen for the various quantities in the equation.

It has not been necessary to use vapor pressure π in any of the reductions this far for the properties of the saturated fluid, except incidentally perhaps as a means of taking account of slight variability in the experimental conditions. But if both temperature and pressure are observed simultaneously, either in this or other apparatus, an independent relation is obtained which, with the calorimetric data, determines the specific volumes of the saturated fluid. For this purpose use is made of Equations [35] and [36], which are corollaries of Clapeyron's equation.

Solving these equations for u and u', the specific volumes of saturated liquid and vapor, respectively, we have

$$u = \frac{\beta}{\theta}\frac{d\theta}{d\pi} \quad [43]$$

$$u' = \frac{\gamma}{\theta}\frac{d\theta}{d\pi} \quad [44]$$

These equations are suitable for calculating the specific volumes within the range where $\frac{\beta}{\theta}$, $\frac{\gamma}{\theta}$, and $\frac{d\theta}{d\pi}$ can be determined with the requisite accuracy.

The method of calculating the ordinary specific heat σ of the saturated liquid and σ' of the saturated vapor is merely another detail of mathematical derivation from the calorimetric data. If we define the specific heat of the saturated liquid as the rate of absorption of heat of the homogeneous saturated liquid, in place, relative to temperature rise—that is, $\frac{dq}{d\theta}$, denoted by the symbol σ—we may obtain the equation for σ' from Equation [38], noting that $dq = \theta d\phi$:

$$dq = \theta d\left(\frac{H}{\theta}\right) + \frac{\alpha}{\theta}d\theta \quad [45]$$

whence

$$\sigma = \frac{dq}{d\theta} = \theta\frac{d}{d\theta}\left(\frac{H}{\theta}\right) + \frac{\alpha}{\theta} \quad [46]$$

and similarly for the vapor,

$$\sigma' = \frac{dq'}{d\theta} = \theta\frac{d}{d\theta}\left(\frac{H'}{\theta}\right) + \frac{\alpha}{\theta} \quad [47]$$

For calculating the entropy of superheated vapor a simple method may be employed if the isothermal throttling experiments can in practice be so carried out that determinations of h are made at temperatures and pressures corresponding to intersections of suitable isothermals and constant-pressure lines on the chart.

From Equation [I] at constant pressure,

$$d\phi = \frac{dh}{\theta} \quad [48]$$

whence by integration

$$\phi = \int \frac{1}{\theta}\left(\frac{dh}{d\theta}\right)_p d\theta \quad [49]$$

For the specific volume in the superheat region, we have from Equation [I] at constant temperature,

$$v = \left(\frac{dh}{dp}\right)_\theta - \theta\left(\frac{d\phi}{dp}\right)_\theta \quad [50]$$

or, at constant entropy,

$$v = \left(\frac{dh}{dp}\right)_\phi \quad [51]$$

It is evident that we may continue and calculate numerous other coefficients and derivatives representing certain thermal properties, such as specific heat at constant pressure, Joule-Thomson effect, etc., for comparison with results of experimental data by other methods. It is not surprising, however, to find that there are practical limitations to the range within which some of the thermal properties may be determined by this method of measurement.

For example, it is obvious that high percentage accuracy would be impossible in determining the specific volume of the liquid at low temperature and pressure where both the measured heat quantity β and the rate of change of pressure with temperature $d\pi/d\theta$ are very small, and the expression for specific volume, u, approaches the indeterminate form $\frac{0}{0}$. But fortunately this is a region where other methods of measurement are relatively easy and capable of great accuracy. On the other hand, as temperature and pressure increase, the magnitudes of the quantities which determine u by the calorimetric method get more favorable for accuracy, while other methods requiring actual measurement of volume are more formidable than at lower temperatures. Furthermore, the state of saturation in the calorimeter is a fundamental condition of the method. This constitutes an advantage in the determination of values of thermal properties at the boundary over methods which rely on extrapolation from observations confined to states in the superheat region.

In the case of approach to the critical state, the fact that the properties of the liquid and vapor phases approach equality might be expected to make it more difficult to maintain perfect separation of the phases, thus giving rise to indeterminateness of the physical processes akin to the mathematical forms which thermal properties are supposed to exhibit in this region. It is certain that for steam the critical state would not be a favorable one for calorimetric measurements on account of the high values of temperature and pressure.

Aside from these limitations there is a range of conditions within which it is possible to determine by the proposed calorimetric method the numerical values of the thermal properties of a given fluid to an accuracy appropriate for engineering purposes. The calculation of these numerical values would not necessitate the setting up of an elaborate system of mutually consistent empirical equations. The values would nevertheless be consistent with thermodynamic criteria to the degree of accuracy fixed by the measurements and the calculations. The thermodynamic criteria will have been already included as independent relations used in the scheme of calculating the several properties from the group of independent experimental quantities.

We have, in what has gone before, the skeleton of a formulation of the thermal behavior of the fluid. The formulation may be exhibited in either of the three ways previously pointed out. The numerical values may be tabulated, interpolating by the usual methods between the determined points. They may be plotted graphically in a variety of ways. They may be used to determine the constants in a series of empirical formulas. Or any combination of the three methods may be used. The details of the precise manner of formulating the data for actual use in thermodynamic calculations is beyond the scope of this paper, which merely aims to establish the basic principles of one method of determining the thermal behavior of a fluid.

A Review of Calorimetric Measurements on Thermal Properties of Saturated Water and Steam[1]

By ERNEST F. FIOCK,[2] WASHINGTON, D. C.

This review has been prepared to assemble the data which are now available on the calorimetric determinations of the thermal properties of saturated water and steam, and to reduce them to a uniform basis for comparison. After a careful analysis of the reports which have appeared in the literature, an attempt is made to point out some possible causes for the variation among the recorded results. Wherever it seemed desirable a thermodynamic interpretation of the experiments is given, and in a number of cases the data have been recalculated. By these means the agreement among the various determinations has been improved in several instances.

It is hoped that this assembly of results presented on a uniform basis may serve as an aid to future International Steam Table Conferences in the choice of base values and tolerances for the International Skeleton Tables.

By means of deviation charts the experimental values for the heat content or enthalpy of the saturated liquid and for the latent heat are exhibited and compared. The agreement is in general quite gratifying.

Several modern steam tables are compared graphically with one another and with the Bureau of Standards experimental results on the thermal properties of the saturated liquid and vapor. A marked improvement in the tables is evident with the increase in scope and the reliability of the basic experimental data.

I—INTRODUCTION

THERE have been numerous attempts in the past to formulate the thermal properties of water and steam, by means of equations, into tables convenient for the use of engineers. These formulations have, through necessity, been based on scattered groups of experimental data, recorded by different investigators in a great variety of units. For the most part the variations in the tabulated values in steam tables may be attributed to three causes: First, the choice of various forms of empirical relations to fit data which in themselves are scattered and somewhat discordant; second, the confusion arising from the use of the different measuring standards; third, the thermodynamic interpretation of the experimental data.

An important advance in the evolution of steam tables was made by the International Steam Table Conference at London in July, 1929. One accomplishment of this Conference[3,4,5] was the establishment of an International Skeleton Table, with tolerances, of the thermal properties of water and steam. It was anticipated that the table there adopted was subject to revision by subsequent conferences with the idea of narrowing the limits and approaching more closely the true values.

The publication of the data from the calorimetric determinations at the Bureau of Standards, presenting new values for the thermal properties of steam over a large portion of the saturation region, has suggested the need of a summary of all available data of a similar kind. This review is given as a supplement, appearing simultaneously with the detailed report of the Bureau of Standards determinations[6] to aid in the comparison of these results with those previously published. By the reduction of all the data to a uniform basis for comparison, it is hoped that the review may serve as an aid in the choice of basic values and tolerances for the International Skeleton Steam Table.

It is often possible, by studying the published descriptions, to reveal important evidence as to reliability, and it has been the aim in this review to bring out such evidence. It is gratifying to find that, in some cases, careful analysis and reduction of published data are rewarded by improvement in the agreement of the results.

The experiments in this field fall logically into two groups: (1) Determinations of the heat content or enthalpy of the liquid; and (2) determinations of the heat of vaporization. The various experiments of each group will be discussed in chronological order as far as is practicable.

II—NOTATION

M = mass of fluid
m = mass of saturated vapor
θ = temperature, centigrade
Θ = temperature, centigrade absolute
π = saturation vapor pressure
P = external pressure
V = internal volume of container for water
u = specific volume of saturated liquid
u' = specific volume of saturated vapor
x = fraction of the water which is vapor
E_s = internal energy of entire water sample
ϵ = internal energy per gram of saturated liquid
ϵ' = internal energy per gram of saturated vapor
H = heat content per gram of saturated liquid $(\epsilon + \pi u)$
H' = heat content per gram of saturated vapor $(\epsilon' + \pi u')$
L = heat of vaporization per gram $= H' - H$

$$\alpha = H - L\frac{u}{u' - u} = H - \beta$$

$$\beta = \frac{Lu}{u' - u}$$

$$\gamma = L + L\frac{u}{u' - u} = L\frac{u'}{u' - u}$$

$$L = \Theta\frac{d\pi}{d\theta}(u' - u) \qquad \text{(Clapeyron equation)}$$

III—ANALYSIS AND REDUCTION OF SOURCE DATA

1-DETERMINATIONS OF HEAT CONTENT OF THE LIQUID

In the temperature range from 0 deg. cent. to 100 deg. cent. the investigations have been numerous and particularly painstaking because the calorie was used as a primary unit of energy and much effort was expended in determining the precise relation between this and other units of energy. This latter knowledge has been necessary in order that all calorimetric data could be reduced to a common basis for comparison. If, as has already been attempted, a heat unit defined arbitrarily and directly in terms of mechanical units is universally adopted and used, the need for these so-called mechanical equivalents of heat vanishes as far as future work is concerned. The difficulties encountered in the preparation of this review emphasize the advantages of adopting some such arbitrarily defined heat unit.

That the experimental determination of the mechanical equivalent of heat referred to water is a difficult task is evidenced in the literature by the diversity of the results recorded. Even after the most careful attempts to reduce the experimental values to a uniform basis, there still exist divergent values for the mechanical equivalents of the various calories.

Since many of the past determinations of heat capacities and of ratios of these give little important information about the heat content, they are accorded only passing mention in this review. More important among them are determinations by Rowland,[7] Griffiths,[8] Schuster and Gannon,[9] Lüdin,[10] Callendar,[11] Romberg,[12] and Laby and Hercus.[13] The results of Barnes[14] and of Jaeger and von Steinwehr[15] yield, on integration, values of heat content which will be discussed more fully later.

(1) Regnault

For a long time the classical work of Regnault[16] furnished the most reliable information available on the specific and latent heats of water. At the time these researches were carried out the physical sciences were in their infancy, but in spite of the many difficulties Regnault's conclusions were remarkably accurate. In the fifty years that followed no similar experiments on water and steam comparable in accuracy are recorded.

No matter how carefully his experiments were done, they could not have yielded results as near to the truth as can now be obtained with the aid of more advanced theory, more definitely established standards, and improved laboratory apparatus. It is not possible, with any considerable degree of certainty, to interpret the temperatures which he recorded in terms of the present international scale. For these reasons, no attempt will here be made to reduce his results to a comparative basis. They are considered instead as an important milestone which it took years to reach, but which has now been left far behind.

(2) Reynolds and Moorby

In the experiments of Reynolds and Moorby[17] the value of the mean calorie was measured directly in terms of mechanical units with a modified Froude brake. This work was done on an engineering scale, and many precautions were taken to insure the precision of the results. The principal corrections were for thermal leakage and liberation of dissolved air. Some errors were probably introduced by formation of vapor, by variations in the speed at which the driving engine ran, and because thermometry at that time was not on an entirely satisfactory basis. On the average the water entered the brake at a temperature of about 1.3 deg. cent. and a pressure of about 2 atmospheres, and left it at a temperature of about 100 deg. cent. and a pressure of about 1.8 atmospheres. A correction was applied for the energy change due to the pressure drop through the system, so that the value recorded is the mean specific heat of water between 1.3 deg. cent. and 100 deg. cent. at a constant pressure of 2 atmospheres. As the mean of 26 separate determinations Reynolds and Moorby report this mechanical equivalent as 4.1832×10^7 ergs per gram degree centigrade along the 2-atmosphere line. If the figure 1.0004 is taken as the ratio between the international and the absolute joule,[18] this value becomes 4.1815 international joules per gram degree centigrade. It may be further corrected to the saturation path by the following method.

The value for the change in heat content with pressure at constant temperature can be evaluated through the relation

$$\left(\frac{\partial H}{\partial P}\right)_\theta = V - \theta\left(\frac{\partial V}{\partial \theta}\right)_P \quad \ldots\ldots [1]$$

in which the right-hand member can be evaluated with sufficient precision from data on specific volumes and coefficients of thermal expansion given in the International Critical Tables. The corrections desired are then the products $\left(\frac{\partial H}{\partial P}\right)_\theta (1 - \pi)$ when the values $\pi = 0.0066$ atmosphere at 1.3 deg. and $\pi = 1$ atmosphere at 100 deg. are substituted. The change in heat content along the saturation path from 1.3 deg. to 100 deg. is greater by $0.206 - 0.076 = 0.13$ international joule per gram than it is along the 2-atmosphere path.

Reynolds and Moorby's value for the change in heat content from 1.3 deg. to 100 deg. along the saturation path becomes $4.1815 \times 98.7 + 0.13 = 412.84$ international joules per gram. The value for the change in heat content of water between 0 deg. and 100 deg. is obtained by adding to this the Bureau of Standards value for the change in H from 0 deg. to 1.3 deg. = 5.49 international joules per gram. The result thus obtained from the work of Reynolds and Moorby is 418.33 international joules per gram for the change in heat content of water between 0 deg. and 100 deg. along the saturation path.

(3) Dieterici

Dieterici's[19] experiments consisted in the introduction of quartz tubes at known temperatures, first empty and then containing known masses of water, into a Bunsen ice calorimeter and observing the contraction in volume due to the fusion of ice. This contraction, which he expressed in milligrams of mercury, is a measure of the heat lost by the tube or the tube and contents when its temperature changed from the initial value θ to 0 deg. cent. By difference the contraction due to the cooling of the water sample alone was obtained. Expressing by $Q]_0^\theta$ this heat lost by the water and by C_m an integrated mean specific heat which is to be experimentally determined, Dieterici's results were evaluated through the equation

$$Q]_0^\theta = m\rho]_0^\theta + MC_m\theta]_0^\theta \quad \ldots\ldots [2]$$

in which

$$m\rho]_0^\theta = \left[(V - Mu) \left(\Theta \frac{d\pi}{d\theta} - \pi \right) \right]_0^\theta \quad [3]$$

This correction $m\rho]_0^\theta$ takes into account the energy changes in the ever-present vapor phase. Since the volume change of the retaining tubes due to changes in temperature and pressure is negligible, the heat exchange of the contents becomes identical with the loss of internal energy.

For any state,

$$E_x = Mx\epsilon' + M(1 - x)\epsilon = M\epsilon + Mx(\epsilon' - \epsilon) \quad [4]$$

and

$$V = Mxu' + M(1 - x)u = Mu + Mx(u' - u) \quad [5]$$

Solving,

$$x = \frac{V - Mu}{M(u' - u)} \quad [6]$$

Hence

$$E_x = M\epsilon + (V - Mu) \frac{\epsilon' - \epsilon}{u' - u} \quad [7]$$

But

$$L = \epsilon' - \epsilon + \pi(u' - u) = \Theta \frac{d\pi}{d\theta} (u' - u) \quad [8]$$

Hence

$$\frac{\epsilon' - \epsilon}{u' - u} = \Theta \frac{d\pi}{d\theta} - \pi \quad [9]$$

and

$$E_x = M\epsilon + (V - Mu) \left(\Theta \frac{d\pi}{d\theta} - \pi \right) \quad [10]$$

But

$$Q]_0^\theta = E_x]_0^\theta = MC_m\theta]_0^\theta + \left[(V - Mu) \left(\Theta \frac{d\pi}{d\theta} - \pi \right) \right]_0^\theta \quad [11]$$

From which

$$[C_m\theta]_0^\theta = \epsilon]_0^\theta \quad [12]$$

Dieterici records experimental values of C_m and θ, and, as shown, the product of these is the specific internal-energy change of the saturated liquid. His values of the correction term $m\rho]_0^\theta = \left[(V - Mu) \left(\Theta \frac{d\pi}{d\theta} - \pi \right) \right]_0^\theta$ were calculated from the best values of u, π, and $\frac{d\pi}{d\theta}$ then available. In order that the values of the contractions which he observed in milligrams of mercury could be converted into more convenient units, he made very careful direct determinations of the volume changes produced by the addition of measured quantities of electrical energy.

With the experimental data now available it is possible to interpret his results directly in international joules without reference to his experimentally determined electrical equivalent of the calorimetrically observed quantity. His results at 100 deg. cent. furnish, in effect, a direct determination of the equivalent of the mean calorie in terms of milligrams of mercury. This value in milligrams of mercury corresponds to the value of the mean calorie in international joules, which is now known to a greater precision than he could have obtained with his observations on electrical equivalent. When this method is used to calculate the results of his measurements, all difficulties arising from the evaluation of his electrical standards and from the changes which electrical units have since undergone are avoided.

From recent experiments it is possible to evaluate the correction term $m\rho]_0^\theta$ more exactly than before. At the same time a term of the magnitude πu can be introduced to convert the internal-energy changes into changes of heat content.

As above

$$Q]_0^\theta = M\epsilon]_0^\theta + \left[(V - Mu) \left(\Theta \frac{d\pi}{d\theta} - \pi \right) \right]_0^\theta \quad [13]$$

But

$$\Theta \frac{d\pi}{d\theta} = \frac{L}{u' - u} = \frac{\beta}{u} \quad [14]$$

Hence

$$Q]_0^\theta = M\epsilon]_0^\theta + \left[(V - Mu) \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta \quad [15]$$

Adding $M\pi u]_0^\theta$ to both sides

$$Q]_0^\theta + M\pi u]_0^\theta = M\epsilon]_0^\theta + M\pi u]_0^\theta + \left[(V - Mu) \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta \quad [16]$$

Whence

$$Q]_0^\theta + M\pi u]_0^\theta = MH]_0^\theta + \left[(V - Mu) \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta \quad [17]$$

Expanding and collecting

$$Q]_0^\theta = MH]_0^\theta + \left[V \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta - M\beta]_0^\theta \quad [18]$$

But

$$H]_0^\theta = [\alpha + \beta]_0^\theta \quad [19]$$

Hence

$$Q]_0^\theta = M\alpha]_0^\theta + \left[V \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta \quad [20]$$

Considering now the experiments at 100 deg. cent., if $Q]_0^\theta$ is expressed in milligrams of mercury and both terms in the right-hand member in international joules, we may write

$$KQ]_0^\theta = M\alpha]_0^\theta + \left[V \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta \quad [21]$$

from which the value of the conversion factor K can be determined. Values of α and β are obtainable from the previous paper,[9] and values of π and u, which enter only in the relatively small correction term, from the best sources now available. There are 13 experiments in the neighborhood of 100 deg., each of which yields a value of K.

The 13 values of K thus obtained yield a mean value of 0.27024 international joules per milligram of mercury when the experiments are weighted according to Dieterici's estimate of their reliability. They are very consistent, the maximum deviation from the mean being about 1 in 720 and the average 1 in 1380. The accuracy of the chosen mean value of K is doubtless greater than the experimental accuracy at temperatures other than 100 deg., because of the greater number of experiments performed at that temperature, and because of the comparative ease of maintaining and determining the steam point.

To transform Equation [20] given above into a form convenient for the calculation of heat content, add $M\beta]_0^\theta$ to both sides and collect.

$$M\alpha]_0^\theta + M\beta]_0^\theta = 0.27024\, Q]_0^\theta - \left[V \left(\frac{\beta}{u} - \pi \right) \right]_0^\theta + M\beta]_0^\theta = MH]_0^\theta \quad [22]$$

$$H]_0^\theta = \frac{0.27024\ Q]_0^\theta}{M} - \frac{V}{M}\left[\frac{\beta}{u} - \pi\right]_0^\theta + \beta]_0^\theta \ldots\ldots [23]$$

At any temperature the terms in the right-hand member of this equation can be evaluated from the same sources as at 100 deg. Dieterici's data give the values of $Q]_0^\theta$ corrected for heat leak, the values of M corrected for buoyancy, and the measured values of V. Hence $H]_0^\theta$ can be evaluated at each temperature for which data are given.

Making use of the Bureau of Standards data his values of H have been reduced to even temperatures for convenience in making comparisons with others. Table 1 shows the results of Dieterici's experiments as obtained by this method of calculation.

TABLE 1 HEAT CONTENT OF SATURATED LIQUID WATER, CALCULATED FROM DIETERICI'S EXPERIMENTS

Temperature θ deg. cent.	Heat content H Int. joules per gram	Temperature θ deg. cent.	Heat content H Int. joules per gram
15	63.10	100	418.75[a]
20	83.82	110	461.1
25	104.6	130	546.6
30	125.6	156	660.6
35	146.2	183	776.5
46	192.2	200	852.6
56	234.2	221	946.2
65	271.8	240	1034.7
78	326.4	259	1126.7
88	368.2	303	1348.9

[a] This value has been made to correspond exactly with the Bureau of Standards value by the method of computation.

The accuracy of the temperature measurements, which were made with mercury in glass thermometers calibrated at the Reichsanstalt, was probably so good that the thermometry did not limit the overall accuracy of the experiments. How nearly the water containers assumed the same temperature as that observed for the bath is less certain. Heat-leak corrections were small, and though there is little discussion of how they were obtained, it is believed that they furnished only a minor portion of the error in the final results. At the high temperatures the values of V become more significant, and higher precision in the determination of these would have increased the accuracy of the results. As a whole the research seems to have been carried out with great care and skill, and claims the admiration of the careful reader.

(4) Barnes

Barnes[14] gives a very detailed account of his researches on the heat capacity of water between 5 deg. and 95 deg., using a flow calorimeter of the so-called "continuous electric" type designed in cooperation with Callendar.[11]

Water was admitted into a vacuum-jacketed glass calorimeter at a steady but controllable rate, and its temperature was raised by means of an electric heater located in the stream between a pair of differential resistance thermometers which indicated the temperature rise. The amount of water which had passed through the calorimeter was determined by weighing. The experiments were performed at a constant pressure differing from the atmospheric pressure by the small pressure head used to maintain the flow.

For the electrical equivalent of the mean specific heat between 5 deg. and 95 deg., Barnes gives 4.1888 joules, referred to the international ohm and the volt defined as 1/1.4342 of the e.m.f. of the Clark cell at 15 deg. In a recomputation of his results in 1909[20] he expressed the belief that the voltage of the Clark cells at 15 deg. as used in 1902 was 1.4333. This reduces the results previously published by 1 part in 798. Thus recomputed, the value of 4.1888 joules per gram for the mean specific heat between 5 deg. and 95 deg. becomes 4.1835 joules per gram. Correcting for the end intervals he obtained the value 4.1849 international joules per gram for the equivalent of the mean calorie along the atmospheric-pressure path. In 1910 the value of the international volt was reassigned, using as a standard the Weston normal cell having an e.m.f. at 20 deg. of 1.0183 international volts. In terms of this standard of 1910, Clark cells made up according to the old specification have an e.m.f. at 15 deg. of 1.4328 volts.[21] This may be considered at least a probable value for the Clark cells used by Barnes in terms of the present system. This value further reduces his mechanical equivalent of the mean calorie along the atmospheric-pressure path by 1 part in 1433, to 4.1820 international joules per gram. This value, corrected to saturation pressure, becomes 4.1830 international joules per gram.

In Laby's[22] critical discussion of the mechanical equivalent of heat, the results of Barnes, among others, are reduced to absolute units. Since the values are desired here in international units, and since Laby discusses only the 20-deg. calorie, no comparison with the results given in his review is included.

Without reference to the report of Barnes in 1909, his values for the specific heats can be transformed into present international units as follows. In his original computations the value assigned to the Clark cell at 15 deg. was 1.4342 volts. As stated above, the e.m.f. of Clark cells made up according to the same specifications is 1.4328 international volts. Therefore the values of specific heat as originally reported can be transformed into present international joules by reducing them by 1 part in 512.

Barnes represents his data as finally reduced by three equations, appropriate over the temperature intervals indicated.

$$(5°\text{–}37.5°)\quad C_p = 0.99722 + 0.0000035\ (37.5 - \theta)^2 + 0.00000010(37.5 - \theta)^3 \ldots\ldots [24]$$

$$(37.5°\text{–}55°)\quad C_p = 0.99722 + 0.0000035\ (\theta - 37.5)^2 + 0.00000010(\theta - 37.5)^3 \ldots\ldots [25]$$

$$(50°\text{–}100°)\quad C_p = 0.99839 + 0.000120\ (\theta - 55) + 0.00000025(\theta - 55)^2 \ldots\ldots [26]$$

These are in terms of his own mean calorie, and yield, on integration with respect to temperature, values for the changes in heat content in mean calories. The integrated equations are

$$H]_0^\theta = 0.99722 - 0.00000117(37.5 - \theta)^3 - 0.000000025(37.5 - \theta)^4 \ldots\ldots [27]$$

$$H]_{37.5}^\theta = 0.99722 + 0.00000117(\theta - 37.5)^3 + 0.000000025(\theta - 37.5)^4 \ldots\ldots [28]$$

$$H]_{55}^\theta = 0.99839 + 0.000060(\theta - 55)^2 + 0.000000083(\theta - 55)^3 \ldots\ldots [29]$$

To transform the values calculated from these equations into a form convenient for comparison, two further corrections are applied. Since the first equation is valid only down to 5 deg., the value of $H]_0^5 = 5.02$ mean calories is supplied from the Bureau of Standards data. Further correction is necessary to reduce the results to the saturation pressure for each temperature recorded. The method of calculation of these corrections has already been described. Table 2 gives the values of heat content calculated from Barnes's equations, the corrections to reduce them to the saturation pressures and, in the last column, the values along the saturation path. The figure 418.30 inter-

[22] Proc. Phys. Soc. London, vol. 38 (1925–26), pp. 169–175.

national joules per gram as derived above from Barnes's own measurements is used for the conversion of mean calories to international joules.

TABLE 2 HEAT CONTENT FROM BARNES'S SPECIFIC-HEAT EQUATIONS

Temperature θ	Heat content (P = 1 atm.) $H_{1atm.}$	$\left(\frac{\partial H}{\partial P}\right)_\theta (1-\pi)$	Heat content ($P = \pi$) H	Heat content ($P = \pi$) H
deg. cent.	Mean calories per gram			Int. joules per gram
10	10.03	0.02	10.05	42.04
20	20.04	0.02	20.06	83.91
30	30.02	0.02	30.04	125.66
40	39.99	0.02	40.01	167.36
50	49.97	0.02	49.99	209.11
60	59.95	0.02	59.97	250.85
70	69.95	0.01	69.96	292.64
80	79.96	0.01	79.97	334.51
90	89.98	0.00	89.98	376.39
100	100.01	0.00	100.01	418.30

The chief uncertainty in the value of the heat content of water at 100 deg. expressed in international joules per gram from the experiments of Barnes lies in the interpretation of the e.m.f. of the Clark cells used. The value which seems most probable to the reviewer is 418.30 international joules per gram.

In a glass apparatus of the type used by Barnes, the evaluation of the heat leak (4 per cent of the total energy supplied in the extreme case), including the heat effects observed and interpreted as due to adsorption or liberation of residual gas in the evacuated jacket, is a difficult task.

The temperature scale used in these experiments was substantially the same as the present international scale. Observations of temperature differences with the differential resistance thermometers were probably sufficiently precise. The precision with which the electrical measurements were made appears to have been ample. The assumption that the walls of the weighing vessel always retained the same mass of liquid may have been a source of error. The possibility of formation of vapor and liberation of dissolved gas within the calorimeter are inherent in the method and the effects are difficult to evaluate.

To obtain an accuracy of better than 1 part in 1000 in this type of experiment requires a degree of refinement in the calorimetry itself which is not easily attained. It appears that there may have been possible sources of systematic error, some of which have been mentioned and several of which may have exceeded 1 part in 10,000. In the absence of positive supporting evidence it seems that Barnes's estimate of accuracy of 1 part in 10,000 may have been too optimistic.

The reader of Barnes's report is impressed with the remarkable care and skill with which the experimental program was planned and executed, and this piece of work remains one of the outstanding contributions to our knowledge of the heat capacity of water.

(5) Callendar

Callendar spent many years in the investigation and formulation of the properties of steam. In his work on the liquid he is responsible for the development of two types of calorimetry which he has described as the continuous electric method and the continuous mixture method. The former method was used by Barnes in the researches already described, and the results of this investigation are correctly attributed to Callendar and Barnes. At a later date Callendar[23] alone performed experiments by the second method to test the ratios of the specific heats reported by Barnes and found good agreement between the methods. He stated that the method of mixtures was more dependable than the electric method because the heat leak was reduced from about 4 per cent to about $^1/_2$ per cent of the total energy changes involved.

[23] Phil. Trans. Roy. Soc. London, vol. A212 (1912–13), pp. 1–32.

In not only this work of 1912, but also in all the succeeding reports which Callendar has published, the reviewer has little opportunity to appraise the experimental work as such, because practically no experimental data are given. Instead, Callendar has chosen always to formulate his experimental data through equations into tables of the properties most desired. These tables must be taken as representing the best values indicated by his own experiments, but the data of other observers are included in the reductions in such a way that it is impossible to separate them.

Beyond the knowledge that Callendar was an exceptionally brilliant, skilful, and painstaking experimenter who devoted much time to investigations in his chosen field, the lack of published experimental data precludes an estimation of the absolute accuracy of his experimental results, or the agreement between these results and his tabulated values.

Therefore, for the purposes of this comparison, the values taken from his latest steam tables[24] are used as best representative of his entire group of measurements.

Callendar's equation for the heat content of the liquid is

$$H = k(\theta - c) + \frac{Lu}{u' - u} \quad [30]$$

in which k and c are constants. The last term in this equation is the quantity β measured experimentally at the Bureau of Standards, and from the relation

$$H = \alpha + \beta \quad [31]$$

it follows directly that, according to the Callendar formula,

$$\alpha = k(\theta - c) \quad [32]$$

and that

$$\frac{d\alpha}{d\theta} = k \quad [33]$$

The quantity α has been very carefully determined by direct calorimetric measurements at this Bureau at each 10-deg. interval from 0 deg. to 270 deg. These results indicate that the value of $d\alpha/d\theta$ is practically constant in the range 50 deg. to 170 deg., but outside this range it varies considerably. Callendar recognized that his equation was inadequate in the region from 0 deg. to the temperature of the minimum specific heat of water, but accepted it nevertheless, because of its simplicity, its degree of approximation to the truth, and the relative unimportance to the engineers of the values calculated from it in the range near the freezing point. His own experimental evidence confirming the validity of the equations at high temperatures is not at hand. According to the Bureau of Standards data the value of $d\alpha/d\theta$ decreases from a practically constant value of 4.17 international joules per gram degree centigrade in the range 50 deg. to 170 deg. to about 4.10 international joules per gram degree centigrade at 270 deg.

Since the quantity $\beta = Lu/(u' - u)$ is small in comparison with α, the discrepancy in the values of H at the higher temperatures is due largely to the difference in the evaluation of the variation of α with temperature.

Callendar's values of H' doubtless have as a basis his numerous experiments in the superheat region. His values of H are from the equation discussed above, which was based on the work of Callendar, Barnes, and probably Dieterici in the high-temperature range.

In Table 3 are shown, in international joules, the values of H and H' from the most recently published Extended Steam Tables.[24]

[24] Proc. Inst. Mech. Eng., no. 3 (1929), pp. 507–527.

TABLE 3 CALLENDAR'S VALUES OF HEAT CONTENT

Temperature θ deg. cent.	Heat content: Of liquid H	Heat content: Of vapor H'
	International joules per gram	
0	0	2488.3
50	208.77	2584.2
100	418.54	2675.7
150	631.62	2751.8
200	852.14	2801.7
250	1087.36	2818.4
270	1187.81	2811.3

(6) Jaeger and von Steinwehr

The experiments of Jaeger and von Steinwehr on the heat capacity of water from 5 deg. to 50 deg. cent., performed in 1911–12 and published in 1915[25] and more completely in 1921,[15] have been the basis for the value of the 15-deg. calorie used by the Reichsanstalt. Their calorimeter containing 50 liters of water at atmospheric pressure was heated electrically, in steps of about 1.4 deg., and the rise in temperature was observed with resistance thermometers. A stirrer aided in the distribution of the heat added, and itself added mechanical energy at the rate of over 60 joules per minute. The heat capacity of the calorimeter, stirrer, and accessories was calculated from the masses of the parts and their specific heats, and was considered constant over the temperature range covered. The time of electrical heating was automatically recorded with sufficient precision by a chronograph. The temperature scale and the electrical units employed were substantially those now in use by international agreement.

The evaluation of the correction which includes thermal leakage and pump energy was carried to considerable lengths theoretically, but there is some doubt that the values so obtained were sufficiently accurate. No statement was made concerning the constancy of the pump speed.

In an effort to gain sensitivity, the measuring current through the thermometer was increased to 0.08 ampere. Such a procedure throws doubt upon the accurate indication of temperature changes to 0.0001 deg., because of the heating of the thermometer itself. This suspicion is supported by the fact that a considerable rate of stirring was required in order that the temperature change of the calorimeter would appear regular during the periods when no energy was being supplied in the heating coil. The temperature intervals were so small that the assumption of the constancy of the specific heat in any interval was entirely justified.

The capacity of the calorimeter was chosen so that the mass of the water sample was large compared to the water equivalent. The calorimeter was not tightly sealed and there was the possibility of the loss of water vapor. Great care was taken with the electrical measurements, and the only questionable point here is the heating of the standard 0.1-ohm resistor due to the current in it, during observations of the current through the heater.

From a total of 111 experiments, 37 were rejected because of known faults in manipulation, etc. An empirical equation of specific heat as a function of temperature was fitted to the remaining 74 points by the method of least squares. The consistency of the experimental points is indicated by the fact that they lie so well on a smooth curve, the average deviation from the curve being 1 part in 2350.

Their equation

$$C_p = 4.20477 - 0.001768\ \theta + 0.000026447\ \theta^2 \ldots [34]$$

yields on integration with respect to temperature

$$\int_1^2 C_p d\theta = H]_1^2 = 4.20477\theta]_1^2 - 0.000884\ \theta^2]_1^2 + 0.000008816\ \theta^3]_1^2 \ldots\ldots [35]$$

[25] Sitzungber. d. Berl. Akad. (1915), p. 424.

The values of changes in heat content along the atmospheric pressure path can be computed from this equation. Corrections to the saturation path are the same as those given in the discussion of the work of Barnes.

Table 4 shows in column 2 the values of H for water under a constant pressure of 1 atmosphere from the above equation, in column 3 the corrections necessary to reduce these to saturation pressures, and in column 4 the values thus reduced.

TABLE 4 HEAT CONTENT FROM JAEGER AND VON STEINWEHR'S SPECIFIC-HEAT EQUATION

Temp. θ deg. cent.	Heat content (P = 1 atm.) H_1 atm.	$\left(\frac{\partial H}{\partial P}\right)_\theta (1 - \pi)$	Heat content ($P = \pi$) H
	International joules per gram

50	209.13	0.08	209.21

2—DETERMINATIONS OF LATENT HEAT

(1) Dieterici

Using a Bunsen ice calorimeter, Dieterici[26] made twenty determinations of the latent heat of water at 0 deg. cent. Considering the early date of this work and the comparative simplicity of his apparatus, the results seem remarkably good. He vaporized the water at pressures slightly below the vapor pressure at 0 deg. cent. from small containers of glass or of platinum surrounded by a considerable quantity of mercury, and observed the increase in volume of the ice-water mixture in the calorimeter around the mercury. Several errors could have affected the final results. Some water could have been lost as vapor from the capsule between the time it was weighed and the time it was connected to the lead-in tube in the calorimeter. Some was doubtless lost as vapor to fill the tube system itself. The adiabatic expansion of the air in the system could have produced some cooling, though Dieterici states that this was negligible. His data for the evaluation of the heat leaks must be taken as given because of the lack of the details of their computation. There is an uncertainty as to the amount of energy involved in the expansion of the vapor after all the liquid had evaporated. Uncertainties in units can be avoided by using the conversion factor $K = 0.27024$ international joules per milligram of mercury as derived above and based on his own determinations of the mean calorie and the Bureau of Standards value of the electrical equivalent of the mean calorie. The twenty experiments thus reduced yield a mean value of 2490.6 international joules per gram as the latent heat at 0 deg. cent. The average deviation of the individual experiments from this mean is 1 part in 847.

(2) Griffiths

Among the earlier determinations of latent heat are those of Griffiths.[27] He reported determinations by a vaporization method under reduced pressures at 30 deg. and 40 deg. That part of his apparatus in which the thermal changes were isolated and observed, consisted essentially of a small oil bath, mechanically stirred and electrically heated, from which water was vaporized. This unit was located inside an iron box containing a large quantity of mercury for thermal ballast and for activating the thermoregulator which automatically maintained the temperature of the surrounding water bath. Temperatures were observed with mercury thermometers carefully calibrated and corrected. Temperature differences between the calorimeter and its surroundings were measured with differential platinum resistance thermometers.

[26] *Ann. Phys.*, vol. 273 (1889), pp. 494–508.

[27] Phil. Trans. Roy. Soc. London, vol. A186 (1895), part I, 261–342.

Because of the method of operation adopted, namely, the evaporation of the entire water sample in the calorimeter, the end effects were rather large and troublesome. The energy supplied by the stirrer amounted to about 1 per cent of the total and could be determined to within 1 part in 50 of itself. Griffiths considered this the limiting error in his experiments. The heat leak was on the average about 0.1 per cent of the total energy change involved, a fact which increases the confidence in the final results.

By passing the vapor through 18 ft. of silver tube in the oil of the calorimeter proper, the danger of priming was lessened. The possibility that the vapor was superheated was small, and the likelihood of error from this source is not large.

The greatest uncertainty in the reduction of these data to a comparative basis lies in the evaluation of the Clark cells used, in terms of present international volts. Assuming that his cells were made up according to the specifications of the Chicago Congress of 1893, their e.m.f. on the present basis becomes 1.4328 international volts.[21] Since Griffiths assigned the value 1.434 volts to his cells at 15 deg., his results as given must be reduced by 1 part in 600 for conversion to present units. The individual experiments have also been corrected to even temperatures with the aid of the Bureau of Standards values of $dL/d\theta$. The mean results from 7 experiments near 30 deg. and 11 near 40 deg. are

$$L_{30^\circ} = 2426.0 \text{ international joules per gram}$$
$$L_{40^\circ} = 2400.5 \text{ international joules per gram}$$

At 30 deg. the individual experiments are in very good agreement, the average deviation from the mean being 1 part in 5170. At 40 deg. the average deviation from the mean is 1 part in 1500. In spite of the greater number of experiments at 40 deg., it appears that the mean value at 30 deg. is probably the more accurate of the two.

(3) A. W. Smith

A. W. Smith[28,29] has made determinations of the heat of evaporation of water at five temperatures below 100 deg. He lays considerable stress on the advantages of the method which he used of allowing quiet evaporation to proceed in a stream of air passing over the surface of the evaporating fluid. In the earlier work the stream of air was allowed to bubble through the water, and the stirring was accomplished in this manner. In these experiments the corrections for thermal leakage were considered negligibly small. In the later experiments which constituted a determination of the latent heat at 100 deg cent., the stirring was accomplished mechanically and the air did not bubble through the liquid. Experiments were run at various rates and the thermal leakage and pump energy effects were thus eliminated, provided they remained the same in any two experiments which were combined. No correction was applied for the heat effect involved in the expansion of the vapor from saturation pressure down to the partial pressure which it exerted in the mixture of air and vapor. In the reports mentioned above there are not sufficient data on the rate of passage of air to permit calculation of this correction. Professor Smith's privately communicated estimate is that, in the experiments at 100 deg. cent., the amount of air was not greater than 1 liter for 5 grams of water evaporated. If this maximum amount flowed in all the experiments at 100 deg., the value of the latent heat from each should be decreased by about 1 joule per gram. For all the determinations below 100 deg. where the specific volume of the vapor is relatively large, this correction is doubtless negligibly small.

The measurements of temperature and of power supplied to the calorimeter were sufficiently precise, so that they do not limit the accuracy of the final results.

The masses of the water evaporated were carefully determined, but where the samples were as small as 2 or 3 grams, as they were in all the earlier experiments, the absolute accuracy becomes more important and is somewhat open to question. No mention is made of the means employed to keep the pump power constant in the stirred calorimeter. A comparison of the results of the individual experiments does not indicate a high degree of reproducibility. For instance, at 100 deg. cent., where the consistency is best, the average deviation from the mean is 1 part in 1000.

A series of four determinations at 100 deg. was made with active boiling and very small flows of air. The average result of this series is 16.7 joules per gram lower than the average of a large series in which the evaporation took place quietly. This low result is explained as being due to the carrying over of unevaporated droplets of water in the air-water stream.

To the reviewer it appears that the danger of priming has often been greatly overestimated. The experimental values for the latent heat are, in nearly every case at hand, independent of the rate of withdrawal of vapor. Mathews[30] records test experiments which indicate the absence of unevaporated droplets in a region above the surface of actively boiling water.

The details of the latter series of experiments by Smith seem too meager to justify his explanation of the low results. For the same reason the formulation of an alternative hypothesis is precluded.

In Table 5 are given the results of Smith's experiments.

TABLE 5 LATENT HEATS FROM SMITH'S EXPERIMENTS

Temperature, deg. cent.	Latent heat, Int. joules per gram
14	2463.5
21	2447.6
28	2431.1
40	2401.4
100	2261.6

The data recorded in the report of 1907 have been converted into present international joules by decreasing the values as recorded in terms of the Clark cell at 15 deg. = 1.434 volts by 1 part in 600 in the latent heats, to conform to the value 1.4328 international volts as previously used in this paper. Corrections to the temperatures indicated have been made using the Bureau of Standards values for $dL/d\theta$.

Application of the above-mentioned correction of one joule per gram for the superheating of the vapor due to its drop in pressure would reduce the latent heat at 100 deg. to 2260.6 international joules per gram. Since one joule per gram is the maximum to which this correction could have amounted, it can be stated only that according to the best information from Smith's experiments the latent heat at 100 deg. is not less than 2260.6 international joules per gram.

(4) Richards and Mathews

Determinations of latent heat at 100 deg. by Richards and Mathews[31] and by Mathews,[30] using a condensation method, were carefully performed. This method possesses the obvious disadvantages that accurate knowledge of the heat capacity of the calorimeter and of the heat content of water is necessary for the reduction of the data. Mathews points out an uncertainty in the heat capacity of his calorimeter equivalent to 1 part in 500 in the latent heat, and calls attention to the fact that the error from this source in the earlier experiments was probably 2 parts in 500. Both papers assume a mean

[28] *Phys. Rev.*, vol. 25 (1907), pp. 145–170.
[29] *Phys. Rev.*, vol. 33 (1911), pp. 173–183.
[30] *Jl. Phys. Chem.*, vol. 21 (1917), pp. 536–569.
[31] *Jl. Am. Chem. Soc.*, vol. 33, (1911), pp. 863–888.

specific heat for water between 20 deg. and 100 deg. of 1.0012 times the specific heat at 21.4 deg.

Because of so-called "premature condensation" it was found necessary to extrapolate linearly the values of latent heat plotted against rate of condensation to an infinite rate. Consideration of heat leak alone, which disappears at the infinite rate, forms a more logical basis for such a procedure. It is assumed in the following that the same method of operation and reduction of the data was used by Mathews as that employed in the earlier work. Heat leak was measured experimentally with no flow of steam through the tube connecting the evaporator and the condenser. The value so determined is greater than the true heat leak during an experiment because of the change in gradient in the connecting tube due to the passage of hot steam through it. On account of the warming of the lower part of the tube thus produced, there is less heat flow down it from the evaporator to the calorimeter.

Let—

- Q = heat transferred to the calorimeter by the condensing steam corrected for everything except the heat leak during the flow period
- A = heat leak per minute as determined experimentally without flow and as actually used in their reduction of the data
- B = the true heat leak per minute with steam flowing
- L_c = latent heat as Richards and Mathews calculated it
- L = value of latent heat as here recalculated
- M = mass of vapor condensed, and
- t = time during which steam was flowing

Then

$$L_c = \frac{Q - At}{M} \quad \text{and} \quad L = \frac{Q - Bt}{M} \qquad [36]$$

Subtracting,

$$L - L_c = \frac{(A - B)t}{M} \qquad [37]$$

or

$$L = L_c + \frac{(A - B)t}{M} \qquad [38]$$

As suggested above $(A - B)$, is a positive quantity and, over the moderate range of flows used in the experiments, is probably constant. Therefore the values of L_c as calculated by Richards and Mathews are always lower than the true experimental values by the amount $(A - B)t/M$. The quantity t/M is the time required for condensation of one gram and is the abscissa of the curve used by them in the extrapolation to infinite flow. As the value of t/M increases, that is, the slower the rate of condensation, the more does L_c deviate linearly from L. It follows that the method of correction to the infinite rate was correct, but that the theory of "premature condensation" was superfluous. The question of the deviations from the straight line, which might appear if the flows could be made to approach infinity, does not enter, because the slope only is of importance in the calculation of the results.

The data from the 1911 paper have been recomputed, using the correction to the water equivalent which Mathews later suggested. The data from both sets of experiments have been calculated, using the Bureau of Standards values for the heat content of water.

Because two different vaporizers were employed in the earlier work, the data must be treated in two parts. The results of the recalculation are given in Table 6.

TABLE 6 LATENT HEATS FROM EXPERIMENTS OF RICHARDS AND MATHEWS

Year	Latent heat at 100 deg. L Int. joules per gram
1911	2256.5
1911	2253.5
1917	2255.2

It appears that it is the systematic errors, especially the uncertainties in the heat capacities of the calorimeters, which limit the accuracy of the final results of these experiments. Professor Mathews expressed the opinion, in a private communication, that the values of the heat capacities of the calorimeters as used in these calculations are slightly low, but he did not wish to suggest definite numerical changes in them. As a heavier vaporizer was used in the second series of 1911, it may be that the water equivalent in this set should have been corrected by more than the two grams originally suggested by Mathews.

(5) Henning

Among the more important determinations of the latent heat of water are those of Henning.[32,33] His method consisted essentially of vaporizing the water from a calorimeter in a thermostatted bath and collecting the distillate in a condenser vessel in which the pressure was maintained as nearly as possible equal to the pressure in the calorimeter by means of an atmosphere of inert gas. Determinations at eleven different temperatures between 30 deg. cent. and 180 deg. cent. are recorded. His own reduction of these values is summarized in terms of present international units in a brief report published in 1919.[34] This summary gives values of latent heats at 10-deg. intervals from 30 deg. to 180 deg., obtained by smoothing the experimental values and interpolating with the aid of empirical equations at intermediate temperatures. His own choice of equations to best fit his data is considered adequate, and probably better than one made by one less familiar with the work. Among the individual experiments at any given temperature there is rather large variation, but in general the experiments were so numerous that the effect of accidental errors on the final results has been reduced. At the higher temperatures the number of experiments was not so large and the results are consequently less certain. In the calculation of the mass of vapor which is evaporated but remains in the calorimeter to fill the space left vacant by the removal of water, an approximation is involved, but the error from this source is negligibly small below 180 deg.

Table 7 shows the values of latent heat which Henning recorded in 1919.

TABLE 7 HENNING'S VALUES OF LATENT HEAT

Temperature, θ deg. cent.	Latent heat, L Int. joules per gram	Temperature, θ deg. cent.	Latent heat, L Int. joules per gram
30	2426.0	110	2228.5
40	2403.8	120	2200.1
50	2380.8	130	2170.3
60	2357.4	140	2139.8
70	2333.1	150	2109.7

90	2282.5	170	2049.4
100	2255.7	180	2019.7

(6) Jakob

Using a method almost identical with that of Henning, but with a new apparatus designed for use at higher temperatures, Jakob,[35] and Jakob and Fritz[36] have continued the latent-heat determinations from 180 deg. These reports give values through 250 deg., but the experiments have since been extended to about

310 deg. cent. This is an unusually comprehensive undertaking, the final results of which are not yet available. Therefore no attempt is made to include a comparison of such preliminary results of this work as are at hand with those of other experimenters.

(7) Carlton-Sutton

The determinations by Carlton-Sutton[37] of the latent heat at 100 deg. deserve special prominence among the other investigations of this important constant. Using a modification of Joly's classical apparatus, he measured the heat of condensation of water directly in terms of the mean calorie without any reference to electrical standards. He weighed in place the steam which was condensed on a glass bulb to change its temperature from 0 deg. cent. to 100 deg. cent. By performing experiments, first with the bulb nearly filled with pure water and then with the bulb containing a much smaller amount of water, he was able to eliminate its heat capacity as well as many other small factors which would otherwise have appeared as corrections. The difference in the masses of steam condensed in two such experiments is that amount which would change the temperature of a mass of water corresponding to the difference of the two bulb fillings from 0 deg. to 100 deg.

If the thermal conditions during the two experiments were alike, as was doubtless very nearly the case, no corrections for heat leak are required. Corrections were applied for thermal changes occurring within the bulb and for various other small elements involved in the method. The correction for the thermal changes in the bulb has been independently recomputed and found valid. Although the water in the bulb was heated under a total pressure greater than its vapor pressure, the method of calculation of the correction takes this into account and reduces the data to mean calories defined by the saturation path.

To obtain an accuracy of 1 part in 5000 requires that the masses be accurate to 0.1 milligram. In this factor the author's estimate seems somewhat optimistic. He considers that the formation of a vapor cloud upon admitting the steam into the condensing chamber at 0 deg. is the limiting error. It seems probable that the error in determining the masses is at least as great.

The deviations among the individual determinations indicate a high degree of experimental precision.

The final reported value of 538.88 mean calories, when interpreted in terms of the Bureau of Standards mechanical equivalent of 4.1875 international joules per gram, yields for the latent heat of water at 100 deg. the value 2256.6 international joules per gram.

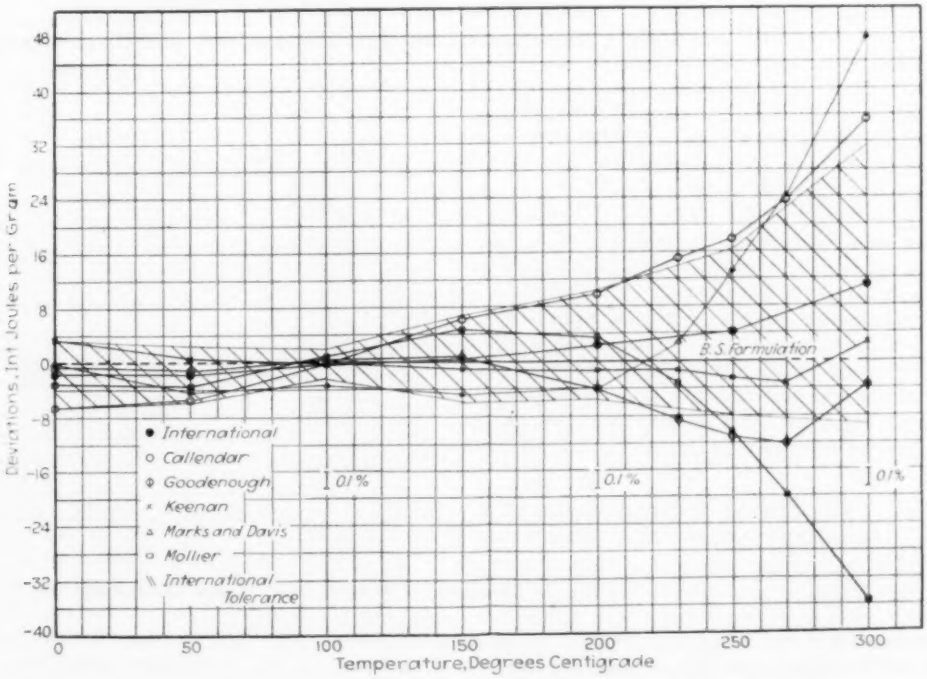

FIG. 4 DEVIATION CHART—HEAT CONTENT OF VAPOR

IV—INTERCOMPARISON OF EXPERIMENTAL DATA

To aid in the comparison of the data they are assembled in tables and deviation charts. Deviations from the Bureau of Standards values as bases are plotted to facilitate the comparison of these more recent data with those published previously.

In Table 8 are shown the values of heat content of the liquid, assembled from the previous sections. By the method of computation, the result of Dieterici is made to agree exactly with that of the Bureau of Standards at 100 deg. Because of the uncertainty in the interpretation of the e.m.f. of the Clark cells used by Barnes, his results, expressed in international joules, involve an uncertainty of considerable magnitude. The results of Callendar are omitted in this table, but appear later in the comparisons of the steam tables. The value in the Bureau of Standards column at 303 deg. is extrapolated and is therefore put in parentheses.

Fig. 1 shows the deviations of the previously published values of heat content of the liquid from the Bureau of Standards values.

In Table 9 are assembled the values of latent heat. Henning's values and those of the Bureau of Standards are calculated from empirical equations which were fitted to the data. The rest of the values are experimental points not smoothed by equations or graphically. The values in parentheses are calcu-

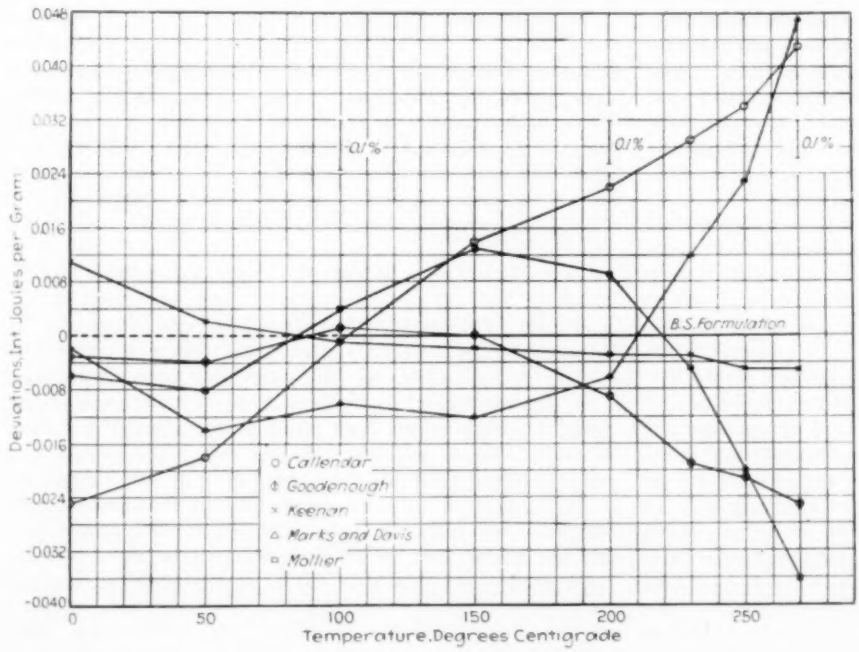

FIG. 6 DEVIATION CHART—ENTROPY OF VAPOR

lated from the Bureau of Standards latent-heat equation outside the range of the experiments.

Fig. 2 shows the deviations of the experimentally determined values of latent heat from the Bureau of Standards latent-heat equation.

V—COMPARISON OF STEAM TABLES WITH BUREAU OF STANDARDS RESULTS

For the purposes of this comparison, deviation charts alone are considered adequate. In Figs. 3 to 6, which are largely self-explanatory, the base lines are broken in the regions not covered by the experiments. The entropy charts are included because values of entropy can be calculated directly from the Bureau of Standards calorimetric measurements.

VI—CONCLUSIONS

For the most part the reviewer believes that the agreement among the experimental results which have been compared is within the limits of the total error involved in the determinations themselves and the conversions to present units.

Referring to the heat-content determinations, the deviation of the Bureau of Standards values from those of Barnes and of Jaeger and von Steinwehr and also of the latter two from each other are, in places, somewhat greater than can be embraced by the estimates which these authors make of their own precision.

The comparisons indicate that the Bureau of Standards latent-heat equation can be used with considerable confidence in the range 0 deg. to 100 deg., though it was derived solely on the basis of the experiments in the range 100 deg. to 270 deg.,

and on the classical conception of the vanishing of the latent heat at an infinite rate at the critical point.

The comparison of the steam tables indicates that the divergence in the tabulated properties of saturated water and steam is considerable. None of these tables comes completely within the limits of tolerance of the International Skeleton Steam Table of 1929, and therefore none can be called an "international table" as specified by the London Conference. A marked improvement is evident in the tables as more and more data of a precise nature became available for use in the formulations. It is believed that, with the progress in experimental equipment and technique, and the mutual understanding of the investigators, the evolution of accurate international tables of the thermal properties of water and steam has progressed beyond the stage of idealism, and that such tables will be a reality before very many years have passed.

FSP-52-31

Effect of Large Boilers at High Capacities on Operating Characteristics and Investment in Boiler Plants

By FRANK S. CLARK,[1] BOSTON, MASS.

This paper treats of the various factors that enter into the design of boiler plants, their effect on investment costs and on operating characteristics. It traces the development of the boiler plant from a number of small units operated at moderate capacities to the present plant of a few large units run at high rates of evaporation. It gives the conditions that limit the sizes and output and shows how, as the demand for larger units increases, these conditions have been overcome. The paper shows the effect of large units in reducing the sizes of buildings to house them, and the number of auxiliary equipment to serve them. It shows the effect of reliability of equipment on increased service factor, with consequent reduced necessity for spare equipment. It states that the governing factors in investment costs for a given condition are the size of the unit and the output obtainable, the former depending on the ability to manufacture, and the latter on the fuel that can be burned in the furnace and the ability of the unit to absorb the heat. Further, it discusses the proportioning of heat-absorbing surfaces between boiler, economizer, and air preheater to obtain the most economic result at minimum cost, and also the effect on operation of large units run at high capacity, and in turn their effect on labor and maintenance cost.

IN THESE days when attention is being concentrated on anything and everything that affects the cost of design and construction of a steam power station or a boiler plant, with a view to keeping investments down to an economical minimum, it is proper and timely that the steam-generating plant should be made the subject of analysis. The chief item of equipment in such a plant is, of course, the boiler or steam-generating unit, but of importance also, and affecting the size, capacity, and type of the unit, are the fuel-burning equipment and the other heat-absorbing units installed.

The trend of steam-generating equipment, like that of electric generators, has been toward increased size and output, and has followed the development of the industry. Limitations other than the ability of the boiler to generate steam held the sizes down, and at about the time of the introduction of the steam turbine there were a number of boilers serving one unit. This frequently necessitated the placing of the boiler-firing aisles at right angles to the axis of the electric-generating room, thus dividing the boiler-operating room into a number of separate operating aisles. In congested city districts it was necessary even to resort to double decking or placing boilers on two floors, one above the other, and in at least one station of this period the boilers were arranged on three different floors. The congestion of equipment, complications of installation, and difficulties of operation due to such conditions are apparent.

This situation was brought about largely by conditions other than the ability of boilers to produce steam at a high rate of generation. Inability of combustion facilities to burn the fuel in sufficient quantities, and of the furnace walls to withstand the punishment due to high rates of combustion, limited the capacity of boilers. Impure feedwater and the maintenance of grates and walls required frequent outages for cleaning and repairs, thus increasing the number of boilers necessary to insure reliability of operation.

The advent of the mechanical stoker for coal, and of the mechanical-atomizing oil burner, bringing with them the use of forced draft, increased the fuel-burning ability, and placed the limitation of capacity on the ability of solid refractory furnace walls to withstand the punishment incident to high rates of combustion. To offset this limitation, first the air-cooled and then the water-cooled furnace was developed. Added momentum to increased rates of evaporation has been given by the use of pulverized coal. Greater service reliability has accompanied these developments, increasing the period of continuous high-capacity operation until service factors exceeding 90 per cent have been attained by a number of large boiler installations, which is comparable to the service obtained from large turbine generators. This has reduced the necessity for spare steam-generating equipment to a point where it is possible to design a plant with a single boiler serving one turbine-generating unit, or with no greater reserve in boiler plant than in turbine plant.

With the removal of the restrictions other than those imposed by the steam generator itself, and with the increasing capacities of plants and of individual units, there have followed demands for boilers of larger and larger steam-generating capacities, until at the present time there are in operation in this country a number of boilers with steaming capacities of over 400,000 lb. per hr. each, with some few on order or being erected whose output will be upward of 800,000 lb. per hr. This increase in steam capacities has been accompanied by increases in steam pressure and temperature which, with greater efficiency of steam utilization, have decreased greatly the amount of steam required per kilowatt-hour of electrical energy produced.

For a given condition investment costs for a boiler plant are determined largely by two considerations: size of individual steam-generating units, and output obtainable from each unit. The first has as its maximum limit the ability of the manufacturer to produce the unit, and as a governing limit the relation of the individual units to the plant as a whole, to the characteristics of load, and to the spare units deemed necessary to provide reliable and continuous operation. The second is governed by the fuel that can be burned in the furnace, and the ability of the unit to absorb heat for the production of the steam.

The size and number of boilers affect the cost, not only of these units themselves, but of the equipment that goes with them and of the building that houses them. For a given output the percentage of building space devoted to aisles and firing floors de-

[1] Consulting Engineer, Stone & Webster Engineering Corp. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

creases appreciably with increase of size of boilers, affecting materially the area of the building and its cubic contents, with consequent influence on the cost of the structure. Supporting steel and its foundations likewise become less costly as sizes of boilers increase and their numbers decrease. Piping for both steam and water becomes larger in size, but of less number of parts, resulting in simplification in arrangement and reduction in cost. Equipment for fuel handling and burning is similarly affected. Setting walls have less area per unit of furnace volume as the sizes of combustion spaces increase, and this has a marked effect on the cost of the installation. Boilers themselves are less expensive per unit of output as their sizes increase. Fans, flues, economizers, air heaters, and other auxiliary equipment are reduced in unit cost with increase in capacity and decrease in number.

To illustrate these statements Table 1 has been prepared which gives a comparison of building areas and investment costs of boiler plants designed for a given steam output and pressure, but with different numbers of steam-generating units installed. The table also gives the proportional costs of main items of construction and equipment, indicating the relation of each item to the total cost. In this comparison are prorated so-called overhead costs, which include in each case an item to cover possible contingencies. The estimates are comparable as to scope and hold good for the case assumed, but many vary somewhat for a similar analysis of a different set of conditions.

TABLE 1 BUILDING AREAS AND INVESTMENT COSTS OF BOILER PLANTS

Number of boilers	4	6	8	12
Sections per boiler	60	40	30	20
Relative building area, per cent	100.00	112.00	127.00	133.00
Relative investment cost per cent	100.00	112.00	124.00	142.00
Proportional cost of main items of construction and equipment:				
Building and foundations	16.10	16.50	16.70	17.10
Boilers, superheaters, settings, etc.	32.00	33.00	34.60	38.00

Piping	9.60	9.50	9.20	9.00
Fuel and ash handling	7.60	7.40	7.20	6.70
Fuel preparation	9.60	8.60	7.90	7.00
Auxiliaries	2.70	2.60	2.40	2.40
Totals	100.00	100.00	100.00	100.00

With small boiler units, low construction costs, low steam pressure, operation at moderate rates of output, and with fuel not so important an item of production cost as it is at present, the boiler plant of fifteen years ago consisted usually of the boiler as the only piece of heat-absorbing equipment. The required draft was produced by a stack of reasonable height. No other equipment except possibly a superheater to give a moderate steam temperature was necessary to gain the desired efficiency. With present-day sizes and capacities, the situation becomes much more complex. The problem now is not solely one of absorbing the heat of combustion, but of the manner in which this is to be done and by what media. Higher steam pressures have raised the temperatures of gases leaving the boiler, as have the higher outputs, and additional equipment has become necessary to recover the heat in the gases, which has brought about extensive use of the economizer and the air heater for these purposes. Within the limits imposed by their operating characteristics, the selection of a size and arrangement of heating surface for each type of equipment must be such as will give the desired overall results for a minimum of cost.

Limitations to size of individual units would appear to be the length of drum or drums which it is possible to manufacture and to support properly. For the riveted type, which can be used for pressures up to 700 lb., it is possible to obtain drums accommodating sixty 4-in. tubes spaced $7^3/_4$ in. between centers with only end suspensions necessary, giving a furnace width of about 39 ft. For pressures involving the use of forged drums, the limit is the size of the ingot from which the drum is forged. At present this would allow a furnace width of about 43 ft. On account of the thickness of the drum shell the suspension is not a serious problem.

With these sizes and the ability to burn the necessary amounts of fuel under them, outputs of more than 500,000 lb. of steam per hour are obtainable from the so-called standard types of boiler. By combining two of these units with one furnace much greater capacities can be obtained, with consequent saving in space occupied and in investment cost. Boilers are now in operation and in process of installation that will develop more than 800,000 lb. of steam per hour.

The limits to the capacity that is obtainable are the fuels it is possible to burn in the furnace, and the ability to maintain proper circulation of water and to deliver the steam without accompaniment of excessive moisture. In general, it may be said that surfaces can be provided to absorb all the heat that can be liberated in a given furnace, and that present designs can recover economically. It therefore becomes a question of method of fuel burning. Fuel burned in suspension as gas, oil, or pulverized coal permits the use of highly preheated air, of rapid and turbulent mixture of air and fuel, of ready and easy regulation of combustion through control of air and fuel to each burner, and efficient utilization of the whole furnace volume. The burning of coal on a grate involves the problem of supplying and regulating a fuel bed of large proportions, together with an air supply at proper pressures and in sufficient quantities to all parts of the bed. This type of combustion equipment also affects the proportioning of heat-absorbing surfaces by the necessity of limiting the preheating of the air to a temperature which will not cause binding of moving parts of the grate or burning of the parts themselves. With both these methods of firing there arises the serious problem of limitation and loss of capacity at high rates of combustion due to clogging of the passages around the tubes by molten ash carried by the gases freezing to the tubes. This becomes more and more serious as the fusing temperature of the ash becomes less, and must be met by the arrangement of tubes that will provide wide spaces between them with consequent slower velocities of entering gases.

It has been stated that the availability for service of large boiler units has become as high as that of the turbine units which they serve. For purposes of reliability and also to take care of variations in load, auxiliary equipment serving the turbine is practically always in duplicate. For the same reasons and also because of practical limitations of sizes obtainable, mechanical-draft equipment is being duplicated in the case of large boilers.

Decrease in number of units means less equipment to operate and maintain, consequently labor and maintenance costs decrease correspondingly. Introduction of automatic-control equipment, and the use of an adequate number of indicating and recording instruments properly placed with their dials and charts congregated so as to give at one point an indication of the performance of a boiler unit and its auxiliaries, are a further aid to decreased operating labor and increased efficiency of operation. While the use of automatic control can be overdone, in general some degree of such control is essential to the realization of the full operating possibilities of large boiler units, and to the reduction of operating labor to a minimum.

Discussion

J. W. ANDREE.[2] The author's statement that it is no longer necessary to have spare steam-generating equipment in modern plants or that the reserve in the boiler plant need not exceed the

[2] Production Engineer, Southern California Edison Company, Los Angeles, Cal.

capacity of the turbine plant is borne out by experience in the Long Beach No. 3 Plant, which went into operation June 20, 1928, and has operated almost continuously from that time to date. The 94,000-kw. turbine in this plant is served steam from three boilers with practically no spare steam-generating capacity. This unit is operated as a base-load unit with a net output of 100,000 kw. continuously.

Excluding preliminary operation during its first month of service, this unit has operated a total of 10,592 hours out of a possible 11,688 hours up to December 1, 1929, or a total out-of-service time of 1096 hour. Of this total out-of-service time, 809 hours was forced out-of-service time, all due to turbine or its auxiliaries and none due to the boiler plant. In addition to the total outage there was 791 hours of reduced-load operation due to boiler or boiler-auxiliary trouble and 1252 hours of reduced-load operation due to turbine or turbine-auxiliary trouble.

Practically all of the outage in the boiler room was caused by draft-fan trouble which could have been greatly reduced with duplicate equipment. There were several cases of split tubes which would have caused a total outage in a plant of one boiler only.

That partial outage time due to turbine or turbine auxiliaries consists of 840 hours of operation at reduced load during a period of blading trouble; the remainder is made up largely of condenser trouble.

J. B. Crane.[3] The paper brings up a subject that is most timely, now that boilers which will deliver 1,000,000 lb. of steam each are in satisfactory operation.

The author, in Table 1, has prepared a summary showing the relative investment cost for four to twelve boilers. The writer gives the same table arranged in a slightly different form (see Table 2), which indicates that the main increase for small boilers is in building, foundations, boilers, superheaters, and settings; and it will be noticed that on these two items increased cost for twelve boilers over four is roughly 50 per cent. This indicates how misleading it is to base capital charges on the horsepower basis or 1000-lb. steam basis and how necessary it is to secure reliable figures on cost in making any comparison of different sizes of equipment. The same thing applies to different pressures.

Higher pressure boilers are less efficient than lower pressures; for example, at 200 lb. pressure the temperature of the water in the boiler is 388 deg. fahr. and the exit temperature from the boiler may be 500 deg. fahr. If the same boiler is built for 450 lb. pressure the temperature of the water in the boiler will be 460 deg. and the exit temperature at the same rating will be 572 deg. The advantage of going to the higher pressure is in the savings effected in the turbine room, and it is necessary to install additional heat-absorbing surface in the way of economizers or air heaters to reduce the higher temperature.

In the design of steam-generating units it is found that the simplest and most economical unit is obtained by determining the amount of fuel to be burned and by designing a furnace that will most satisfactorily burn the fuel. Between the furnace and the superheater there should be installed sufficient heating surface to reduce the temperature of the gases to that required for the proper steam temperature to be delivered from the superheater. After determining the efficiency for which the unit is to be built and the exit temperature necessary to secure this efficiency, an air heater is designed for the maximum size with standard materials and the temperature determined at the entrance to the air preheater. This leaves a difference in temperature between the outlet of the superheater and the entrance to the air preheater; and sufficient absorbing surface, in the additional convection surface in the boiler or in the economizer surface, or in a combination of the two, is installed to give this temperature difference. With this design a study is then made to see that there is sufficient volume in the drums to obtain dry steam and that proper circulation will result with the heat-absorbing surfaces laid out, and a check is made to see if some other combination of economizer and air preheater is more economical.

Considerable study has been given to this type of equipment in the past few years, with the result that it has been possible to reduce the total heating surface required at least 50 per cent in order to give the same efficiency.

In an effort to reduce the amount of high-pressure surface it has been necessary to increase the draft loss, and the addition of economizers and air preheaters has meant the installation of induced-draft fans instead of natural draft.

We find the following methods are in use in comparing the fan cost on any particular job:

1 Consider the fan power as costing the same per kilowatt-hour as the cost of manufacturing current at the station, with no capital charges.

2 Consider fan power as costing the same per kilowatt-hour as sales price of the current to other customers using the same amount of current at the same load factor.

3 Consider that additional equipment must be installed in the station to take care of the fan power and that this equipment will cost the same per kilowatt as the main equipment in the station.

4 Assume that there is enough excess capacity so that it is not necessary to capitalize the power necessary for the fans.

5 Assume that this excess capacity must earn the same as equivalent power-station capacity.

It will be seen that, under the foregoing methods of figuring the cost of fan power, widely varying results are obtained as to the effect of increased efficiency as against increased fan power necessary to secure higher capacities or higher efficiencies. Otherwise, most consulting engineers use similar methods in comparing costs.

Ollison Craig.[4] The author has discussed the economy of installing large boiler units and operating them at high capacities. There is no doubt that the trend to larger sizes and greater capacities will continue. The author has pointed out present limitations to both size and operating capacities. If the trend is to continue, these limits must of necessity be removed. The whole history of engineering has consisted of a continuing series of boundaries and limitations which have been continuously passed, new limitations being erected.

It might be interesting to speculate as to the means that will extend the present limitations. This writer would like to make a guess that the boiler limitations will be extended by the use of small tubes and forced circulation, permitting more heat-absorbing surface in a given space, providing means for greater heat absorption per unit of area, and making possible design of gas passages which will maintain most nearly the ideal velocity of gases.

[3] High Pressure Specialist, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

[4] Consulting Engineer, Riley Stoker Corporation, Worcester, Mass. Mem. A.S.M.E.

Limitation of fuel-burning capacity in the case of fuel burned on stokers is a function of two dimensions. In the case of powdered-coal firing the limitation is a function of three dimensions. For this reason the limit of coal burning with powdered-coal firing will exceed the limit with stoker firing. Powdered-coal firing can take advantage of any furnace area that can be used with stoker firing. In addition, increasing furnace height permits an increase in coal-burning capacity with powdered-coal firing approximately proportioned to increase in height. With stoker firing, coal-burning capacity is increased only slightly with increased furnace height and that only with certain limits.

This writer will then make another guess, and probably less of a guess than in the first case, that powdered-coal firing will extend fuel-burning capacities beyond anything possible with stokers and will develop to meet demand for increased capacities for a considerable period of time in the future.

A. R. MUMFORD.[5] Table 1 of the paper indicates that if a plant of given capacity is designed for twelve units instead of four, the cost of boilers, superheaters, settings, etc., will increase approximately 70 per cent. It is assumed that the large units differ from the small units only in the amount of heating surface per unit inasmuch as the boilers of the four-unit plant contained 60 sections each, whereas the boilers of the twelve-unit plant contained 20 sections each. Under such conditions the cost of this item, although the principal factor in the increase in investment costs as shown, is not as overshadowing as it might be in a plant which altered the unit design itself as the capacity was increased. The reduction in boiler cost can be said to be entirely in the drum cost—namely, the substitution of one drum for three. If it is assumed that the setting cost is roughly proportional to the perimeter of the unit, then a 50 per cent reduction in setting cost is obtained by substituting one large unit for three small units. The saving in setting cost undoubtedly constitutes a large part of the total saving in the boiler, superheating, setting, etc., item in Table 1. It seems that a boiler unit designed for high capacities should be especially designed and not necessarily be a small boiler grown up, and, further, such changes in design of boiler will permit more capital economy in the use of surface combinations.

A recent study of preliminary proposals from boiler manufacturers indicated that about 75 per cent of the cost of a boiler alone was represented by drums in a bent-tube boiler, and presumably by drums and headers in a straight-tube boiler. Any attempt to reduce the cost of a boiler by designing it for higher steam generation is usually met by an increase in drum sizes which, because of their proportion of the total cost, causes the boiler cost of a high-rating unit to be nearly the same as that of a low-rating unit. In other words, the drum sizes would be proportioned to the steam output without a definite relation to the amount of heating surface. The general reason for the relation of drum sizes to rates of generation seems to be that a certain area of water surface is required for a unit of generation. It seems that the area of the drum at the water level is usually taken as the steam-releasing surface. Experiments made during the moisture investigation at Kips Bay Station cast grave doubts on the existence of any definite water surface in high-capacity boilers. Further, if it is assumed that the maximum rate of generation at which dry steam was produced with no auxiliary equipment indicated the proper drum size, then the drums ought to have been about four times the diameter they are if releasing surface was to control. The boilers were made to produce dry steam at four or five times the original dry point by the use of auxiliary moisture equipment and at comparatively low cost. From the standpoint of moisture in steam the writer believes that the cost of large units can be reduced by substituting effective auxiliary separating equipment for large drums.

Small units operating at low rates of generation usually have a large volume of water below the water level, so that a cessation of water supply is not as dangerous as it is in large units operating at high rates of generation. The drum sizes of the large units are often increased to increase the water reserve and to steady the water level. Chemical concentration studies of a large high-rating unit indicate that approximately 50 per cent of the volume below the water level is filled with steam. If the supply of heat to the boiler surface is suddenly and drastically reduced when the unit has only 50 per cent of its volume filled with water, it is apparent that a change of water level will take place which will be of such a magnitude that reserve water capacity in practical drum sizes will be insufficient to maintain a visible water level. The writer believes that this problem can best be answered by increasing the feed-pump capacity to the extent which will result in a minimum drop in water pressure when a control valve opens wide. If the pressure is permitted to drop too far, the other units on the line will be adversely affected. The increased investment in pumping machinery will offset to some extent the saving resulting from the removal of water storage from the drums, but it is probable that a balance can be reached which will result in a net decrease in investment.

If a boiler is designed so that all of its surface will be working as hard as does the first pass of existing boilers, and if the indications and their interpretations, which the writer has found in one case, are found to apply generally, then large units will be even more economical than the author has shown them to be. The investment in economizers, superheaters, and air heaters is more nearly proportional to surface than that of boilers, in the writer's experience, so the assignment of duty to each type of surface can be readily made for a given set of load conditions and fuel cost. Until a real high-rating boiler is developed, the maximum reduction in investment possible as a result of increased unit capacity cannot be realized.

In properly assigning duty to the various types of heating surface, a consideration of changes in surface spacing will indicate the possibilities of investment reduction under the heading of draft systems. In one instance a new unit was designed to have a 75 per cent increase in steam capacity with only a 12 per cent increase in fan-drive power over another unit, by opening up the gas passages. The necessity for such balancing of heat absorption and draft loss is evident to any one who has faced the problem of materially increasing the capacity of a given unit.

In any consideration of hard driving the effect of the precipitation of dissolved solids in the boiler water becomes of great importance, as the author has indicated. Because of the greater temperature differences at high absorbing rates, scales which have not been dangerous in the past become dangerous, and unless the boiler water is properly conditioned many of the advantages of large units will be lost by the necessity of frequent outages for internal cleaning. The writer tends to overemphasize this phase of operation because most of his experience has been in plants using 90 per cent make-up. However, a 5 per cent make-up plant will, with as pure water as New York City drinking water, develop dangerous scales in from 36 to 54 weeks in high-rating boilers unless the water is carefully conditioned.

In general it is felt that, although large units are now economically justified under suitable loads, as the author has said, high-rating units will become even more economical from an investment standpoint as their uses increases and provides a breath of experience necessary for alteration to design.

H. B. LAWRENCE.[6] The author brings out some of the features

[5] Engineer, New York Steam Corporation, New York, N. Y. Mem. A.S.M.E.

[6] Engineer, H. L. Doherty & Co., New York, N. Y. Mem. A.S.M.E.

that have been instrumental in the demand for increasing the size of boiler units. This demand has gone hand in hand with the increasing production of kilowatt-hours by steam power, the decreasing amount of coal used per kilowatt-hour, the increasing size of steam-turbine units, the increase in steam pressure and temperature.

On such items with which all are familiar, there is no especial need of further emphasis or to draw attention to them at this time.

When one turns to the matter of investment, time of construction, and period of getting into service, however, one finds more difficulty in obtaining for discussion figures that are representative; and while there has been an improvement fully worth while on the matter of investment, so that the overall operating maintenance and fixed charges show a correct tendency, there remains a need to give the matter of cost further study toward the end of more reduction.

The operating ratios of representative groups of utilities have certainly not kept pace with the tremendous gains in economy, whether they are gains in production or distribution. Increases in fuel prices, wages, and rate reductions are responsible in a large measure for the rather limited betterment of the operating ratio.

A boiler plant containing four 350,000 lb. per hour boiler units can be put in for about $2,500,000 when the fuel is Illinois bituminous. An oil-burning plant of the same size would cost about $2,360,000, and a natural-gas plant would cost about $1,860,000. These figures are probably not correct, but they are relative and represent the boiler plant.

Obviously there need be nothing in a plant of such size for burning coal or oil or gas that would fail for lack of reliability or any other feature, and the writer believes that it can be shown, as the author aptly points out, that if we decrease the number of boilers, the cost of the boiler plant will come down.

However, if one satisfactorily answers the questions of an engineering and thermal nature, such, for instance, as the effect of size on reliability, simplicity, spare or reserve capacity, ease of operation, time of construction, auxiliary power, there remains a number of matters of as great or possibly greater importance to consider in the question of size, such as:

1 To forecast as closely as possible the growth and rate of growth of the plant.

2 To have available some ideas as to obsolescence, whether from physical limitations or from advancement of the art.

3 To know the effect on manufacturing cost.

4 To study commodity prices, wage levels, fuel prices, and cost of money.

A casual glance at curves of cost of money, bond yields, and commodity prices indicates that a plant built in the period, say, from 1917 to 1921 would suffer from relatively high bond yields and commodity prices.

Over a long period the general business curves can be divided into sections representing cycles, and if one is to construct plants that embody good engineering in the full sense of the word, he would have to inject into the question something more than the physical characteristics. Such a study will often determine size.

After all, size per se does not give the thing that is wanted, and the writer feels that all situations must be studied in the light of the conditions that exist and are likely to exist, paying especial attention to the economic, geographic, and social factors and governing the question of capacity and increments of capacity by all the means at command.

Author's Closure

Mr. Crane in his discussion emphasizes the futility of expressing cost comparisons on a horsepower basis. This is timely and true. Horsepower and per cent of rating are obsolete terms so far as modern practice is concerned.

Mr. Craig's prophecy as to methods that will be adopted to increase outputs is interesting. A few forced circulation boilers are being used abroad, but to the author's knowledge nothing is being done commercially in this country.

It is recognized that the types of boiler to be used for different capacities will not necessarily be the same, as is pointed out by Mr. Mumford. The object of the paper was to bring out certain relations between number and size of boilers and their effect on costs. To have assumed a different type of boiler for each case would have introduced another variable, and the value of the comparison would have been lessened correspondingly.

FSP-52-32

Flow Characteristics of Some Lead Cable Sheath at Temperatures Above Atmospheric

By C. L. CLARK[1] and C. UPTHEGROVE,[2] ANN ARBOR, MICH.

This paper gives results of an investigation on three types of lead cable sheath differing only in the antimony content, which was, respectively, 0.06, 0.6, and 1.2 per cent.

At room temperature all three compositions elongated at more or less fixed rates with loads as low as 245 lb. per sq. in. The results would indicate that a similar behavior would be obtained with still lower loads and that the behavior of lead at 70 deg. fahr. should be similar to that of plain carbon steel at a temperature above its equicohesive range.

Increasing antimony content does not result in a decrease in the rate of flow at the lower temperatures, but in a lowered resistance to creep.

At a temperature of 80 to 120 deg. cent. the higher antimony content results in a decrease in the rate of creep, while the lower antimony results in a comparatively high rate of creep.

ALTHOUGH lead is a material which finds wide commercial application, relatively little has been published concerning its physical properties. Especially is this true of its flow characteristics, or its strength, at temperatures slightly above normal. Contradictory statements may be found as to the elastic-limit values and the conditions under which lead will flow under a constant load. Claims have been made that commercial lead will sustain indefinitely, in tension, loads well over the 200 lb. per sq. in. elastic limit as reported by Shoji. As power lead cable sheathing is subjected to varying pressures and to temperatures which may be well above normal, it appeared desirable to investigate its flow characteristics.

In addition to this practical reason for desiring to know the behavior of lead at elevated temperatures, there is also one of theoretical interest. At the present time considerable attention is being given to the behavior of steel at elevated temperatures. It has been claimed by some that the critical temperature in this work is the lowest temperature of recrystallization or the equicohesive temperature. This temperature has been reported to be about 800 deg. fahr. for plain carbon steel, and experiments have shown fairly conclusively that at any temperatures above this, for example, at 1000 deg. fahr., steel behaves very differently than it does at 600 deg. fahr. The equicohesive temperature for lead has been reported as below 70 deg. fahr., and accordingly lead at room temperature should behave similarly to plain carbon steel when at temperatures above its equicohesive range. If such is the case, lead would be expected to flow under any given load, no matter how small, at room temperature which may be assumed to be approximately 70 deg. fahr. This should not be considered to mean, however, that lead cannot safely be used at room or slightly elevated temperatures, as the rate of flow with the smaller loads is sufficiently low so as not to interfere with its commercial usefulness.

Material

Three types of conductor paper-and-lead cables of 350,000 circular units were furnished by The Detroit Edison Company as the source of lead for this investigation. The three types differed from each other only as to the antimony content. The cable sheathing was used in preference to regular sheet lead in that it was desired to retain any possible effects that might be due to the method of fabricating.

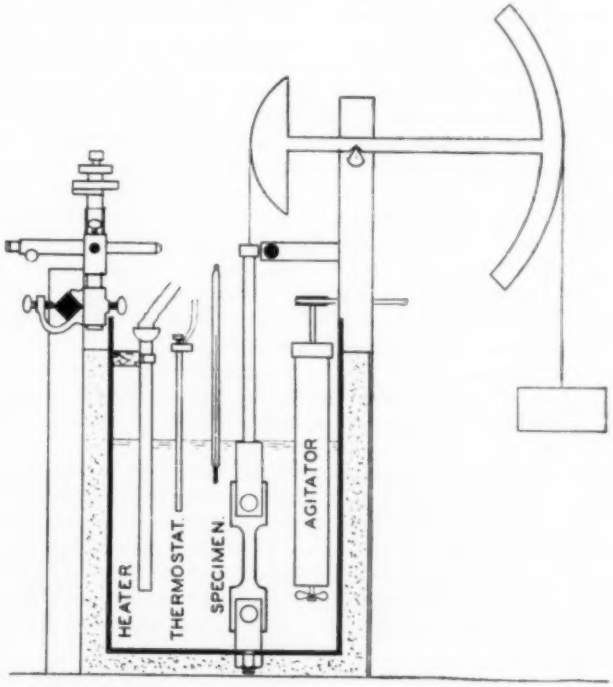

Fig. 1 Apparatus for Flow Tests on Lead

The antimony contents of the three types selected were:

Type of cable sheath	A	B	C
Antimony content, per cent	0.6	1.2	0.06

Arsenic and bismuth contents were also determined, but were found to show no appreciable variation. The three samples of cable sheath may be considered as representative of the compositions generally encountered in this field.

Contributed by the Joint Research Committee on the Effect of Temperature on the Properties of Metals and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Procedure

The temperatures selected for the creep tests were 25 deg. cent. (77 deg. fahr.), 40 deg. cent. (104 deg. fahr.), 60 deg. cent. (140 deg. fahr.), 80 deg. cent. (176 deg. fahr.), 100 deg. cent. (212 deg. fahr.), and 120 deg. cent. (248 deg. fahr.). Loads of 245 and 368 lb. per sq. in. were used. These loads correspond to pressures within the cables of 45 and 75 lb. per sq. in. and may be assumed to approach the extremes of the pressures normally encountered in commercial practice. The loads were maintained for a period of 360 hours (15 days), unless failure occurred.

Transverse specimens were used for all temperatures and load conditions rather than longitudinal specimens in that the investigation was primarily concerned not with a longitudinal stretching of the cable sheath but rather with a possible expansion in diameter due to internal pressure.

In order that a comparison between the flow of longitudinal and transverse specimens might be made, longitudinal specimens of all three compositions were run at 80 deg. cent. Longitudinal specimens of the 0.06 per cent antimony lead were also run at 25, 40, and 100 deg. cent.

Creep Apparatus

The apparatus used in the creep tests is shown in Fig. 1. The load is applied by means of a lever system, the arms of which are in a ratio of two to one. Arcs whose radii are in the ratio of two to one are fastened to each end of the lever, and the load and the specimen are in turn fastened to the arcs. The specimen is suspended in an oil tank between two holders or adapters which are of a saddle-like arrangement and which permit the specimen to adjust itself to the applied load. The lower holder or adapter is fastened to the bottom of the tank, while the upper adapter is connected by a wire to the arc on the short arm of the lever. The arrangement of the lever and attached arcs permits the load to be applied in a constant direction and also keeps the ratio of the lever arms constant regardless of the position of the lever. The apparatus is constructed to permit the simultaneous testing of four specimens.

Flat specimens, which were approximately $5^1/_2$ in. long and 0.125 in. in thickness were used. The reduced section or gage length was 0.5 in. wide as compared to $1^1/_2$ in. in the unreduced sections.

An oil bath of the proper viscosity to be fluid at the lower temperatures and which did not fume at the upper temperatures was used as the heating medium. Two knife-blade immersion heaters were used for heating the bath, and uniformity of temperature was maintained by circulation of the oil with a motor-driven pump. The temperature was maintained within a fraction of a degree centigrade by a Central Scientific Company thermostat.

The elongation or flow of the specimen was determined by means of a micrometer telescope by measuring the relative change in position of a mark or line on the upper specimen holder and a fixed point of reference on the apparatus. The micrometer telescope which permitted reading accurately to 0.01 mm. or 0.00039 in. was mounted so that it could be readily moved from one specimen to another.

It is recognized that the method of measuring the elongation does not record only that occurring in the gage section, but that occurring over the entire test specimen. In spite of the enlarged sections at each end of the specimen and the method of supporting, some flow necessarily occurred outside of the gage sections. As the purpose of the investigation was, however, primarily to determine the comparative flow characteristics, it was not considered necessary to attempt to limit the elongation measured to the 2-in. gage length.

Short-Time Tensile Tests

Preliminary to the creep tests, short-time tensile tests were made on the three samples of lead cable sheath at room temperatures. These tests were made for the purpose of determining the effect of the antimony content on the breaking strength and also to obtain a comparison of the transverse and longitudinal properties of the three materials. The results are given in Table 1.

TABLE 1 SHORT-TIME TENSILE TESTS ON THREE CABLE SHEATHING LEADS

Specimen number	Composition	Direction of specimen	Breaking stress, lb. per sq. in.	Elongation, per cent in 2 in.
CT	0.06 Sb	Transverse	2013	29.2
CL	0.06 Sb	Longitudinal	2158	33.0
AT	0.60 Sb	Transverse	2000	19.8
AL	0.60 Sb	Longitudinal	2118	33.0
BT	1.20 Sb	Transverse	3234	29.0
BL	1.20 Sb	Longitudinal	3096	28.2

For the particular samples of lead cable sheath the antimony up to 0.6 per cent was found to have no effect on the breaking strength. Increasing the antimony to 1.2 per cent resulted in a very appreciable increase in strength. Differences between longitudinal and transverse breaking strengths are relatively small, the order being reversed in the case of the higher antimony content.

Long-Time Creep Tests

Long-time creep tests were conducted on transverse specimens of the 0.6 and 1.2 per cent antimony leads at 25, 40, 60, 80, 100 and 120 deg. cent. (77, 104, 140, 176, 212, and 248 deg. fahr.) and on longitudinal specimens of these two leads at 80 deg. cent. (176 deg. fahr.). Similar tests were conducted on both transverse and longitudinal specimens of the 0.06 per cent antimony lead at 25, 40, 80, and 100 deg. cent. (77, 104, 176, and 212 deg. fahr.). Two tests were conducted on each type of lead specimen at each temperature, one with a load of 245 lb. per sq. in. and the other with a load of 368 lb. In the performance of these tests, the specimen was brought to heat and the load applied after sufficient time had been allowed to permit a state of equilibrium to be reached. Elongation readings were taken immediately before and after the application of the load. The results obtained from the transverse specimens of the three leads are shown in Figs. 2 through 7, while those from the transverse and longitudinal specimens at 80 deg. cent. (176 deg. fahr.) are compared in Figs. 8 and 9.

As seen from these curves, the tests in each case were continued for 360 hours, unless rupture was obtained before that length of time had elapsed. Elongation readings were taken at intervals and plotted against time. The slope of these lines therefore represents the rate of elongation of the specimen under the given load.

The slope, or rate of elongation, of each curve has been computed and the results are given in Table 2 and Fig. 10. The rate of elongation is expressed in inches per inch per hour. An examination of the values in either the table or figure will best reveal the behavior of these three leads under the conditions to which they were subjected.

At either 100 or 120 deg. cent. (212 or 248 deg. fahr.) the particular specimens of the 1.2 per cent antimony lead cable sheathing examined are seen to offer the greatest resistance to creep of the three leads tested. The remaining two leads are of about the same strength at 100 deg. cent. in so far as the small loading is concerned, but on the basis of the larger load the 0.06 per cent antimony lead cable sheathing flows at the more rapid rate of flow. At 80, 60, 40, and 25 deg. cent. (176, 140, 104, and 77 deg. fahr.) the 1.2 per cent antimony lead elongates at a more rapid rate than does the 0.6 per cent anti-

mony lead. The 0.06 per cent antimony lead was not tested at all of these temperatures. At 80 deg., on the basis of the larger load, it is the weakest of the three leads studied, while at 40 and 25 deg., it offers about the same resistance to deformation under fixed load as does the 0.6 per cent antimony lead and consequently is stronger than the 1.2 per cent.

In regard to creep tests on longitudinal and transverse specimens at 80 deg. cent. (176 deg. fahr.) shown in Figs. 7 and 8, the results can again best be compared by considering the numerical values of the rates of creep. These, together with

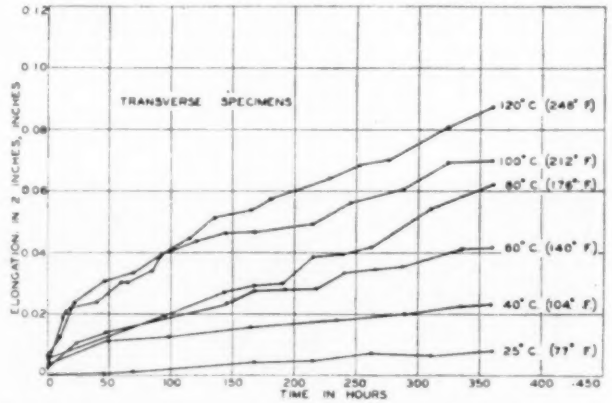

FIG. 2 FLOW TESTS ON 1.2 PER CENT SB LEAD WITH CONSTANT LOAD OF 245 LB. PER SQ. IN. AND AT INDICATED TEMPERATURES

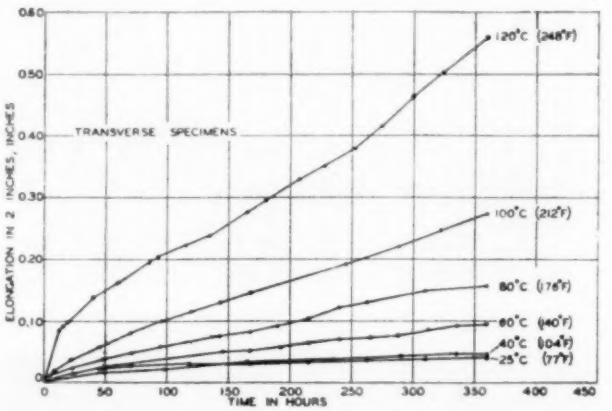

FIG. 3 (SAME AS FIG. 2 EXCEPT 368 LB.)

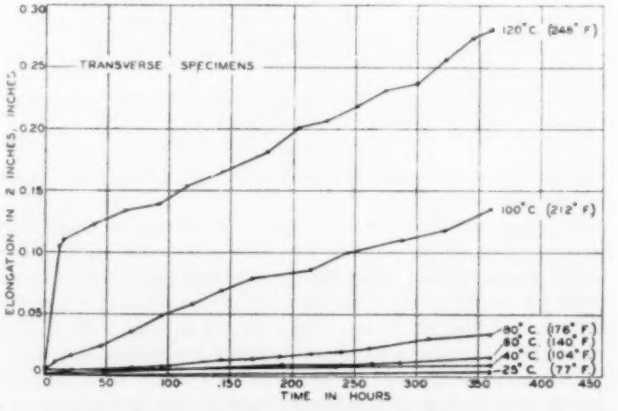

FIG. 4 FLOW TESTS ON 0.6 PER CENT SB LEAD WITH CONSTANT LOAD OF 245 LB. PER SQ. IN. AND AT INDICATED TEMPERATURES

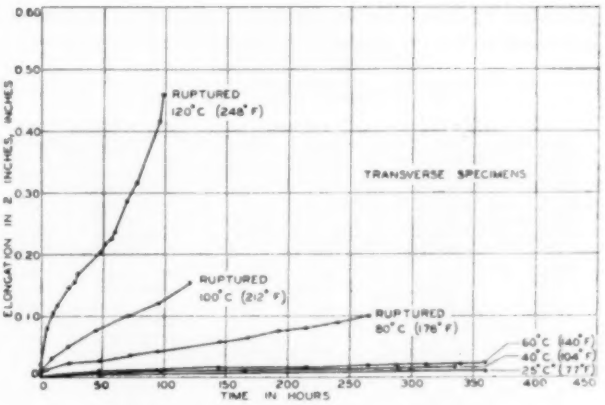

FIG. 5 (SAME AS FIG. 4 EXCEPT 368 LB.)

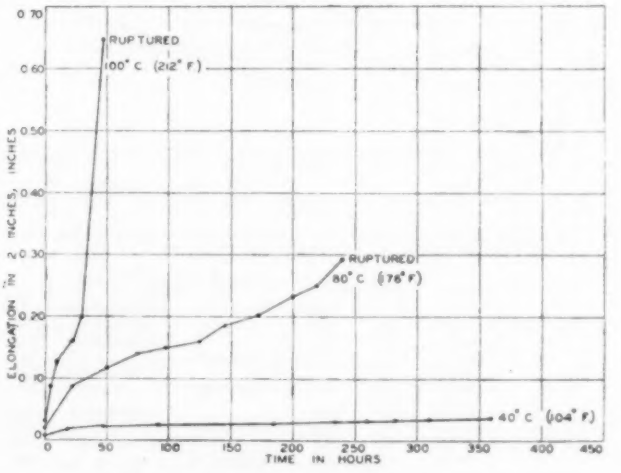

FIG. 7 (SAME AS FIG. 6 EXCEPT 368 LB.)

corresponding values obtained with 0.06 antimony lead at 25, 40, and 100 deg. cent., are given in Table 3.

The results show no consistently superior values to be given by either type of specimen. At 40 and 100 deg. cent. the longitudinal specimens of the particular specimens of the 0.06 per cent antimony lead cable sheathing elongated at a faster rate than did the corresponding transverse ones, while at 25 and 80 deg. cent. the opposite was true. Corresponding tests conducted on

the other two leads at 80 deg. cent. showed the longitudinal specimens to be the stronger in all cases except one.

CONCLUSIONS

The results obtained allow certain conclusions to be drawn regarding the effect of antimony content, temperature, and magnitude of stress upon the creep characteristics of certain specimens of lead cable sheath. Because of the extreme instability of the lead-antimony alloys, care should be used in extending these conclusions to other alloys of similar composition

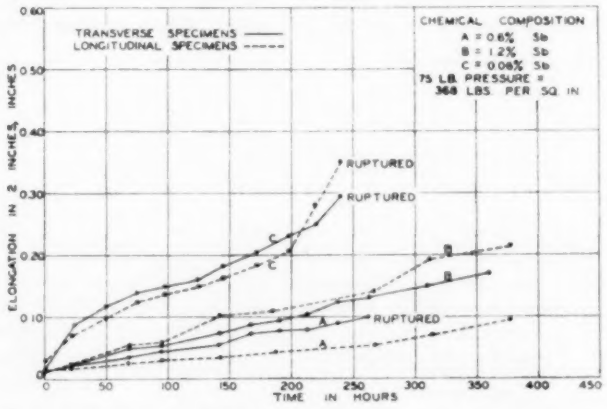

FIG. 9 FLOW TESTS ON LEAD AT 80 DEG. CENT. (176 DEG. FAHR.)

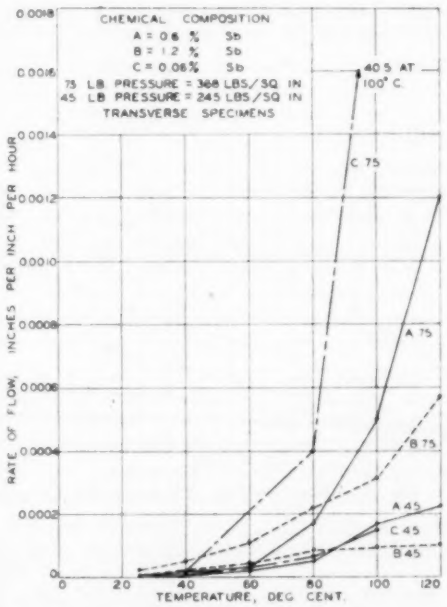

FIG. 10 VARIATION IN RATE OF CREEP OF LEAD WITH COMPOSITION AND TEMPERATURE

or to alloys of the same composition but which have been fabricated differently.

At room temperature all three compositions of lead cable sheath elongated at more or less fixed rates with loads as low as 245 lb. per sq. in. The results would indicate that a similar behavior would be obtained with still lower loads and that the behavior of lead at 70 deg. fahr. should be similar to that of plain carbon steel at a temperature above its equicohesive range.

Increasing antimony content does not result in a decrease in the rate of flow at the lower temperatures, but results in a lowered resistance to creep.

At a temperature of 80 to 120 deg. cent., the higher antimony

content results in a decrease in the rate of creep, while the lower antimony results in a comparatively high rate of creep.

Exceptions may be found to these findings at intermediate temperatures, compositions, or loads due to several reasons, chief of which are variations in grain size of the lead, the mutual solubility of the lead and antimony, and the amount, size, and distribution of the excess antimony particles. No explanation is offered at this time.

The authors wish to express their appreciation to The Detroit Edison Company for the financial aid given to this work, and to C. F. Hirshfeld, Chief of Research for The Detroit Edison Company, for his kindly interest and advice.

Discussion

R. L. Peek, Jr.[3] As an approximation to the type of analysis suggested by Dr. Nadai it should be possible, if determinations of creep are made under several loads at each temperature, to compute from the elongation the approximate average cross-section at any instant, and hence, approximately, the instantaneous average stress intensity. From such data there could then be obtained the rate of creep as a function of elongation for a constant stress intensity. When, as in some of the results given in this paper, the rate of creep for a constant load (increasing stress intensity) is constant through a considerable range of elongation, it would seem that the rate for a constant stress intensity must be decreasing and perhaps approaching zero for some limiting value of the elongation, i.e., that here there is also some strain hardening, or some similar effect.

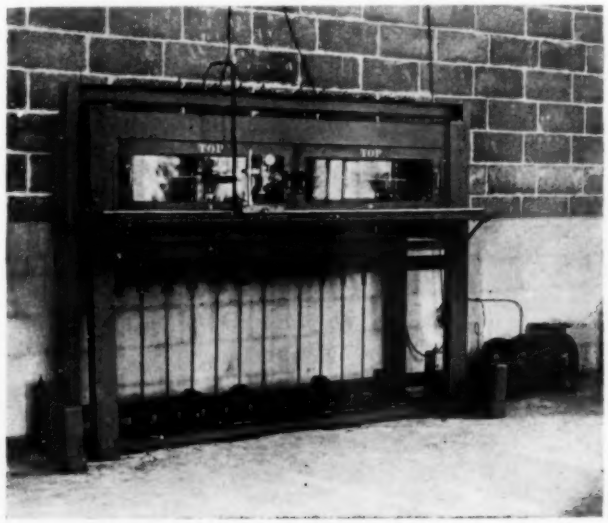

Fig. 13 Test Racks With Air-Cooling Equipment

H. F. Moore.[4] This paper presents interesting and valuable results and is of especial interest in emphasizing the importance of flow at room temperatures of certain of the softer metals. A series of flow tests of lead cable sheathing is in progress at the University of Illinois under the auspices of the Utilities Research Commission, and it is thought that some comment on these tests may be of interest in connection with this paper.

The tests at Illinois are being made on unalloyed lead, lead alloyed with antimony, and lead alloyed with tin. At present most of the tests have been on unalloyed lead. The general arrangement of the test racks are shown in Figs. 11, 12, and 13. Lead specimens with a minimum section 1/4 in. wide are subjected to the direct load of dead weights. The elongation of the specimen is measured by means of a microscope with micrometer-controlled travel. To each specimen are clamped two pieces

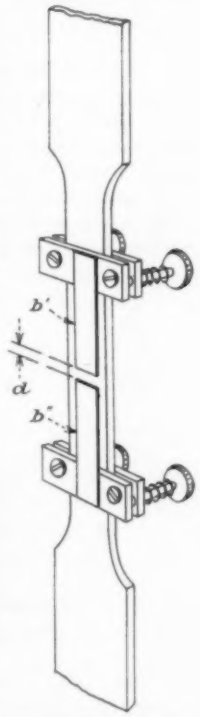

Fig. 14 Methods of Clamping Brass Strips to Specimens

[4] Research Professor of Engineering Materials, University of Illinois, Urbana, Illinois.

of brass (b' and b'') as shown in Fig. 14, and the distance between the edges of the brass pieces (b in Fig. 14) is measured by the traveling microscope shown in Fig. 13, and in somewhat greater detail in Fig. 15. Tests are run at (1) room temperature, (2) at a temperature approximately 32 deg. fahr., and (3) at a temperature approximately 150 deg. fahr. Fig. 11 shows the rig for room temperature tests. The six specimens in the center of this test rack are arranged so that they may be readily loaded and unloaded, and are tested in cycles of eight hours under load followed by 16 hours with load released.

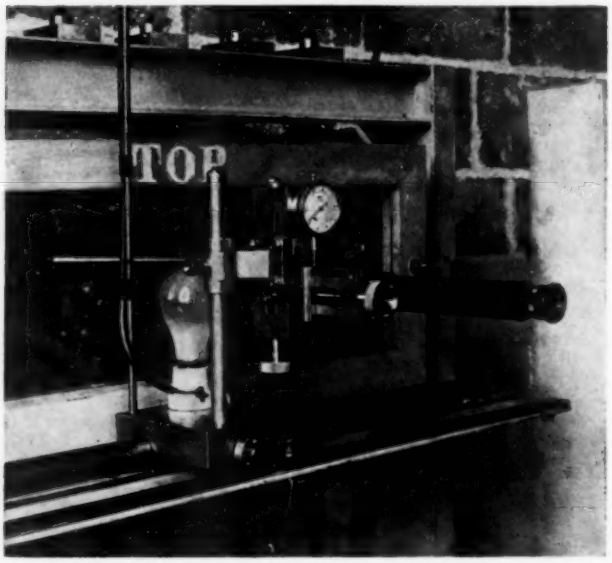

FIG. 15 TRAVELING MICROSCOPE FOR MAKING MEASUREMENTS

Fig. 12 shows the rig for 150 deg. fahr. The specimens are enclosed in a heat-insulating chamber, which is heated by a small electric heater, and the temperature is controlled by a thermostat circulation. A good degree of uniformity of temperature is secured by baffles. Fig. 13 shows the rig at 32 deg. fahr. The air is cooled by means of a Frigidaire unit. All three test racks are suspended from springs so adjusted that the racks rest lightly on sponge-rubber pads. This insures a minimum of vibration in the specimens.

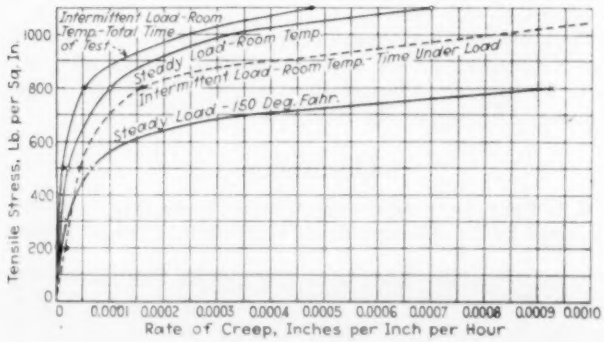

FIG. 16 TEST RESULTS WITH AN UNALLOYED-LEAD TRANSVERSE SPECIMEN—INTERMITTENT LOAD, EIGHT HOURS ON AND SIXTEEN HOURS OFF

Fig. 16 shows some results which have been obtained with unalloyed lead. Test data for tests at 32 deg. fahr. are not yet available. In general these tests are in agreement with those of the authors, but the unalloyed lead seems to have a somewhat greater rate of flow than does the antimony-lead alloys reported by the authors. Attention is called to the relatively high rate of flow at 150 deg. fahr. as compared with that at room temperature, and also to a comparison of rate of flow under steady load with rate under intermittent loading. As might be expected, if the rate of flow is measured by the entire elapsed time of test it is somewhat less for intermittent loading than for steady load. However, if the rate of flow is measured by the time the specimens were actually under load it was to be greater for intermittent loading than for steady load.

The Heat-Balance Test as a Means of Obtaining Evaporative Efficiencies of Steam-Generating Equipment

By B. J. CROSS,[1] NEW YORK, N. Y.

The efficiency of any energy-converting apparatus is determined by a division of the energy output by the energy input. In the case of boiler and furnace this is attained by weighing the coal or other fuel and weighing the water evaporated. The paper attempts to show that the efficiency as determined by the heat-balance method should have equal value with an efficiency as obtained by the test of weighing the coal and water.

THE fundamental operation for the determination of the efficiency of any energy-converting apparatus is the division of the energy output by the energy input. This is the direct method and should always be employed when these two quantities can be accurately determined. For the determination of the efficiency of a boiler and furnace, this method entails the weighing of the coal or other fuel delivered to the furnace and the weighing of the water evaporated in the boiler. The steam represents the operator's energy requirement and the coal represents the price he must pay for it. It is quite logical therefore to seek out these fundamental quantities.

There is often, however, some difficulty in the direct weighing of the coal and water. Water, especially, is often difficult to weigh under the conditions that exist in the boiler room. In small plants where the water is fed cold to the boiler or economizer or to closed heaters it is usually not a difficult matter to install tanks ahead of the boiler-feed pumps and weigh or measure all of the water fed to the boiler. In many cases, however, the weighing of water is very difficult and often practically impossible. The practice of feedwater heating by stage bleeding of turbines has introduced many difficulties. The water cannot be handled in open tanks at temperatures approaching the boiling point. The water as it comes from the condensers does not represent the total amount fed to the boilers, as a considerable quantity is bypassed through the heaters.

The greatest difficulty is in the quantities to be handled. Boilers that evaporate 300,000 to 500,000 lb. of water an hour are now fairly common, and a few are operating or have been projected to operate at capacities up to 800,000 lb. per hour. Testing facilities have not kept pace with the development in size and capacities of boilers, and it is improbable that any attempt will be made to weigh water to boilers at these rates. The expense of making complete evaporative tests on such large units would be very great and would usually be considered prohibitive.

The weighing of the coal used does not present so great a problem as does the water. In the first place its amount is only about one-tenth of that of the water. Even when it is to be used in powdered form, it can be weighed without difficulty, although special tanks or bins must be used. The greatest possibility for error is in judging the quantity of coal on the grates or in the pulverized-coal bins at the start and end of the test. This error is reduced in per cent by making the test of long duration. However, if it is impractical or impossible to weigh the water, it is of little avail to weigh the coal. Whether the water can be weighed is usually the deciding question as to the possibility of making the evaporative test.

If it is not possible to weigh the water evaporated, the only alternative for the purpose of determining the efficiency of a steam-generating unit is the heat-balance method. This method consists of the measurements of losses and subtracting their sum from 100. It would more accurately be called the method of losses. It is the purpose of this paper to present a discussion of this method.

The Heat Balance

The heat balance is a part of all complete evaporative tests where fuel and water are weighed. The heat absorbed as determined by the weight of water evaporated and its increase in heat content plus the sum of all the losses should equal 100 per cent. While all of the losses cannot be measured, those that can be measured can be determined quite accurately, while those that cannot be readily measured are small and are of the order of less than 0.1 per cent. The item "unaccounted-for losses" in the heat balance, therefore, consists almost entirely of errors. These errors are commonly considered to lie in the measured losses. The following is a discussion of these losses and of the degree of precision with which they can be measured. The losses that can be measured are as follows:

1 The loss due to the sensible heat above room temperature in the dry flue gases.

2 The loss due to steam in the flue gases. This steam comes from three sources: from evaporation of the moisture in the fuel, from the water formed when the hydrogen of the fuel combines with oxygen, and from the water vapor present in the air used for combustion.

3 The loss due to incomplete combustion of carbon. This loss is evidenced by the presence of carbon monoxide in the flue gases.

4 The loss due to unburned solid carbon. This loss is represented by the carbon or combustible in the refuse from the ashpit and various settling chambers and the carbon in the refuse that is carried up the stack with the gases.

5 The loss due to the heat radiated from the surfaces of the unit. This loss cannot be directly measured, but can be estimated and a figure set as a high limit.

Fig. 1 shows a heat-flow diagram of a steam-generating unit. The quantities are all to scale. This diagram is to show the relative magnitude of the various quantities. The individual losses are small compared to the heat absorbed, and a comparatively large error in their determination will have a proportionally small effect on the efficiency.

The Dry-Gas Loss

The loss due to heat in the dry flue gases is the largest item of the heat balance. It is also the item that is susceptible to the largest error. The greatest precautions should, therefore, be used in its determination.

The formula for determining the weight of dry flue gases per pound of coal is usually written

$$\left[\frac{11\ CO_2 + 8\ O_2 + 7\ N_2 + 7\ CO}{3\ (CO_2 + CO)}\right] \times C_b$$

in which the various gases are expressed in per cent by volume and C_b is the carbon burned per pound of coal.

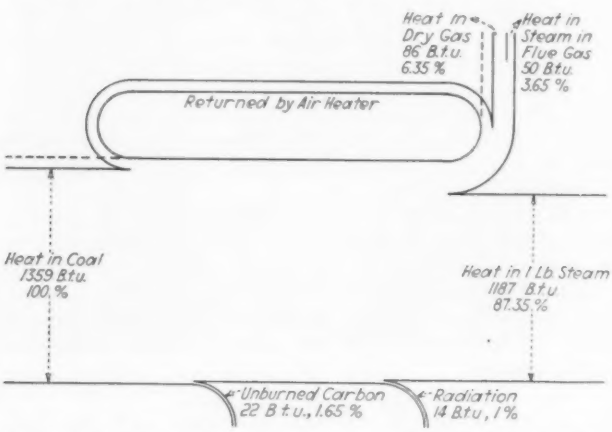

Fig. 1 Heat-Flow Diagram of a Steam-Generating Unit

This may be changed to

$$\left[\frac{4\ CO_2 + O_2 + 7\ (CO_2 + O_2 + N_2 + CO)}{3\ (CO_2 + CO)}\right] \times C_b$$

But as $(CO_2 + O_2 + N_2 + CO)$ constitute 100 per cent, the formula in its simplest form becomes

$$\left[\frac{4\ CO_2 + O_2 + 700}{3\ (CO_2 + CO)}\right] \times C_b$$

The entire expression for the heat lost in the dry gases is

$$\left[\frac{4\ CO_2 + O_2 + 700}{3\ (CO_2 + CO)}\right] \times C_b \times \left[0.24\ (t_2 - t_1)\right]$$

The items that are measured are CO_2, O_2, and CO in per cent by volume, t_2 the flue-gas temperature, and t_1 the air temperature. C_b, the carbon burned, is obtained by subtracting the unburned carbon per pound of coal from the carbon as reported by analysis.

Flue-Gas Analysis

The most important measurements in the determination of the dry-gas loss are the CO_2 and the flue-gas temperature. The oxygen and CO are small quantities, and considerable error in their determination causes only a small error in the result. C_b, the carbon burned, will vary only slightly with an error in the unconsumed carbon. It is improbable that any considerable error will be made in room air temperature.

The possible error in measuring CO_2 is influenced almost entirely by the location of the sampler. Once the sample is in the Orsat, its analysis can be made with an accuracy of plus or minus 0.2 per cent. The difficulty lies in obtaining a true sample. A great many devices have been tried in the attempt to obtain a single sample that is representative of the composition of the gas. Probably the best way is to use simple open-end pipes, taking as many samples in as many locations as the resources at hand permit. In wide settings as many as six samplers distributed across the setting may be necessary. A preliminary traverse of the breeching may be made and the variation in composition of the gases determined. The greater the variation the larger will be the number of sampling points necessary. In modern units where often both economizers and air heaters are employed, the gases are apt to be rather thoroughly mixed by the time they leave the system and the sampling thereby be simplified. Air leakage between the various units increases the difficulty of sampling and should be kept at a minimum.

The error in the per cent of CO_2 due to sampling and analysis should with proper care not exceed 0.5 per cent.

Temperature Measurement

As in the sampling and analysis of gases, the possible error in the determination of temperature of the flue gases is due almost entirely to the location of the instrument used. The solution similarly is to use as many points as possible. A temperature traverse may be made and the number of points to be used and their locations be thus determined. The use of thermocouples in this measurement permits a large number of temperature measurements to be made in a section of the breeching with a minimum of effort and expense. In a breeching, for example, of 5 ft. by 15 ft., five couples may be located at 3-ft. intervals. Each couple may then be moved to five positions. There can

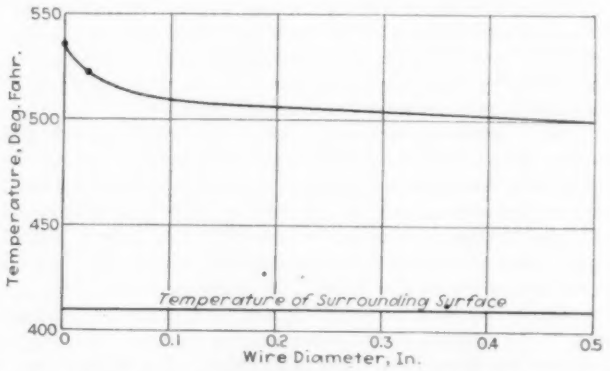

Fig. 2 Effect of Thermocouple-Wire Diameter on Radiation Error

thus be made 25 readings at as many points in the section. If a little care has been taken in wiring the couples to a convenient switch, these 25 measurements can be made in not more than five minutes. A potentiometer should preferably be used in measurements, as there is then no error due to the resistance of the leads.

The thermocouple used for measurement of gas temperature should be made of wire as small in diameter as possible consistent with durability. Theoretically, in a stream of hot gas inclosed by walls at a lower temperature than the gas, the junction of the couple can never reach the gas temperature. It is receiving heat from the gases and radiating heat to the walls of the duct. The temperature it indicates is therefore an equilibrium temperature and lies somewhere between the gas temperature and the wall temperature. The smaller the diameter of the wire the closer will be the indicated temperature to the true temperature.

Fig. 2 shows the effect of wire diameter on the indicated temperature. This chart is taken from Bulletin 145 of the U. S. Bureau of Mines and is based on experimental data by Kreisinger and Barkley. In practice No. 22 B. & S. gage wire, which is 0.025 in. in diameter, has been found to be well suited. It is

large enough to be fairly durable and is not too large to cause a serious error due to radiation. In gas ducts, the walls of which are insulated and where the gas velocity is fairly high, the error due to radiation should not be large. In boiler settings where the gas velocities are low and the couple can "see" the comparatively cooler boiler surfaces the radiation error may be considerable.

The junction of a thermocouple is best made by welding. Copper constantan couples can be welded in an ordinary bunsen burner or even in the flame of a small gasoline blow torch. Iron-constantan couples require a higher temperature, and an oxygen-gas flame or an electric arc must be used. The wires should be butt welded, the junction being but little if any larger in diameter than the wire. Fig. 3 shows some examples of good and bad thermocouple junctions. The hot junction of a couple is shown at *a*. The wire of the couple should project well beyond its protection tube. The error due to the conduction of heat along the wire is thus minimized. A good butt weld is shown at *b*. A couple with a bead is shown at *c*. The wire has been held in the flame too long, and the surface tension of the molten metal has drawn the melted metal from the ends of the wires, causing the thin sections near the head. Such a weld is fragile, and in addition there is apt to be a large error due to radiation. At *d* is shown a couple with too short an exposure to the gas. The outside supporting pipe and the insulation are always at a lower temperature than the wire of the couple, and heat is conducted from the wire. All that can be said in favor of *e* and *f* is that they are easy to make. The greatest advantage in the use of a thermocouple in measuring flue-gas temperatures lies in the small mass of the active part of the instrument. In examples *e* and *f* this advantage is sacrificed.

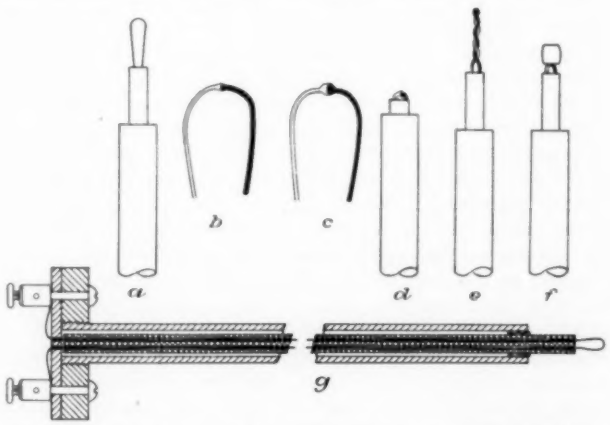

FIG. 3 EXAMPLES OF GOOD AND BAD THERMOCOUPLE WELDS

A completed couple is shown at *g*. It consists of a $^1/_4$-in. iron pipe which supports the wire in a suitable insulation. This insulation may consist of porcelain or glass tubing. The head holding the binding posts may be made of fiber or wood. The cost of such a couple should not exceed $1, labor included, and the wire can be renewed at the cost of a few cents.

A good portable potentiometer should be part of the equipment of the boiler room. Thermocouples can replace mercury thermometers in most temperature measurements. While the first cost of the potentiometer is higher than that of the thermometers, the upkeep is apt to be considerably lower. Bulletin 145 of the U. S. Bureau of Mines is recommended as a text on the use of thermocouples.

The calibration error of a couple over the range of temperatures found in flue gases should not exceed 2 or 3 deg. The largest chance for error is due to the location of the couple and the radiation of heat to cooler surrounding surfaces. In ducts, the walls of which are well insulated, the temperature of the walls will not be far below that of the gases. The error due to radiation should not exceed 10 deg. fahr. The combined error due to radiation and location should not exceed 15 deg. fahr.

Fig. 4 shows the loss due to heat in the dry flue gases at various temperatures plotted against CO_2. Thus at 15 per cent CO_2 and 500 deg. temperature, an error of 0.5 per cent in CO_2 and 15 deg. in temperature will cause an error of 85 B.t.u. or 6 per cent of the total quantity of heat lost. But this represents an error of only 0.5 per cent in the efficiency. At a temperature of 300 deg. and 15 per cent CO_2, the same errors in measurement will cause an error of 65 B.t.u., or 9 per cent of the total loss. But again this represents an error of only 0.55 per cent in the efficiency.

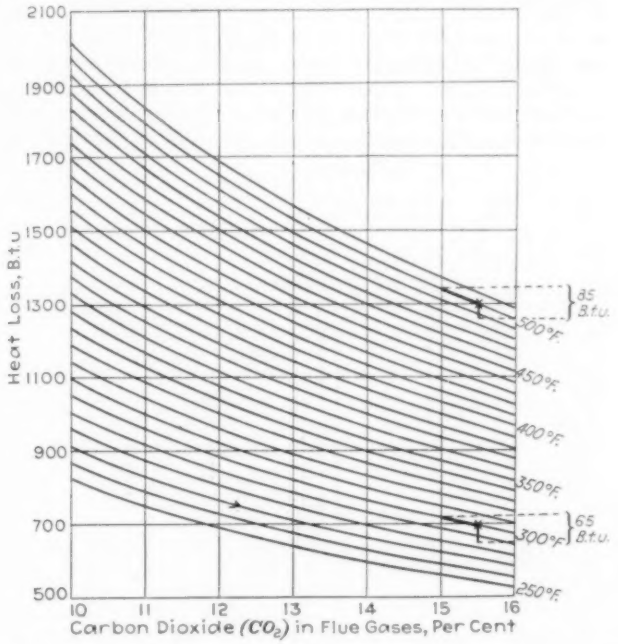

FIG. 4 VARIATION OF DRY-GAS LOSS WITH CO_2 AND TEMPERATURE

STEAM IN FLUE GASES

The loss second in importance in size is that due to moisture in the flue gases. This moisture comes from three sources: from the moisture in the fuel, from the water vapor present in the air used for combustion, and from the moisture formed by the combustion of hydrogen in the fuel.

Where the moisture W_m must first be evaporated, as is the case with the moisture in the fuel and that formed by burning hydrogen, the loss is equal to $W_m = [1050 + 0.48\ (t_2 - t_1)]$. As the latent heat of evaporation is large in comparison with the second term, the loss is almost constant. It would take a considerable error in t_2, the flue-gas temperature, to appreciably affect the final result. An error of 15 deg. in the temperature affects the efficiency about 0.25 per cent.

The equation for the heat in steam in flue gases is sometimes written

$$\text{loss} = W_m\ [(212 - t) + 970.4 + 0.48\ (t_2 - 212)]$$

This implies that the moisture is evaporated at a temperature of 212 and superheated to the temperature of the stack gases. Actually the water is evaporated not at atmospheric pressure but at its own partial pressure. A more nearly correct expression, which also has the advantage of being simpler is

$$\text{loss} = W_m\,[1050 + 0.48\,(t_2 - t_1)]$$

The actual difference in results by the two methods is, however, small.

As the loss due to moisture in the air used for combustion is very small, usually less than 0.1 per cent, any error in its determination need not be considered.

Loss Due to Unburned Carbon

The loss due to unburned carbon is difficult to measure. If this loss occurred entirely in the ashpit, its determination, while apt to be rather laborious, would be comparatively simple. A large part of the unburned carbon, however, passes out of the stack with the gases. This is true both of stokers and of powdered-coal-fired furnaces. The ashpit loss can be determined by the weight of the refuse and its analysis. The loss of carbon in the

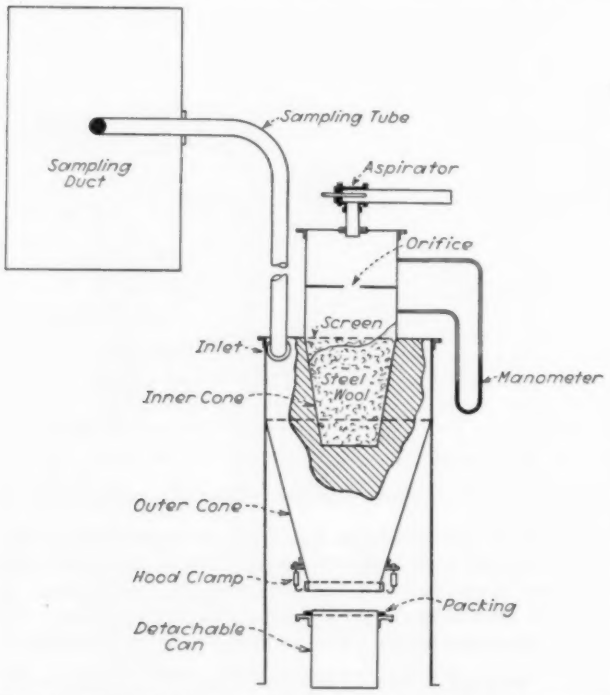

Fig. 5 Arrangement of Collector for Determination of Dust in Flue Gases

stack gases can be determined with a fair degree of accuracy by aspirating a known weight of gases through a collector and filter. Such a device is shown in Fig. 5. The purpose of the flow measurement by means of the orifice is to obtain the correct velocity at the sampler intake and also to obtain a quantitative measure of the total amount of refuse carried up the stack. The fraction sampler area over total area of the duct is the proportion of the total gases that must be drawn through the apparatus. The assumption is made that the velocity at the point of sampling is the average velocity in the duct. The error in quantity of refuse so determined may be as great as 10 per cent. The error in quality (i.e., carbon content) is due chiefly to the loss of fine particles and is usually on the high side. The combined error of sampling in quantity of refuse and quality of the sample obtained should not exceed 20 per cent. If the total loss due to unburned solid carbon is 1.5 per cent, the maximum error in the efficiency would then be 0.3 per cent.

The error in the chemical analysis of the refuse is probably on the high side. The method for determining the combustible consists of burning the sample in a muffle furnace and calling the loss in weight carbon, which is assumed to have a heat value of 14,600 B.t.u. per lb. Actual calorimetric determinations of the combustible have shown a heat value averaging about 13,800 B.t.u. per lb. The combustible as determined by the loss in weight on burning is apparently not pure carbon.

The Radiation Loss

The loss due to radiation of heat from the boiler setting cannot be directly measured. The rate of radiation from such surfaces has, however, been the subject of much study and is of the order of about 250 B.t.u. per sq. ft. per hour. Boiler and furnace walls are usually well insulated, and there are few parts of a setting where the hand cannot be comfortably held.

As in most plants boilers are set in battery or adjacent to each other, the radiation amounts in part to a mutual exchange and the loss is reduced. The rate of 250 B.t.u. per sq. ft. per hour can be safely said to be a maximum figure. The surface exposed need not be accurately measured but only approximated.

The actual loss due to radiation is practically constant regardless of rating. It can be estimated for normal rating of the boiler, and the loss at any rating may then be computed by dividing by the per cent rating. The per cent loss due to radiation will thus vary considerably with rating. At moderate ratings it will be in the neighborhood of 1 per cent. The error in computing this loss will not exceed 25 per cent of the loss and would cause an error of 0.25 per cent in efficiency.

Sampling and Analysis of Fuel

The error in the heat value of the fuel may result from two causes: the sampling of the coal at the plant and the analysis of the sample in the laboratory. The error of sampling, even when the most careful methods are used, may be considerable. If the coal is moist, as is often the case, the time consumed in sampling must be kept at a minimum in order that the loss of moisture may be kept low. On the other hand, time is required to reduce the sample in size and to mix it thoroughly so that the samples taken may be representative. The best way out of this dilemma is to take separate samples for the moisture content and for the heat-value determination. Investigations are now in progress to determine the accuracy with which coal may be sampled, the preliminary results of which indicate that an error of 150 to 200 B.t.u. may be expected. The error of analysis of coal is smaller. A chemist is expected to check his own determination within 40 to 50 B.t.u. Different laboratories should check within 75 B.t.u. The combined error due to sampling and analysis may easily be 200 B.t.u.

For the purpose of a heat-balance test an error of 200 B.t.u. in the heat value of the fuel is, fortunately, not serious. The equation for efficiency by the heat balance method is

$$\frac{\text{B.t.u. of coal—losses}}{\text{B.t.u. of coal}}$$

As the term "B.t.u. of coal" appears in both the numerator and the denominator, the error is largely compensated.

Loss Due to Incomplete Combustion of Carbon to CO

In a comparison of heat balances of tests made 10 or 15 years ago with those made more recently, one of the noticeable differences is in the CO reported in the flue gases. Where it was once common to report percentages of CO from 0.5 to 1, in the more recent tests this item is usually zero. This difference is due to the increase in size of combustion chambers and the use of air over the fuel bed. As the amount of CO is small—usually it is not measurable—and as the same per cent of error in its determination applies as for CO_2 determination, the error in the determination of this loss can safely be neglected.

Unaccounted-For Losses

If radiation has been accounted for by the method previously described, the unaccounted-for losses should consist only of the undetermined items of the gas analysis and sensible heat in refuse. The undetermined constituents of the stable gases consist of unburned hydrogen and hydrocarbons. The loss due to these constituents can almost invariably be neglected because they usually exist only in traces.

The amount of heat lost due to the sensible heat in the ash and refuse is usually very small, although if ashes are rejected from the furnace in molten state the loss may be appreciable. However, in this special case the loss may readily be calculated.

The possible errors of the items of the heat balance as discussed in the preceding paragraphs are to be considered as the maximum errors when all reasonable precautions have been taken to obtain accurate measurements of the factors involved. These errors are for the greater part accidental rather than constant. They may be plus or minus in direction and just as apt to be compensating as additive. Considered under the most unfavorable circumstances where they will be additive, the total error in the sum of the losses will be the sum of the errors of the individual losses. The total maximum error in obtaining the efficiency of a boiler and furnace by the heat-balance method may be determined therefore by summing up the individual errors. Thus the total error of a carefully made heat-balance efficiency test will be as follows:

1 Error in dry-gas loss, per cent	0.5
2 Error in loss from steam in flue gases, per cent	0.1
3 Error in loss in incomplete combustion, per cent	0.4
4 Error in radiation loss, per cent	0.2
5 Error due to sampling and analysis of fuel, per cent	0.2
Total error in efficiency, per cent	1.4

If there is added 0.1 per cent for the unmeasured losses, the total possible error in efficiency by this method is 1.5 per cent.

To those who like to report the results of a boiler test to the second decimal place, the admission of a possible error of 1.5 per cent in a heat-balance test would seem to condemn such a test. However, if one investigates the possibility of errors in a weighed-coal-and-water test, he will find that, even though all measurements are made with great care, the probable error of such a test will not be greatly different from that of the heat-balance test. Unlike the efficiency as determined from the heat balance, the efficiency as determined from a weighed-coal-and-water test is greatly affected by an error in the heat value of the fuel. An error of 150 B.t.u. in the heat value will cause an error in efficiency of over 1 per cent.

The heat absorbed per pound of steam evaporated is determined by the temperature of the feedwater and the temperature and pressure of superheated steam. The temperature of the feedwater can be determined to within 2 deg. fahr. and that of the superheated steam to within 5 deg. fahr. The combined error of these two temperatures is 0.4 per cent. Even neglecting the possibility of error in the weighing of coal and water, it is seen that the error of a weighed-coal-and-water test may easily be 1.5 per cent.

A comparison between the efficiency as obtained from weighed water and coal and the efficiency as determined by heat balance is shown in Figs. 6 and 7. These show graphically the results of a series of complete tests on a stoker-fired boiler and a pulverized-coal-fired boiler. In these charts the efficiency by weighed water and coal is plotted upward from the zero ordinate; the losses are plotted downward from the 100 per cent line. The amount by which the sum of the total losses does not meet the efficiency as obtained by the evaporative tests or the amount by which they overlap represents what usually is called the unaccounted-for losses, but which should more correctly be called the error of the tests.

It will be seen that the maximum error in these diagrams is 3 per cent. As it has been shown that the maximum probable error of both the heat-balance test and weighed-water-and-coal test is in the neighborhood of 1.5 per cent, a combined error of 3 per cent is possible.

It has not been the purpose of this paper to depreciate the weighed-coal-and-water test. Tests should be made by this method whenever possible. Such tests should also be checked

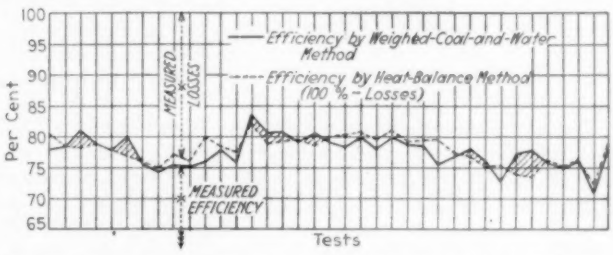

Fig. 6 Results of 36 Complete Weighed-Coal-and-Water Tests of Stoker-Fired Boiler, With Heat Balances to Check

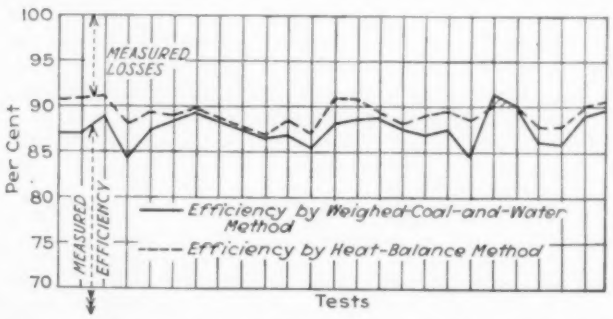

Fig. 7 Results of 25 Complete Weighed-Coal-and-Water Tests of Pulverized-Coal-Fired Boiler, With Heat Balances to Check

by means of a heat balance whenever possible. This paper has attempted to show that the efficiency as determined by the heat-balance method (or by the method of losses, as it would more accurately be called) should have equal value with an efficiency as obtained by a weighed-coal-and-water test.

Discussion

Vincent M. Frost.[2] The writer is much interested in the presentation of this subject as his company has made use of a combination of the standard weighed-coal-and-water method and the heat-balance method for several years. Our plants are equipped to weigh both coal and water for testing of the largest boilers. In weighing the water, however, it is necessary to do so at a temperature low enough to prevent flashing into steam, and this results in making the boiler tests with water considerably colder than normally supplied.

For many of our operating tests, therefore, we have weighed the coal, used the boiler-steam-flow meter to determine the boiler output and approximate rating, and after computing the losses, from the data of flue-gas analysis, flue-gas temperature, ultimate analysis and heat value of the coal, loss in the refuse, and making a definite allowance for radiation and unaccounted-for loss, determined the "probable efficiency," as we have termed it, by difference.

[2] Assistant to the General Superintendent of Generation, Public Service Electric and Gas Company, Newark, N. J. Mem. A.S.M.E.

Attention has been called to the possible error in the coal weights. In making tests of large stoker-fired boilers, we have frequently made the test of 96 hours in order to reduce the possible error due to the condition of the fuel bed to a negligible value.

The loss due to the carbon in the refuse is not an item to be dismissed lightly when one is attempting to chase down an elusive efficiency and determine whether the combustion is as efficient as might be or has been claimed.

With a stoker equipped with a clinker grinder and deep pit burning 20,000 to 30,000 lb. of coal per hour, not only is there a very large amount of refuse to be handled and sampled, but the refuse from a given test does not begin to be rejected from the furnace in from 6 to 12 hours after it entered the clinker pit.

The writer foresees one great advantage from the general use of the proposed scheme, in that a definite value for radiation and unaccounted-for will of necessity be used, and there should no longer be tests reported with high efficiencies and negative radiation and unaccounted-for losses in order to balance.

The results of any boiler test, no matter how made, which shows by a heat balance negative "radiation and unaccounted-for" should be taken with a "grain of salt."

It is believed that the radiation loss in many instances will be very much larger than "1 per cent at moderate ratings" as suggested by the author. Its actual value will be very much influenced by the type of setting of both boiler and furnace and the size of the furnace as compared to the size of the boiler.

On the eleventh page the equation for the efficiency by the heat-balance method is given as

$$\frac{\text{B.t.u. of coal} - \text{losses}}{\text{B.t.u. of coal}}$$

with the statement that, due to the fact that the B.t.u. of the coal appears in both the numerator and denominator, the error is largely compensated.

If the equation is rewritten into the form

$$1 - \frac{\text{Losses}}{\text{B.t.u. of coal}}$$

it will be seen that the value used of B.t.u. of the coal is a direct factor and the value of the error is from 0.25 to 0.35 per cent, depending upon the relative heat value of the coal as between, say, 12,000 and 14,000 B.t.u.

In the paper reference is made to the efficiency as determined from a weighed-coal-and-water test, and it is stated that an error of 150 B.t.u. in the heat value will cause an error in efficiency of over 1 per cent. This should be qualified to the extent of stating the heat value of the coal to which the 150 B.t.u. correction is to be made.

The efficiency as determined by a weighed-coal-and-water test may be expressed in a simplified form as follows:

$$\frac{\text{Lb. of steam per hour per lb. of coal} \times \text{B.t.u. per lb. of steam}}{\text{B.t.u. per lb. of fuel}}$$

This fraction has the same form as that given for the per cent losses as given above, and the B.t.u. per pound of coal thus appears as a direct factor. The largest error involved in the coal measurement of a test of a stoker-fired boiler is in determining the relative amount of fuel in the furnace at the end of the test as compared to that at the beginning.

A similar situation exists in the determination of the amount of pulverized fuel in the weighing bins at the beginning and end of the test, particularly if they are determined on a volumetric base.

A. A. Markson.[3] The paper is valuable to the profession, not only because of its subject, but because it is a most timely contribution. The writer has had some experience in boiler testing in which the purpose of the testing has always been to obtain data of value to the operation rather than in the mere compilation of academic figures. It is only natural, then, for him to have used the methods the author suggests, for they constitute a very powerful analytical weapon in which any skill of the engineer is repaid by the economy of securing the data. This is always a controlling factor in the work of a power-plant research department. In short, the operating returns obtained from any test are in the last analysis only valuable to the extent of the skill and ability employed in making the test, drawing the correct conclusions, and, finally, seeing that the conclusions are carried into execution.

The author makes a good point in the last paragraph in that his paper should really be called "Evaporative Efficiencies by the Method of Losses." The writer does not think this statement can be made too strong.

To illustrate: A series of tests were made on a Coxe stoker-fired boiler and economizer about five years ago at one of our stations. These tests were run at ratings of 200 to 375 per cent, and there were nine in the series of 12 to 24 hours' duration. The following items were obtained in order to make an error-proof heat balance:

1 Coal was weighed.
2 Water was weighed.
3 Cinders caught by cinder-vane fan were weighed.
4 All ashes were weighed.
5 Gas analyses and temperatures were obtained and checked with extraordinary care.
6 In addition the usual data called for in the paper were gathered.

It was rather surprising, then, to find that the real heat balance showed "unaccounted-for" 3.7 to 14.1 per cent, going up with the rating.

This was finally traced to an unexpectedly high cinder loss, the existence of which would never have been suspected if only the readily ascertainable losses had been determined.

On the other hand, large units have been under continuous testing at Kips Bay Station substantially in accordance with the author's outline. The "unaccounted-for" was estimated at 2 per cent. Recently five weighed tests were run, which lasted from 48 to 72 hours each. The "unaccounted-for" was between 2.8 and 2.2 per cent on all tests, which showed that the estimate of 2 per cent previously used was not a bad one.

It therefore seems that the method of losses is peculiarly adapted to powdered-coal furnaces and is not reliable to a sufficient extent on tests of stokers at high ratings and is likely to be misleading owing to the task of ascertaining the carbon losses. A few matters of technique occur in the paper which the writer would like to discuss.

The weighing of water is not necessary, even when facilities are at hand. In the writer's organization there are at least four test engineers who can meter water or steam in any quantity to better than 2 per cent. The steam and water meter in skilful hands is just as reliable as weighed water, although the precision is slightly less. What these men can do any engineer should be able to do if he will take the time to become acquainted with this Society's report on fluid meters.

One can easily picture an engineer in the case of the high "unaccounted-for" tests just mentioned if the output had been determined by means of a flow meter. He would blame the whole

[3] Mechanical Engineer, New York Steam Corporation, New York, N. Y. Jun. A.S.M.E.

thing on the flow meter. This is wrong, and the continued persistence of steam engineers in refusing to rely on the meters is certainly a reflection on their own technique. Hydraulic engineers get good results without weighing half of Niagara Falls to a turbine. Why not steam engineers? If commercial recorders are not trusted, how about using manometers? If orifices and venturi tubes are unknown quantities, how about checking them?

In conclusion, it is the writer's opinion that in many cases the study of the often glossed over "unaccounted-for" is the way to more effective boiler testing. Deducting radiation losses which can be estimated closely, a theoretically good boiler-test series should have positive and negative "unaccounted-for." Using the maximum possible error is "safe" but not informative. The distribution of accidental errors in boiler testing follows the law of probability as it does in all measurements. If a test or a series of tests, when the data have been closely analyzed, shows a positive unaccounted-for beyond the precision of the data, this should be closely looked into because it represents a systematic rather than an accidental error and not infrequently pictures the possible room for improvement of efficiency.

HENRY KREISINGER.[4] The heat-balance method of making boiler tests is less costly than tests made by weighing water and coal. However, that does not mean that the heat-balance method of making a boiler test requires less skill and experience than the weighed-coal-and-water test. In order to be able to make an accurate heat-balance test one must be thoroughly familiar with the operation of the plant. He must know where the losses are before he attempts to measure them. If one is not familiar with the plant and its operation, he should spend several days at the plant watching the operation and studying all possible means in which losses may occur. He may even find it necessary to make some preliminary measurements in order to determine what apparatus and instruments he should use in measuring the losses during the test.

The author has described rather thoroughly the method of measuring the dry-gas losses, the losses due to water vapor in the products of combustion, and has outlined the method of estimating the radiation losses. He has also described the method of determining the incomplete combustion losses due to combustible in flue dust and in the refuse from the ashpit. These are the principal losses in the process of making steam. Of these losses the one due to combustible in the flue dust and cinders carried out the stack in the stoker-fired plants is usually given too little attention. A great amount of care is given to the sampling of ashpit refuse and the determination of its carbon content. The cinders going out the stack are usually passed by with an inaccurate estimate or very superficial measurement. And yet the loss due to combustible in the cinders may amount to several per cent, and if neglected may introduce serious error in the test. This is especially true when the boiler is fired with stokers of the forced-draft type. Therefore, an engineer who wishes to make a fairly accurate heat-balance test should give this one loss great attention and study the methods by which he can determine these losses accurately.

H. W. BROOKS.[5] Like Mr. Cross and Mr. Kreisinger, the writer has been brought up in that school of engineering thought which feels that a boiler test without a heat balance is not a boiler test. If one will read carefully the power test codes, he will find that the Society is substantially on record in the same belief. Generally speaking, therefore, both the weighed-water test and the heat-balance test are essential. Where conditions necessitate the sacrifice of one to the other, the thorough and experienced boiler tester will usually prefer to sacrifice the former.

Much remains, however, to be done in the perfection of technique in the heat-balance test. The writer is somewhat inclined to take issue with the author as to the rather narrow limitations of maximum error which he has established on the various items. As examples, only two specific cases may be mentioned—namely, "loss of unburned combustible" and "radiation and unaccounted-for." When dealing with the small all-cold Scotch marine boilers in the early days of the pulverized-fuel tests at the Philadelphia Navy Yards, when the writer first was learning to understand the then known limits of heat release per cubic foot of furnace volume in pulverized-coal furnaces, he used exactly the method outlined by the author in his own tests for solid unburned combustible. In spite of the fact that "radiation and unaccounted-for" ran in some cases as high as 21 per cent, the losses of unburned carbon as shown by the dust-sampling method rarely showed over 4 to 7 per cent. There was an obvious discrepancy here which was afterward checked up by the use of a rather complicated but quite accurate chemical balance computation suggested about three years ago by one of the professors of the University at Sheffield, England, and published by "Fuels in Science and Practice." This method was later worked out graphically by Mr. E. G. Bailey and presented before this Society. In this manner it was ascertained that the loss shown by the sampling method was less than 40 per cent of the actual loss. Later when the writer reduced the "radiation and unaccounted-for" to the eventual figure of around 6 to 8 per cent, he still found about the same ratio of discrepancy between the two methods. He has also found this discrepancy on many stationary boiler tests, proving that there is much yet to be learned in the sampling of pulverulent materials in suspension.

With regard to radiation loss, on the Philadelphia work prior to the powdered-coal tests a very accurate research had been made by the Navy for the specific purpose of determining radiation losses from the boiler. These tests had been made with oil firing and under specially careful and competent supervision. In them it was found that the method suggested of estimating radiating losses at 250 B.t.u. per sq. ft. lent itself to wide variations of inaccuracy, particularly at the lighter loads. Having had the same experience on stationary boiler tests where radiation was measured by the Nichols heat flowmeter (which accurately measures the radiation from masonry walls), the writer is inclined to believe that this is one of the most fruitful sources of error on light-load heat balances.

A negative "radiation and unaccounted-for" item is nearly always an evidence of lack of care and inaccuracy in the test. No boiler under fire can conceivably absorb heat from surrounding boiler-room atmospheric temperature. In other words no boiler can conceivably be a refrigerator in any possible manner. Heat balances, therefore, showing negative "radiation and unaccounted-for" can generally be regarded with considerable suspicion.

A. A. ADLER.[6] Boiler tests reported on the basis of water evaporated to fuel used will always make a strong appeal. This is due to the simplicity of the factors involved and the fact that it seems like a direct measurement. It may be true that the handling of water and coal, paralleling as nearly as possible operating conditions, will offer mechanical difficulties in an attempt at accurate measurement. The appeal becomes the stronger when the direct measurements are supported by a heat balance which includes gas analyses and flue-temperature readings.

Tests using gas analyses and flue temperature only are less

convincing because they depend on theoretical considerations not always clear to those for whom they are intended. There is always room for discussion as to where samples should be taken to be truly representative. Moreover, it makes a difference whether air leakage is through the fuel bed or if it takes place at other points.
